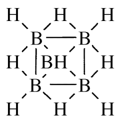
Borides: Carbon boride, CB_6, and silicon borides SiB_3 and SiB_6 are hard, crystalline solids, produced in the electric furnace; magnesium boride, $Mg_3\ B_2$, brown solid, by reaction of boron oxide and magnesium powder ignited, forms boron hydrides with HCl; calcium boride, $Ca_3\ B_2$, forms boron hydrides and hydrogen gas with HCl.

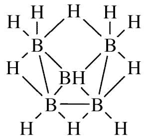
Nitride: Boron nitride, BN, white solid, insoluble, reacts with steam to form NH_3 and boric acid, formed by heating anhydrous sodium borate with ammonium chloride, or by burning boron in air.

Sulfide: Boron sulfide, B_2S_3, white solid, unpleasant odor, irritating to the eyes, reactive with water to form boric acid and hydrogen sulfide, formed by reaction of boron oxide plus carbon heated in a current of CS_2 at red heat.

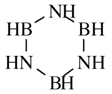
The great number of compounds of boron is due to the readiness with which boron atoms form, to some extent, chain structures with other boron atoms, and, to a far greater extent, cyclic compounds, both with other boron atoms, and with atoms of carbon, oxygen, nitrogen, phosphorus, arsenic, the halogens, and many other elements. Examples of them are shown below, beginning with the two pentaboranes $B_5\ H_9$ and $B_5\ H_{11}$:



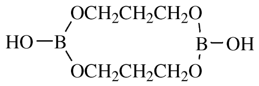
B_5H_9 Pentaborane (9)



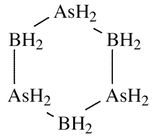
B_5H_{11} Pentaboranze (11)



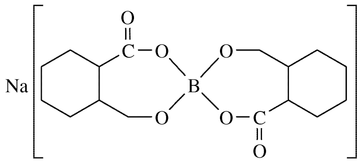
hexahydro-*s*-triazatriborine (also called *borazine*)



2,8-dihydroxy-1,3,7,9-tetroxa-2,8-diboracyclododecane



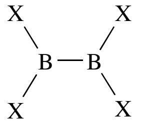
dodecahydro-*s*-triarsatriborine (also called *s*-triphosphatri-borane or *borarsane*)



sodium dis(salicylato-*O*,*O′*)borate (1–)

Halides: Since simple boron compounds have only three electron pairs in the valence shell of boron, they tend to be electron acceptors. Its simple molecules are formed by sp^2 hybrid sigma bonds lying in a plane. Its strong tendency to form an octet is shown by the tetrahedral boron compounds involving sp^3 hybridization. Boron halides include the trifluoride, BF_3, the trichloride, BCl_3, the tribromide, BBr_3 and the triiodide, BI_3, which range in mp from −127 to +43°C. Typical methods of forming the boron halides are: treatment of boron oxide with hot concentrated H_2SO_4 in a reaction mixture with calcium fluoride to produce BF_3, and by heating boron, or boron oxide plus carbon with chlorine to produce the chloride.

In addition to the simple halides, boron forms fluorine complexes containing the fluoroborate ion (BF_4^-) Subhalides of boron are known (B_2X_4) of the structure:



and B_4X_4 of the structure

BOSONS. Those elementary particles for which there is symmetry under intra-pair production. They obey Bose-Einstein statistics. Included are photons, pi mesons, and nuclei with an even number of particles. (Those particles for which there is antisymmetry are *fermions.*) See **Mesons**; **Particles (Subatomic)**; and **Photon and Photonics**.

BOSTONITE. A rather rare rock type, dense, with an occasional feldspar phenocryst and grayish in color. It is composed almost wholly of alkaline feldspar, being analogous to aplites. The type locality is Salem Neck, Massachusetts, close to Boston, for which it was named.

BOUGUER AND LAMBERT LAW. In homogeneous materials, such as glass or clear liquids, the fractional part of intensity or radiant energy absorbed is proportional to the thickness of the absorbing substance.

Summing over a series of thin layers or integration over a finite thickness gives the relation

$$\log I_0/I = k_1 b$$

where I_0 is the intensity or radiant power incident on a sample b centimeters thick and I is the intensity of the transmitted beam. The constant k_1 depends on the wavelength of the incident radiation, the nature of the absorbing material and other experimental conditions. Verification of the law fails unless appropriate corrections are made for reflection, convergence of the light beam and spectral slit width, as well as possible scattering, fluorescence, chemical reaction, nonhomogeneity, and anisotropy of the sample. Formerly, the constant k_1 was called the absorption coefficient. It is now preferable to avoid this term and to call the ratio I/I_0 the transmittance. The law was first expressed by Bouguer in 1729 but it is often attributed to Lambert, who restated it in 1768.

BOULANGERITE. A mineral compound of lead-antimony sulfide, $Pb_5Sb_{4s}S_{11}$. Crystallizes in the monoclinic system; hardness, 2.5–3; specific gravity, 6.23; color, lead gray.

BOURNONITE. An antimony-copper-lead sulfide corresponding to the formula $PbCuSbS_3$. It is orthorhombic, and repeated twinning often produces crosses or wheel-shaped crystals. It is brittle; fracture, subconchoidal; hardness, 2.5–3; specific gravity, 5.83; luster, metallic; color and streak, dark gray to black; opaque.

Bournonite is found with galena, chalcopyrite, and sphalerite. There are many European localities; it was first found in Cornwall, England, by Count Bournon, for whom it was later named. Bournonite occurs in Bolivia and Peru and in the United States in Arizona, Montana, Nevada and Utah. Bournonite is also known as *wheel ore*.

BOYLE-CHARLES LAW. This law states that the product of the pressure and volume of a gas is a constant which depends only upon the temperature. This law may be stated mathematically as

$$p_2v_2 = p_1v_1[1 + a(t_2 - t_1)]$$

where p_1 and v_1 are the pressure and volume of a body of gas at temperature t_1, p_2 and v_2 are the pressure and volume of the same body of gas at another temperature t_2, and a is the volume coefficient of expansion of the gas. If the temperature is expressed in degrees absolute, this expression becomes

$$\frac{p_2v_2}{T_2} = \frac{p_1v_1}{T_1}$$

which is the ideal gas law, so-called because all real gases depart from it to a greater or lesser extent. See also **Characteristic Equation**.

BOYLE, ROBERT (1627–1691). Boyle was an Anglo-Irish scientist who is known for his research in chemistry, physics, and medicine. He is also remembered for his inventions and also for his study of philosophy and theology. He was educated at Eton College from 1635 to 1639. Beginning in 1644, he began doing experimental scientific work and he is considered one of the founders of modern science.

Boyle was one of the founders and key members of the Royal Society, a group of scientists who conducted experiments under the patronage of King Charles the Second.

In 1667, Boyle repeated the air pump experiments of von Guericke with an improved version of the apparatus so that it created a nearly perfect vacuum in a container. When he pumped air out of a pipe that was placed in a container of water, he was able to raise the water a little over 10 m, but no more. He continued further experiments of his own and published his results in "*New Experiments Physico-Mechanical,*" a later edition which includes his famous gas law. Boyle's Law states that the pressure of a given mass of gas is inversely proportional to the volume. Boyle is credited for realizing the true nature of elements. He believed all matter was made up from extremely small particles, which were combined together in varying ways to form the different chemical substances. In "Skeptical Chymist," he expressed his views. He attacked the old theories of the alchemists. He was the first to suggest that matter can be classified in terms of similar chemical properties. Boyle is remembered as a scientist who gave important weight to the atomic theory of matter. He is recognized for his development of the experimental method, his careful observation, recording, and reporting of results.

Boyle was a very religious man and is also known as a devout Christian. Interestingly, he wrote many articles on theology. His Boyle Lectures defended Christianity against atheists.

See also **Boyle's Law**.

J.M.I.

BOYLE'S LAW. This law, attributed to Robert Boyle (1662) but also known as Mariotte's law, expresses the isothermal pressure-volume relation for a body of ideal gas. That is, if the gas is kept at constant temperature, the pressure and volume are in inverse proportion, or have a constant product. The law is only approximately true, even for such gases as hydrogen and helium; nevertheless it is very useful. Graphically, it is represented by an equilateral hyperbola (see Fig. 1). If the temperature is not constant, the behavior of the ideal gas must be expressed by the Boyle-Charles law.

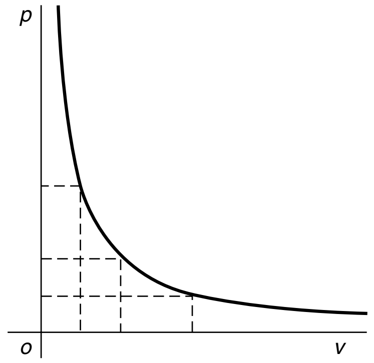

Fig. 1. Equilateral hyperbola representing Boyle's law. The rectangular areas (PV) are all equal

The Boyle temperature is that temperature, for a given gas, at which Boyle's law is most closely obeyed in the lower pressure range. At this temperature, the minimum point (of inflection) in the pV-T curve falls on the pV axis. See **Compression (Gas)**; and **Ideal Gas Law**.

B. P. An abbreviation of "Before Present." This term is an indication of time calculation, used especially when referring to radiometric dating.

BRAGG'S CURVE. There are two types of curves to which Bragg's name is occasionally given: 1. A graph for the average number of ions per unit distance along a beam of initially monoenergetic alpha particles, or other ionizing particles, passing through a gas. 2. A graphical relationship between the average specific ionization of an ionizing particle of a particular kind, and some other variable, such as the kinetic energy, the residual range, or the velocity of the particle.

BRAGG'S LAW. The law expressing the condition under which a crystal will reflect a beam of x-rays with maximum distinctness, at the same time giving the angle at which the reflection takes place. For x-ray reflection it is customary to use the complement of the angle of incidence and reflection, that is, the angle which the incident or the reflected beam makes with the crystal planes, rather than with the normal. Let this "Bragg angle" be θ. If the planes or layers of atoms are spaced at a distance d apart, and if λ is the wavelength of the x-rays, Bragg's law is expressed by the equation

$$\sin\theta = \frac{n\lambda}{2d}$$

The condition for an intensity maximum is that n must be a whole number. For example if the planes of rock salt parallel to the natural cubical faces are spaced at $d = 2.814 \times 10^{-8}$ centimeters or 2814 x-units, and if the incident rays have a component of wavelength $\lambda = 714$ x-units, the above equation gives sin; $\theta = 0.1269n$. Then if the crystal is rotated slowly, there will be a distinct reflection where θ reaches $7°17'$ $(n = 1)$, again at $14°42'$ $(n = 2)$, also at $22°23'$ $(n = 3)$, etc. See also **Crystal**.

BRAGG SPECTROMETER. An instrument for the x-ray analysis of crystal structure, in which a homogeneous beam of x-rays is directed on the known face of a crystal, C, and the reflected beam detected in a suitably placed ionization chamber, E. As the crystal is rotated, the angles at which

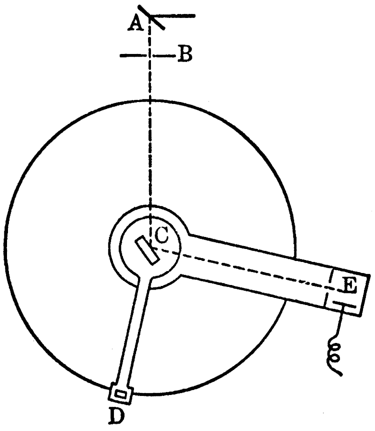

Fig. 1. Bragg spectrometer

the equation expressing Bragg's law is satisfied are identified as sharp peaks in the ionization current. See Fig. 1. This is one of the early, classical instruments in the laboratory field.

BRAGG'S RULE. An empirical relationship whereby an elements for mass stopping power of an element of alpha particles is inversely proportional to the one-half power of the atomic weight. This relationship is also stated in the form that the atomic stopping power is directly proportional to the one-half power of the atomic weight. The wide usefulness of the Bragg rule is due to the fact that it leads to relations between the stopping powers of different elements for alpha particles. It also applies to other charged particles as well as alpha particles, and to the same degree of approximation, which is about ±15%.

See **Particles (Subatomic)**.

BRAGG, WILLIAM LAWRENCE SIR (1890–1971). Bragg was an Australian physicist. When he was a small boy, he shattered his elbow and an X-ray was taken. William Bragg's X-ray was the first medical X-ray in Australia. He received his early education at St. Peter' College in his birthplace, proceeding to Adelaide University to take his degree in mathematics with first-class honors in 1908. He came to England with his father in 1909 and entered Trinity College, Cambridge, as an Allen Scholar, taking first-class honors in the Natural Science Tripos 1912. Bragg's father, William Henry Bragg, was also a professor of physics and the two men worked together. They determined the crystal structures of basic substances such as diamonds, zinc blende, and calcite to mention a few. In 1915, he received with his father, the Nobel Prize in Physics for work in X-ray crystallography.

BRAZING. Brazing may be defined as the joining of metals through the use of heat and a filler metal whose melting temperature is above 840°F (450°C), but below the melting point of the metals being joined. A more exact name for many brazing processes would be "silver brazing," since the filler metal used most often is a silver alloy. Brazing may be the most versatile method of metal joining today. Brazed joints are strong-on nonferrous metals and steels, the tensile strength of a properly made joint will often exceed that of the metals joined. Brazed joints are ductile, able to withstand considerable shock and vibration. Brazing is essentially a one-operation process. There is seldom any need for grinding, filing, or mechanical finishing after the joint is complete. In comparing brazing with welding, it should be noted that welding, by its nature, presents problems in automation. A resistance weld joint made at single point is relatively easy to automate, but once the point becomes a line (a *linear joint*), the line has to be *traced*.

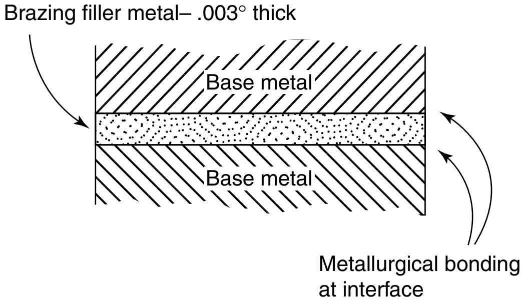

Fig. 1. The principle by which the filler metal is drawn through the joint to create a bond between the base metals is capillary action. In brazing, heat is applied broadly to the base metals. The filler metal is then brought into contact with the heated parts, whereupon the filler metal melts instantly and is drawn completely through the joint. (*Lucas-Milhaupt, Inc., A Handy & Harman Company*)

In contrast, a brazed joint is made in a completely different way from a welded joint. The first big difference is in temperature. Brazing does not melt the base metals; therefore, brazing temperatures are invariably lower than the melting points of the base metals, and they are always lower than welding temperatures for the same base metals. Brazing joins metals by creating a *metallurgical bond* between the filler metal and the surfaces of the two metals being joined. See Fig. 1. The principle by which the filler metal is drawn through the joint to create this bond is *capillary action*. In brazing, heat is applied broadly to the base metals. The filler metal is then brought into contact with the heated parts. It is melted instantly by the heat in the base metals. Because of this action, brazing joins almost any configuration with equal ease. See Fig. 2.

The six basic steps in brazing are: (1) *Good fit and proper clearance*—Because brazing depends upon capillary action to distribute the molten filler metal between the surfaces of the base metals, care must be taken to make certain that the clearance between the base metals is right, which in most cases can be described as a *close clearance*. (2) *Cleaning the metals*—because oil, grease, rust, scale, dirt, etc. form barriers between the base metal surfaces and the brazing materials. (3) *Fluxing the parts*—With few exceptions, flux is applied to the joint surfaces before brazing. A coating of flux on the joint area shields the surfaces from air, preventing oxide formation. The flux also dissolves and absorbs any oxides that form during heating, or that were not completely removed in the cleaning procedure. (4) *Assembly for brazing*—After cleaning and fluxing, the parts must be held in firm position for brazing. The simplest way to hold parts together is by gravity, providing the shape and weight of the parts permit. Where there are several assemblies to braze and their configurations are too complex for self-support or clamping, a brazing support fixture is indicated. (5) *Brazing the assembly*—which involves the application of heat. Commonly a torch is used to furnish the heat. Well suited to automation (providing other variables permit) is furnace brazing, a method that has been used quite successfully in the manufacture of heavy-duty electrical contacts. If the furnace has an inert atmosphere, fluxing can be eliminated. (6) *Cleaning the brazed joint*.

The physical properties of the filler metal are based on its metallurgical properties. The composition will determine whether the filler metal is compatible with the metals being joined—capable of wetting them and flowing completely through the joint area. There are also special

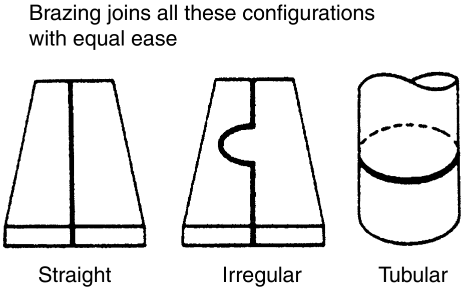

Fig. 2. Representative brazing joint configurations. (*Lucas-Milhaupt, Inc., A Handy & Harman Company*)

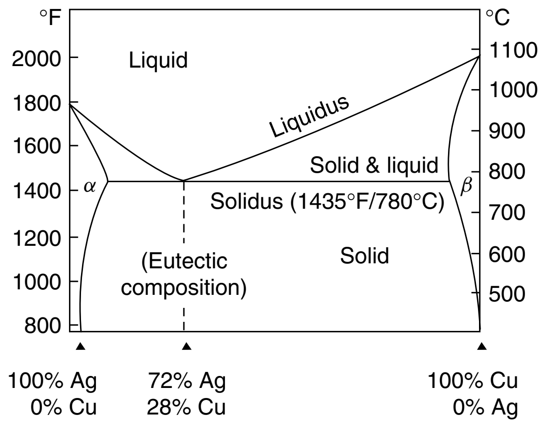

Fig. 3. Silver-copper equilibrium diagram. For a 72% silver-28% copper alloy, liquidus and solidus temperatures are the same. Alloys to the left or to the right of this eutectic composition do not go directly from a solid to a liquid state, but pass through a "mushy" range where the alloy consists of both solid and liquid states. Some brazing alloys are formulated to melt in a narrow temperature range. They are very fluid when melted and thus flow easily into close-clearance joints. Other brazing alloys are formulated for a wide melting range. Their relatively sluggish flow is desirable for filling wide gaps, or for building up stress-distribution fillets at the joint edges. (*Lucas-Milhaupt, Inc., A Handy & Harman Company*)

requirements, such as brazing in a vacuum where a filler metal free of any volatile elements, such as cadmium or zinc, must be selected. Some electronic components require filler metals of exceptionally high purity. Corrosion-resistant joints require filler metals that are both corrosion-resistant and compatible with the base metals jointed. The melting behavior of the filler metal is based on its metallurgical composition. Since filler metals are alloys, they usually do not melt in the same manner as pure metals, which go from a solid to a liquid state at one temperature. An important exception is the eutectic alloys which do melt in the same way as pure metals. One such eutectic composition is a simple silver-copper alloy (72% Ag and 28% Cu), also known as *Harman's Braze 720*, which melts completely at a single temperature, 780°C (1435°F). The melting behavior is shown by Fig. 3.

In all brazing applications, a critical factor is the "flow point" of the brazing filler material. This is the temperature above which the filler metal is liquid and flows readily, as distinguished from the melting point, when melting begins. Since in brazing the base metals must not be melted, a filler metal whose flow point is lower than the melting point of either of the base metals being joined must be used. A practical problem sometimes arises wherein there are two brazed joints in relatively close proximity (Fig. 4). So that the second brazing operation will not adversely affect the

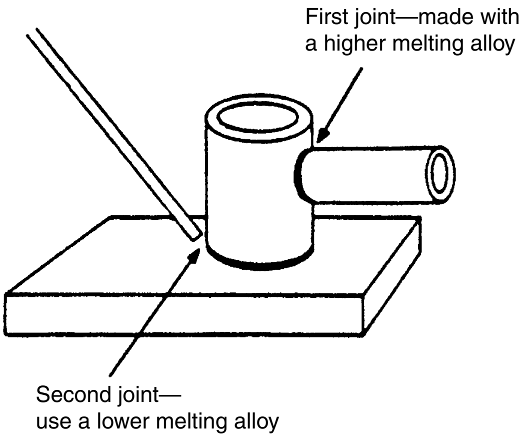

Fig. 4. Demonstration of the use of a higher melting alloy for first joint and a lower melting alloy for an adjacent second joint so that first joint will not be disturbed when the second joint is made. (*Lucas-Milhaupt, Inc., A Handy & Harman Company*)

first operation, the filler metal selected for the second joint will have a flow point that is lower than that used for the first joint.

Brazing is widely used in assembling heat exchangers, piping systems, electrical products, cutting tools, bicycles, and control instruments, among many other applications.

BREEDER REACTOR. See **Nuclear Reactor**.

BREWSTER ANGLE. The Brewster angle, or polarizing angle, of a dielectric is that angle of incidence for which a wave polarized parallel to the plane of incidence is wholly transmitted (no reflection). An unpolarized wave incident at this angle is therefore resolved into a transmitted partly-polarized component and a reflected perpendicularly-polarized component. See Fig. 1.

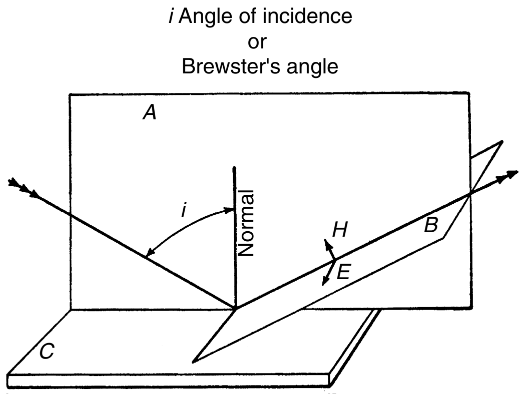

Fig. 1. Brewster angle. *A*, incident plane (plane of polarization or plane of magnetic vector, after reflection); *B*, plane of vibration (plane of electric vector, after reflection); *C*, reflecting surface (dielectric)

BRIGHTENERS. See **Detergents**.

BRILLOUIN ZONE. See **Fermi Surface**.

BRINELL HARDNESS TEST. The standard method of measuring the hardness of metals. The smooth surface of the metal is dented by a steel ball under force. The standard load and time are 500 kg for 60 seconds for soft metals and 3000 kg for 30 seconds for steel and other hard metals. The size (diameter) of the resulting dent is measured, and the hardness determined from a chart or formula.

BRIX SCALE. See **Specific Gravity**.

BROCHANTITE. A mineral composed of basic copper sulfate corresponding to the formula $Cu_4(SO_4)(OH)_6$, crystallizing in the monoclinic system in needle-like prisms, or forming druses or masses. Hardness, 3.5–4; specific gravity, 3.9; vitreous luster; color, green; streak, green; transparent to translucent.

Brochantite is a secondary mineral occurring in the oxidized zones with other copper minerals, and is found in the Ural Mountains, in Rumania, in Sardinia; Cornwall, England; Chile. In the United States this mineral has been found at Bisbee, Arizona, Utah, in the Tintic District and in Inyo County, California. Brochantite was named for Brochant de Villiers.

BROMINE. [CAS: 7726-95-6]. Chemical element, symbol Br, at. no. 35, at. wt. 79.904, periodic table group 17 (halogens), mp −7.2°C, bp 58.8°C, density 3.12 g/cm^3 (20°C). Bromine is one of the few elements that is liquid at standard conditions. The element volatilizes readily at room temperature to form a red vapor that is very irritating to the eyes and throat. Liquid bromine causes painful lesions upon contact with the flesh. Bromine has two stable isotopes ^{79}Br and ^{81}Br. Elemental bromine finds limited application as a chemical intermediate and as a sanitizing, disinfecting, and bleaching agent. Both the inorganic and organic compounds of the element find extensive commercial usage. Bromine was discovered in 1826 by Antoine-Jérôme Balard, who identified the element as a component of sea-water bitterns. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^5$. Ionic radius Br^- 1.97 A, Br^{7+} 0.39 Å. Covalent radius 1.193_5. First ionization

potential 11.84 eV; second 19.1 eV; third 25.7 eV. Oxidation potentials $2Br^- \rightarrow Br_2(1) + 2e^-$, −1.065 V; $2Br^- \rightarrow Br_2(aq) + 2e^-$, −1.087 V; $Br^- + H_2O \rightarrow HBrO + H^+ + 2e^-$, −1.33 V; $Br^- + 3H_2O \rightarrow BrO_3{}^- + 6H^+ + 6e^-$, −1.44 V; $\frac{1}{2}Br_2 + 3H_2O \rightarrow BrO_3{}^- + 6H^+ + 5e^-$, −1.52 V; $\frac{1}{2}Br_2 + H_2O \rightarrow HBrO + H^+ + e^-$, −1.59 V; $Br^- + 6OH^- \rightarrow BrO_3{}^- + 3H_2O + 6e^-$, −0.61 V; $Br^- + 2OH^- \rightarrow BrO^- + H_2O + 2e^-$, −0.70 V.

Other important physical properties of bromine are described under **Chemical Elements**.

Bromine is only moderately soluble in H_2O (3.20 g/100 ml) but markedly so in nonpolar solvents, e.g., carbon tetrachloride, as is consistent with the covalent character of the Br−Br bond. It dissolves more readily in alkali bromide solutions due to the formation of the tribromide ion ($Br_3{}^-$), and in certain associated solvents, such as concentrated H_2SO_4 and ethyl alcohol. Its aqueous solution is more stable than that of chlorine, since the tendency of Br_2 to hydrolyze to unstable hypobromous acid and hydrogen bromide is less than the corresponding reaction for chlorine. Bromine exhibits in common with the other halogens a marked readiness to form singly charged negative ions, as would be expected from the fact that these atoms need only one electron to acquire an inert gas configuration. Its electron affinity (3.53 eV) is between that of chlorine and iodine. The bromides range in character from ionic to covalent compounds, many of them having bonds of intermediate nature. In addition to its negative univalence, bromine forms essentially covalent linkages with negative elements, in which it has positive valences 1, 3, and 5.

Bromine occurs as bromide in seawater (0.188% Br), in the mother liquor from salt wells of Michigan, Ohio, West Virginia, Arkansas, and in the potassium deposits of Germany and France.

Production

In the United States, nearly all bromine is derived from natural brines. The Arkansas brines which contain a minimum of 4000 ppm bromide account for over half of this production. Recovery is effected by a *steaming-out* process. After heating fresh brine, the solution is fed to the top of a tower. Chlorine and steam are injected at the bottom of the tower. The chlorine oxidizes the bromide and displaces one resultant bromine from solution. For brines of lower concentration, air instead of steam is used to sweep out the bromine vapors after chlorination.

Hydrogen Bromide and Hydrobromic Acid

HBr, is formed directly from the elements, effectively when catalyzed by sunlight, by heated charcoal or platinum, or more conveniently by hydrolysis of phosphorus tribromide. Treatment of bromides with H_2SO_4 yields mixtures of HBr and bromine. The H−Br bond is considered to be partly covalent. Hydrobromic acid is a strong acid in aqueous solution. Its salts are the bromides, all of which are water-soluble except those of copper(I), silver, gold(I), mercury(I), thallium(I) and lead(II), the divalent ions of the elements of the second and third transition series, and the salts of the heavy alkali ions with many bromo-complex anions, e.g., Cs_2PtBr_6, $RbAuBr_4$, etc. The main uses of HBr and hydrobromic acid are in the production of alkyl bromides (by replacement of alcoholic hydroxyl groups or by addition to olefins) and inorganic bromides.

Sodium Bromide

This is a high-tonnage chemical and one of the most important of the bromide salts commercially. High-purity grades are required in the formulation of silver bromide emulsions for photography. The compound, usually in combination with hypochlorites, is used as a bleach, notably for cellulosics. The production of sodium bromide simply involves the neutralization of HBr with NaOH or with sodium carbonate or bicarbonate.

Calcium Bromide

Because of its ready solubility, calcium bromide forms solutions of high density which when properly formulated are finding increasing use as functional fluids in oil well completion and packing applications.

Lithium Bromide

LiBr finds use as a desiccant in industrial air conditioning systems.

Zinc Bromide

$ZnBr_2$ is used as a rayon-finishing agent, as a catalyst, as a gamma-radiation shield in nuclear reactor viewing windows, and as an absorbent in humidity control. It too finds use in high density formulated functional fluids in oil well applications. Zinc bromide is prepared either by the direct reduction of bromine with zinc, or by reacting HBr with zinc oxide or carbonate.

Other Bromides

Aluminum bromide $AlBr_3$ is used as a catalyst and parallels $AlCl_3$ in this role. Strontium and magnesium bromides are used to a limited extent in pharmaceutical applications. Ammonium bromide is used as a flame retardant in some paper and textile applications; potassium bromide is used in photography. Phosphorus tribromide PBr_3 and silicon tetrabromide $SiBr_4$ are used as intermediates and catalysts, notably in the production of phosphite esters.

Hypobromous Acid and Hypobromites

Hypobromous acid HOBr results from the hydrolysis of bromine with H_2O and exists only in aqueous solution. The compound finds limited use as a germicide and in water treatment; also it can be used as an oxidizing or brominating agent in the production of certain organic compounds. Although hypobromous acid is low in bromine content, concentrated hypobromite solutions can be formed by adding bromine to cooled solutions of alkalis.

Bromic Acid and Bromates

Bromic acid, $HBrO_3$, can exist only in aqueous solution. Bromic acid and bromates are powerful oxidizing agents. Bromic acid decomposes into bromine, oxygen, and water. Many oxidizing agents, e.g., hydrogen peroxide, hypochlorous acid, and chlorine convert Br_2 or Br^- solutions to bromates. The decomposition reactions of bromates vary considerably. Lead(II) bromate and copper(II) bromate give the metal oxides and Br^-; silver, mercury(II) and potassium bromates give the metal ion, Br^- and oxygen, while zinc, magnesium, and aluminum bromates give the metal oxide, Br_2 and oxygen.

Halogen Compounds

Bromine forms a number of compounds with the other halogens. Its binary iodine compounds are discussed under iodine; other interhalogen compounds of bromine include bromine monochloride, bromine monofluoride, bromine trifluoride, and bromine pentafluoride. The nonexistence of higher chlorides of bromine, differing from iodine, can readily be explained in terms of the oxidation potential of Br(III) and Br(V). The monochloride, bromine chloride, BrCl, exists in pure state only at very low temperatures in the solid form. Dissociation in the gas phase is approximately 40% at 25 °C and increases slowly with increasing temperature; less than 20% occurs in the liquid phase. With many substrates, bromine chloride reacts much more rapidly than does bromine itself to introduce bromine substituents. Bromine monofluoride, BrF, is also somewhat unstable, decomposing spontaneously at 50 °C to Br_2, BrF_3, and BrF_5. It has never been prepared pure since it is always in equilibrium with Br_2 and BrF_5. It is a gas at room temperature, reacting readily with water, phosphorus, and the heavy metals. Bromine trifluoride, BrF_3, is much more stable than the monofluoride. It is obtained directly from the elements at 10 °C, or by fluorination of univalent heavy metal bromides. It is a liquid, bp 127.6 °C, mp 8.8 °C. There is evidence (high Trouton constant) that it undergoes self-ionization to form $BrF_2{}^+$ and $BrF_4{}^-$. The former is found in the acidic addition products it forms with gold(III), antimony(V) and tin(IV) fluorides, BrF_2AuF_4, BrF_2SbF_6 and $(BrF_2)_2SnF_6$. The latter occurs in the tetrafluorobromates, such as $KBrF_4$ and Ba $(BrF_4)_2$. The solvent properties of BrF_3 are consistent with its indicated dissociation, i.e., reactions involving the two classes of compounds mentioned take place as if BrF_3 acts as a fluoride ion donor or acceptor as H_2O is a proton donor or acceptor in the H_2O system. For example, potassium dihydrogen phosphate, KH_2PO_4 gives KPF_6, a mixture of HNO_3 and B_2O_3 gives NO_2FB_4, etc. Bromine trifluoride fluorinates many of the metal halides and oxides. Bromine pentafluoride, BrF_5, is prepared from BrF_3 and fluorine. It is thermally stable. It is a very active fluorinating agent, converting to fluorides most metals, their oxides and other halides, and being hydrolyzed by H_2O probably to hydrofluoric and bromic acids.

The polyhalide complexes of bromine include $(PBr_4)(IBr_2)$ formed by reaction of phosphorus pentabromide and iodine monobromide, and dissociating in certain organic polar solvents to the ions $PBr_4{}^+$ and $IB_2{}^-$. Other polyhalides include NH_4IBr_2, $[(CH_3)_4N][IBr_2]$, Cs[IFBr], Rb[IClBr], and Cs[IClBr]. Most of these compounds hydrolyze readily, ionize in polar

nonreacting solvents to the corresponding polyhalide ions, and decompose on heating to give the metal halide of greatest lattice energy.

Oxides

In binary combination with oxygen, bromine forms at least three compounds. Bromine(I) oxide, Br_2O, is a dark brown solid that is stable only in the dark below −40°C. It is prepared by passing dry gaseous bromine through dry mercury(II) oxide and sand. Bromine(I) oxide, in carbon tetrachloride at low temperatures, reacts with alkali hydroxide to give hypobromites. Bromine(IV) oxide, BrO_2, is obtained by reaction of the elements in a cooled electric discharge tube. It is yellow, and is stable only at low temperatures. The compound appearing in the older literature as tribromine octoxide, Br_3O_8, is actually bromine trioxide, BrO_3, or dibromine hexoxide, Br_2O_6 (cf. chlorine). It is obtained from the low temperature, low pressure reaction of ozone and bromine; it is stable only at low temperatures and is soluble in H_2O with decomposition. Bromine(VII) oxide may be present among the decomposition products of BrO_2, or BrO_3, but no other evidence for its existence has been found.

Organic Bromine Compounds

Commercially important organic bro mine compounds include: (1) methyl bromide CH_3Br formed by reacting methanol with HBr or hydrobromic acid. The compound is a highly toxic gas at standard conditions. Because of its toxicity, it is used as a soil and space fumigant. In many organic syntheses, the compound is used as a methylating agent; (2) ethylene dibromide (1,2-dibromoethane) is used in combination with lead alkyls as an antiknock agent for gasoline. The compound also is used as a fumigant; (3) methylene chlorobromide (bromochloromethane) is a low-boiling liquid of low toxicity and is useful as a fire-extinguishing agent in portable equipment and aircraft; (4) bromotrifluoromethane is increasingly employed as a fire extinguishant in permanently installed systems protecting high-cost installations, such as computer rooms, where its low toxicity and especially its freedom from corrosivity are important considerations; (5) acetylene tetrabromide (1,1,2,2-tetrabromoethane) is made by adding bromine to acetylene. The compound is comparatively dense and finds use as a gage fluid and in specific gravity separations of solids. It is also used as part of the catalyst system for the oxidation of *p*-xylene to terephthalic acid; (6) tris(2,3-dibromopropyl) phosphate may be prepared by the reaction of phosphorus oxychloride with 2,3-dibromopropanol, or by the addition of bromine to triallyl phosphate. This viscous fluid was used as a flame retardant in a number of polymer systems, but has been displaced from most, or all, of these uses, because it is a mutagen and suspect carcinogen; (7) tetrabromobisphenol A is produced by the direct bromination of bisphenol A. The compound is used extensively as a flame retardant and usually is incorporated into the polymer backbone structure of epoxy resins, unsaturated polyesters, and polycarbonates; (8) tetrabromophthalic anhydride, made by the catalytic bromination of phthalic anhydride in fuming H_2SO_4, also finds use as a reactive flame retardant in the formulation of polyol systems (for polyurethane foams) and in unsaturated polyesters; (9) decabromodiphenyl ether, and others of the lower brominated diphenyl ethers, are finding increasing use as flame retardants in a variety of thermoplastic polymer systems; (10) vinyl bromide has also found major use in flame-retarding modacrylic textile fibers when introduced as a co-monomer in the synthesis of the polymer itself.

Alkanes and arenes, e.g., ethane and benzene, respectively, react with bromine by *substitution* of bromine for hydrogen (hydrogen bromide also formed)—ethane to yield ethyl bromide C_2H_5Br plus further substitution products; benzene, in the presence of a catalyst, e.g., iodine, phosphorus, iron, to yield bromobenzene C_6H_5Br plus further substitution products; toluene, under like conditions to benzene, to yield orthobromotoluene and parabromotoluene $CH_3C_6H_4Br$ plus further substitution products, but at the boiling temperature, in sunlight, dry, and in the absence of a catalyst, to yield alkyl side-chain substitution products, benzyl bromide $C_6H_5CH_2Br$, benzal bromide $C_6H_5CHBr_2$, and benzotribromide, $C_6H_5CBr_3$.

Alkenes, alkynes, and arenes, e.g., ethylene, acetylene and benzene, respectively, react (1) with bromine by *addition*, e.g., ethylene dibromide $C_2H_4Br_2$ (1,2), acetylene tetrabromide $C_2H_2Br_4$ 1,1,2,2, hexabromocyclohexane $C_6H_6Br_6$; also carbon monoxide yields carbonyl bromide $COBr_2$; (2) with hypobromous acid by *addition*, e.g., olefins form, for example, ethylene bromohydrin $CH_2Br\cdot CH_2OH$; (3) with hydrogen bromide by *addition*, to form, for example, ethyl bromide $CH_3\cdot CH_2Br$ from ethylene. When the two olefin carbons have unequal numbers of hydrogens, the carbon to which one bromide or one hydroxyl attaches can be controlled by the reaction conditions.

Oxygen-function compounds, e.g., ethyl alcohol, acetaldehyde, acetone, acetic acid, react (1) with bromine, to form *bromo-substituted* corresponding or related *compounds*, e.g., ethyl alcohol or acetaldehyde to yield bromal $CBr_3\cdot CHO$, acetone to yield bromoacetone $CH_2Br\cdot CO\cdot CH_3$; acetic acid to yield, at the boiling temperature, dry, and in the absence of a catalyst, monobromoacetic acid $CH_2Br\cdot COOH$, dibromoacetic acid $CHBr_2\cdot COOH$, tribromoacetic acid $CBr_3\cdot COOH$, the substitution taking place on the alpha-carbon (the carbon next to the carboxyl-group-COOH), (2) with phosphorus bromides, to form corresponding *bromides*, e.g., ethyl bromide C_2H_5Br, ethylidene dibromide CH_3CHBr_2, acetone bromide $(CH_3)_2CBr_2$, acetyl bromide CH_3COBr, (3) with hydrobromic acid, concentrated, alcohol forms the corresponding bromide.

Bromoform is made by reaction of acetone or ethyl alcohol with sodium hypobromite; carbon tetrabromide by reaction of CS_2 plus bromine Br_2 in the presence of iron, heated; or by one reaction of bromoform with aqueous hypobromite solutions. Use is made of the diazo-reaction to introduce bromine into aryl compounds.

Many of the bromo-compounds are used as reagents or as intermediate compounds in organic chemistry. When alkyl bromocompounds are treated (1) with NaOH dissolved in alcohol, hydrogen bromide is removed, e.g., ethyl bromide $CH_3\cdot CH_2Br$ yields ethylene $CH_2{:}CH_2$, ethyl dibromide $CH_2Br\cdot CH_2Br$ yields acetylene $CH\vdots CH$; (2) with magnesium or zinc and alcohol, bromine is removed, e.g., ethylene dibromide $CH_2Br\cdot CH_2Br$ yields ethylene $CH_2{:}CH_2$, acetylene tetrabromide $CHBr_2{:}CHBr_2$, yields acetylene $CH\vdots CH$.

BROOKITE. Brookite, composed of titanium dioxide, TiO_2, is an orthorhombic mineral of the same chemical composition as rutile and octahedrite. It was named for the English mineralogist H.J. Brooke. See also **Rutile**; and **Titanium Dioxide**.

BRONZE. See **Copper**.

BROWN, HERBET C. (1912–). An English-born chemist who was the recipient of the Nobel prize for chemistry with Wittig, Georg in 1979. Via his work in organic synthesis, he discovered new routes to add substituents to olefins selectively. His early education was irregular and disjointed as a result of family circumstances and the economic depression of the 1930s. He eventually received his Ph.D. from the University of Chicago. The reduction of carbonyl compounds with diborane was the topic of

his thesis. The bulk of his career has been spent at Purdue University. http://www.chem.purdue.edu/faculty.htm

See also **Boron**.

BROWNIAN MOTION. The random movement observed among microscopic particles suspended in a fluid medium. The phenomenon was observed in 1827 with suspensions in liquids, colloids, by Robert Brown, English botanist, who is said to have attributed it to living organisms. Not until the kinetic theory was developed was it generally understood to be due to the thermal agitation of the suspending medium. A smoke particle floating in the air, for example, is battered on all sides by the high-speed air molecules. The resultant displacement is for the most part nearly zero, but there are statistical inequalities which now and then reach such magnitude as to produce motions visible in a high-powered microscope, and which result in an irregular migration of the particle. In fact, such particles may be regarded essentially as huge molecules, with mean square speeds of thermal motion proportionately smaller as their masses are larger than that of the true molecules of the surrounding medium.

In a series of papers published from 1905 to 1908, Einstein successfully incorporated the suspended particles into the molecular-kinetic theory of heat. He treated the suspended particles as being in every way identical to the suspending molecules except for the vast difference of their size. He set forth several relationships that were capable of experimental verification and he invited experimentalists to "solve" the problem.

Several workers undertook this task. The most notable of these was Perrin. Perrin's special success was due to his technique for preparing particles to suspend that were of uniform and known size. The uniformity was achieved by fractional centrifuging, and the size was established by noting that they could be coagulated into "chains" whose length could be measured and whose "links" could be counted. The microscopic observation of these uniform particles enabled Perrin and his students to verify the Einstein results and to make four independent measurements of Avogadro's number. See Fig. 1. These results not only established an understanding of Brownian movement, but also they silenced the last critics of the atomic view of matter.

Probably the simplest example of Perrin's experiments was his test of the Law of Atmospheres. If it is assumed that air is at rest and has the same temperature from ground level upward, it can be shown that the pressure (and concentration) of the air falls off exponentially with increasing altitude. For particles of mass m and density ρ suspended in a medium of density ρ' at absolute temperature T, the ratio of the particle concentrations n_1 to n_2 at heights h_1 and h_2 is given by

$$\frac{n_1}{n_2} = \exp\left[-\frac{mg(\rho - \rho')N_0(h_1 - h_2)}{\rho RT}\right]$$

where N_0 is Avogadro's number, g is the acceleration of gravity, and R is the universal gas constant. Although the concentration of air varies slowly with height, the concentration of the relatively heavy particles varied significantly over a height change of a few millimeters. By observing the concentration variation as a function of height, all quantities in the given equation were known except Avogadro's number, which could, therefore, be determined.

An exceptionally interesting and complete paper on Brownian motion was prepared in 1985 by B.H. Lavenda (University of Camerino, Italy). In a very workmanlike manner the author reviews the impact of the Brownian motion concept on other important topics of science, as previously mentioned, and continuing to the present time. In recent years, study of Brownian motion has led to the invention of mathematical techniques for the general investigation of probabilistic processes. For example, such techniques have been applied in the control of electromagnetic "noise," and they have contributed to the comprehension of the dynamics of star clustering, and the development and adaptation of ecological systems, not to mention studies of stock and commodity prices.

In another paper, R. Kuho (Keio University, Japan) illustrates in a rather technical and mathematical fashion the relationship between Brownian motion and non-equilibrium statistical mechanics. In this paper, the author describes the linear response theory, Einstein's theory of Brownian motion, coarse-graining and stochastization, and the Langevin equations and their generalizations.

BRUCITE. The mineral brucite is magnesium hydroxide corresponding to the formula $Mg(OH)_2$; iron and manganese may occasionally be present. The crystals are usually tabular rhombohedrons of the hexagonal system; it may also occur fibrous or foliated. Brucite has one perfect cleavage parallel to the prism base; hardness, 2.5; specific gravity, 2.39; luster, pearly to vitreous; commonly white but may be gray, bluish or greenish; transparent to translucent. Brucite is a secondary mineral found with serpentine and metamorphic dolomites. It has been found in Italy, Sweden, and the Shetland Islands; and in the United States in New York, Pennsylvania, Nevada and California. Brucite was named in honor of Archibald Bruce, an American physician.

BUBBLE CAP. See **Distillation**.

BUCHNER, EDUARD (1860–1917). A German chemist who was awarded the Nobel prize for chemistry in 1907. His works included the synthesis of diiodoacetamid through alcoholic fermentation caused by enzymes, as well as the discovery of zymase, the first enzyme to be isolated. He received his Ph.D. at the University of Munich, where he became a lecturer. Later, he taught and performed research at Tübingen, Berlin, and Würzburg.

BUCKMINSTERFULLERENE (Buckyballs). C_{60}. Spherical aromatic molecule with a hollow truncated-icosahedron structure, similar to a soccer ball. First reported in the mid 1980s. Capable of enclosing ions or atoms in a host-guest relationship. See also **Carbon Compounds**.

BUFFER (Chemical). When acid is added to an aqueous solution, the pH (hydrogen ion concentration) falls. When alkali is added, it rises. If the original solution contains only typical salts without acidic or basic properties, this rise or fall may be very large. There are, however, many other solutions that can receive such additions without a significant change in pH. The solutes responsible for this resistance to change in pH, or the solutions themselves, are known as *buffers*. A weak acid becomes a buffer when alkali is added, and a weak base becomes a buffer upon the addition of acid. A simple buffer may be defined, in Brønsted's terminology, as a solution containing both a weak acid and its conjugate weak base.

Buffer action is explained by the mobile equilibrium of a reversible reaction:

$$A + H_2O \rightleftarrows B + H_3O^+$$

in which the base B is formed by the loss of a proton from the corresponding acid A. The acid may be a *cation*, such as NH_4^+, a *neutral molecule*, such as CH_3COOH, or an *anion*, such as $H_2PO_4^-$. When alkali is added, hydrogen ions are removed to form water, but so long as the added alkali is not in excess of the buffer acid, many of the hydrogen ions are replaced by further ionization of A to maintain the equilibrium. When acid is added, this reaction is reversed as hydrogen ions combine with B to form A.

The pH of a buffer solution may be calculated by the mass law equation

$$\mathrm{pH} = \mathrm{p}K' + \log \frac{C_B}{C_A}$$

in which pK' is the negative logarithm of the apparent ionization constant of the buffer acid and the concentrations are those of the buffer base and its conjugate acid.

A striking illustration of effective buffer action may be found in a comparison of an unbuffered solution, such as 0.1 *M* NaCl with a neutral phosphate buffer. In the former case, 0.01 mole of HCl will change the pH of 1 liter from 7.0 to 2.0, while 0.01 mole of NaOH will change it from 7.0 to 12.0. In the latter case, if 1 liter contains 0.06 mole of Na_2HPO_4 and 0.04 mole of NaH_2PO_4, the initial pH is given by the equation:

$$\mathrm{pH} = 6.80 + \log \frac{0.06}{0.04} = 6.80 + 0.18 = 6.98$$

After the addition of 0.01 mole of HCl, the equation becomes:

$$\mathrm{pH} = 6.80 + \log \frac{0.05}{0.05} = 6.80$$

while, after the addition of 0.01 mole of NaOH, it is

$$\mathrm{pH} = 6.80 + \log \frac{0.07}{0.03} = 6.80 + 0.37 = 7.17.$$

The buffer has reduced the change in pH from ±5.0 to less than ±0.2.

Figure 1 shows how the pH of a buffer varies with the fraction of the buffer in its more basic form. The buffer value is greatest where the slope of the curve is least. This is true at the midpoint, where $C_A = C_B$ and pH = pK'. The slope is practically the same within a range of 0.5 pH unit above and below this point, but the buffer value is slight at pH values more than 1 unit greater or less than pK'. The curve has nearly the same shape as the titration curve of a buffer acid with NaOH or the titration curve of a buffer base with HCl. Sometimes buffers are prepared by such partial titrations instead of by mixing a weak acid or base with one of its salts. Certain "universal" buffers, consisting of mixed acids partly neutralized by NaOH, have titration curves that are straight over a much wider pH interval. This is also true of the titration curves of some polybasic acids, such as citric acid, with several pK' values not more than 1 or 2 units apart. Other polybasic acids, such as phosphoric acid, with pK' values farther apart, yield curves having several sections, each somewhat similar to the accompanying curve. At any pH, the buffer value is proportional to the concentration of the effective buffer substances or groups. See also **pH (Hydrogen Ion Concentration)**.

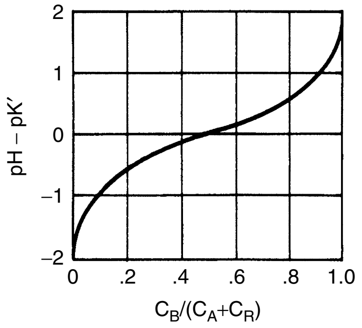

Fig. 1. The pH of a simple buffer solution. Abscissas represent the fraction of the buffer in its more basic form. Ordinates are the difference between pH and pK'

Table 1 gives approximate pK' values, obtained from the literature, for several buffer systems.

TABLE 1. REPRESENTATIVE BUFFER SOLUTIONS

Constituents	pK'
H_3PO_4; KH_2PO_4	2.1
HCOOH; HCOONa	3.6
CH_3COOH; CH_3COONa	4.6
KH_2PO_4; Na_2HPO_4	6.8
HCl; $(CH_2OH_3)CNH_2$	8.1
$Na_2B_4O_7$; HCl or NaOH	9.2
NH_4Cl; NH_3	9.2
$NaHCO_3$; Na_2CO_3	10.0
Na_2HPO_4; NaOH	11.6

Buffer substances which occur in nature include phosphates, carbonates, and ammonium salts in the earth, proteins of plant and animal tissues, and the carbonic-acid-bicarbonate system in blood. See also **Acid-Base Regulation (Blood)**.

Buffer action is especially important in biochemistry and analytical chemistry, as well as in many large-scale processes of applied chemistry. Examples of the latter include the manufacture of photographic materials, electroplating, sewage disposal, agricultural chemicals, and leather products.

BULKING AGENTS (Foods). See **Bodying and Bulking Agents (Foods)**.

BUNSEN, ROBERT WILHELM (1811–1899). Born in Germany, Bunsen is remembered chiefly for his invention of the laboratory burner named after him. He engaged in a wide range of industrial and chemical research, including blast-furnace firing, electrolytic cells, separation of metals by electric current, spectroscopic techniques (with Kirchhoff), and production of light metals by electrical decomposition of their molten chlorides. He also discovered two elements, rubidium and cesium.

BURETTE. A long, slender, graduated glass tube used in volumetric analysis, particularly titrations. An average-size burette will contain 50 milliliters of reagent and will be graduated down to tenths of a milliliter. The amount of reagent required to effect a given reaction, such as neutralization of an acid with a base, is determined by taking the difference between the starting and ending readings of the graduations. So that the end-point can be determined with maximum precision, the bottom portion of the burette is in the form of a tapered, narrow tip, such that the exiting droplets are quite small. Flow of reagent from the burette is controlled by a ground glass stop cock which is an intimate part of the total glass assembly. For laboratories where numerous titrations requiring the same reagent are made routinely, a so-called automatic burette is available. Essentially, this simplifies the reagent refilling operation.

Other types of microanalytical apparatus, such as chromatography, have replaced manual titration methods, particularly where a procedure can be tooled for making tens of thousands of similar determinations automatically.

BUTADIENE. [CAS: 106-99-0]. $CH_3CH{:}C{:}CH_2$, 1,3-butadiene (methylallene), formula weight 54.09, bp −4.41°C, sp gr 0.6272, insoluble in H_2 O, soluble in alcohol and ether in all proportions. Butadiene is a very reactive compound, arising from its conjugated double-bond structure. Most butadiene production goes into the manufacture of polymers, notably SBR (styrene-butadiene rubber) and ABS (acrylonitrile-butadiene-styrene) plastics. Several organic syntheses, such as Diels-Alder reaction, commence with the double-bond system provided by this compound.

Butadiene came into prominence as an important industrial chemical during World War II as the result of the natural rubber shortage. Originally, butadiene was made by the dehydrogenation of butylenes. Later, the naphtha cracking for ethylene and propylene, with a byproduct C_4 stream, created another source of butadiene. The basis for one butadiene recovery process is the change in relative volatility of C_4 hydrocarbons in the presence of acetonitrile solvent. The latter makes the separation easier. The C_4 mixed charge goes to an extractive distillation column where it is separated in a solvent environment into a solvent-butadiene stream and a byproduct butane-butylenes stream (overhead). The acetonitrile is recovered from the butane-butylenes. Butadiene is stripped from the fat solvent, after which it goes to a postfractionator for recovery as a 99.5% pure product.

Other solvents used in the extractive distillation include *n*-methyl pyrrolidone, dimethyl formamide, furfural, and dimethyl acetamide.

BUTANE. See **Organic Chemistry**.

BUTYL ALCOHOLS. Butyl alcohols encompass the four structurally isomeric 4-carbon alcohols of empirical formula $C_4H_{10}O$. One of these, 2-butanol, can exist in either the optically active $R(-)$ or $S(+)$ configuration or as a racemic (±) mixture.

Physical and Chemical Properties

The butanols are all colorless, clear liquids at room temperature and atmospheric pressure with the exception of *t*-butyl alcohol which is a low melting solid (mp 25.82°C); it also has a substantially higher water miscibility than the other three alcohols. Physical constants of the four butyl alcohols are given in Table 1.

Physical constants for the optically pure stereoisomers of 2-butanol have been reported as follows:

	$d^t{}_4$	n_D^{20}	$[\alpha]^{27}D$
(*S*)-(+)-2-butanol	0.8025^{27}	1.3954	+13.52
(*R*)-(−)-2-butanol	0.8042^{25}	1.3970	−13.52

Butyl alcohol liquid vapor pressure–temperature responses, which are important parameters in direct solvent applications, are presented in Figure 1.

The butanols undergo the typical reactions of the simple lower chain aliphatic alcohols.

Manufacture

The principal commercial source of 1-butanol is *n*-butyraldehyde, obtained from the Oxo reaction of propylene.

Uses

The largest-volume commercial derivatives of 1-butanol are *n*-butyl acrylate and methacrylate. These are used principally in emulsion polymers

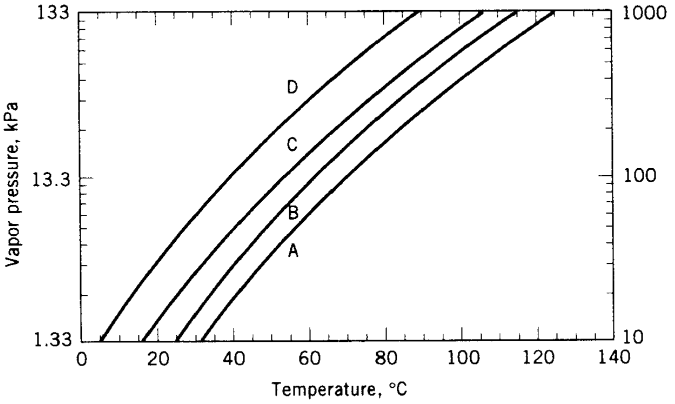

Fig. 1. Vapor pressure of butyl alcohols: A, *n*-butyl; B, isobutyl; C, *sec*-butyl; D, *t*-butyl. To convert kPa to mm Hg, multiply by 7.5

TABLE 1. PHYSICAL PROPERTIES OF THE BUTYL ALCOHOLS (BUTANOLS)

Common Name	*n*-Butyl alcohol	Isobutyl alcohol	*sec*-Butyl alcohol	*t*-Butyl alcohol
systematic name	1-butanol	2-methyl-1-propanol	2-butanol	2-methyl-2-propanol
formula	$CH_3(CH_2)_3OH$	$(CH_3)_2CHCH_2OH$	$CH_3CH(OH)C_2H_5$	$(CH_3)_3COH$
critical temperature, °C	289.90	274.63	262.90	233.06
critical pressure, kPa[a]	4423	4300	4179	3973
normal boiling point, °C	117.66	107.66	99.55	82.42
melting point, °C	−89.3	−108.0	−114.7	25.82
heat of fusion, kJ/mol[b]	9.372	6.322	5.971	6.703
heat of vaporization at normal boiling point, kJ/g[b]	43.29	41.83	40.75	39.07
liquid density, kg/m^3 at 25°C	809.7	801.6	806.9	786.6[c]
refractive index at 25°C	1.3971	1.3938	1.3949	1.3852
flash point, closed cup, °C	28.85	27.85	23.85	11.11
dielectric constant, ε	17.5^{25}	17.93^{25}	16.56^{20}	12.47^{30}
solubility in water at 30°C, % by weight	7.85	8.58	19.41	miscible
solubility of water in alcohol at 30°C, % by weight	20.06	16.36	36.19	miscible

[a] To convert kPa to mm Hg, multiply by 7.50.
[b] To convert kJ to kcal, divide by 4.184.
[c] For the subcooled liquid below melting point.

for latex paints, in textile applications and in impact modifiers for rigid poly(vinyl chloride).

Isobutyl alcohol has replaced *n*-butyl alcohol in some applications where the branched alcohol appears to have preferred properties and structure.

Health, Safety, and Environmental Considerations

All four butanols are thought to have a generally low order of human toxicity. However, large dosages of the butanols generally serve as central nervous system depressants and mucous membrane irritants.

All four butanols are registered in the United States on the Environmental Protection Agency Toxic Substances Control Act (TSCA) Inventory, a prerequisite for the manufacture or importation for commercial sale of any chemical substance or mixture in quantities greater than 454 kg (1000 lbs.). Additionally, the manufacture and distribution of the butanols in the United States are regulated under the Superfund Amendments and Reauthorization Act (SARA), Section 313, which requires that anyone handling at least 4545 kg (10,000 lbs.) a year of a chemical substance report to both the U.S. EPA and the state any release of that substance to the environment.

Storage and Handling

The C-4 alcohols are preferably stored in baked phenolic-lined steel tanks. However, plain steel tanks can also be employed provided a fine-porosity filler is installed to remove any contaminating rust.

Storage under dry nitrogen is also recommended since it limits flammability hazards as well as minimizing water pickup.

BUTYLATED HYDROXYTOLUENE (BHT). See **Antioxidants**.

BUTYLENES. Butylenes are C_4H_8 mono-olefin isomers: 1-butene, *cis*-2-butene, *trans*-2-butene, and isobutylene (2-methylpropene). These isomers are usually coproduced as a mixture and are commonly referred to as the C-4 fraction. These C-4 fractions are usually obtained as by-products from petroleum refinery and petrochemical complexes that crack petroleum fractions and natural gas liquids. Since the C-4 fractions almost always contain butanes, it is also known as the B—B stream. The linear isomers are referred to as butenes.

Physical Properties

For any industrial process involving vapors and liquids, the most important physical property is the vapor pressure. Table 1 presents values for the constants for a vapor-pressure equation and the temperature range over which the equation is valid for each butylene.

TABLE 2. PHYSICAL PROPERTIES OF THE BUTYLENES

Property	Values

Table 2 presents other important physical properties for the butylenes. Thermodynamic and transport properties can also be obtained from other sources.

Chemical Properties

The carbon–carbon double bond is the distinguishing feature of the butylenes and, as such, controls their chemistry. The carbon–carbon bond, acting as a substitute, affects the reactivity of the carbon atoms at the alpha positions through the formation of the allylic resonance structure. This structure can stabilize both positive and negative charges. Thus allylic carbons are more reactive to substitution and addition reactions than alkane carbons. Therefore, reactions of butylenes can be divided into two broad categories: (*1*) those that take place at the double bond itself, destroying the double bond; and (*2*) those that take place at alpha carbons.

The electron-rich carbon–carbon double bond reacts with reagents that are deficient in electrons, e.g., with electrophilic reagents in electrophilic addition, free radicals in free-radical addition, and under acidic conditions with another butylene (cation) in dimerization.

Manufacture

The C-4 isomers are almost always produced commercially as by-products in a petroleum refiner–petrochemical process.

There are other commercial processes available for the production of butylenes. However, these are site- or manufacturer-specific, e.g., the Oxirane process for the production of propylene oxide; the disproportionation of higher olefins; and the oligomerization of ethylene. Any of these processes can become an important source in the future. More recently, the Coastal Isobutane process began commercialization to produce isobutylene from butanes for meeting the expected demand for methyl-*tert*-butyl ether (MTBE).

New Technology. Several technologies are emerging for the production of isobutylene to meet the expected demand for isobutylene: (*1*) deep catalytic cracking; (*2*) superflex catalytic cracking; (*3*) dehydrogenation of butanes; and (*4*) the Coastal process of thermal dehydrogenation of butanes.

Separation and Purification of C-4 Isomers. 1-Butene and isobutylene cannot be economically separated into pure components by conventional

distillation because they are close boiling isomers. 2-Butene can be separated from the other two isomers by simple distillation. There are four types of separation methods available: (*1*) selective removal of isobutylene by polymerization and separation of 1-butene; (*2*) use of addition reactions with alcohol, acids, or water to selectively produce pure isobutylene and 1-butene; (*3*) selective extraction of isobutylene with a liquid solvent, usually an acid; and (*4*) physical separation of isobutylene from 1-butene by absorbents.

There are three important processes for the production of isobutylene; (*1*) the extraction process using an acid to separate isobutylene; (*2*) the dehydration of *tert*-butyl alcohol, formed in the Arco's Oxirane process; and (*3*) the cracking of MTBE.

Handling and Analysis

Storage and Transportation. Handling requirements are similar to liquefied petroleum gas (LPG). Storage conditions are much milder. Butylenes are stored as liquids at temperatures ranging from 0 to 40°C and at pressures from 100 to 400 kPa (1–4 atm). Their transportation is also similar to LPG; they are shipped in tank cars, transported in pipelines, or barged.

Health and Safety

Butylenes are not toxic. The effect of long-term exposure is not known; hence, they should be handled with care. They are volatile and asphyxiants. Care should be taken to avoid spills because they are extremely flammable. Physical handling requires adequate ventilation to prevent high concentrations of butylenes in the air.

Commercial Utilization

Pricing of butylenes determines the end use of butylenes in different geographic areas. The use pattern of butylenes in the United States, Europe, and Japan is shown in Table 3 as a percentage of supply in 1984.

C

CADMIUM. [CAS: 7440-43-9]. Chemical element, symbol Cd, at. no. 48, at. wt. 112.41, periodic table group 12, mp 321°C, bp 765°C, density 8.65 g/cm^3 (20°C). Elemental cadmium has a hexagonal crystal structure. Cadmium is a silver-white metal, malleable and ductile, but at 80°C becomes brittle. It remains lustrous in dry air and is only slightly tarnished by air or H_2O at standard conditions. The element may be sublimed in a vacuum at a temperature of about 300°C, and when heated in air burns to form the oxide. Cadmium dissolves slowly in hot dilute HCl or H_2SO_4 and more readily in HNO_3. The element first was identified by M. Stromeyer in 1817. Naturally occurring isotope. 106, 108, 110–114, 116. ^{113}Cd is unstable with respect to beta decay (0.3 MeV) into ^{113}In ($t_{1/2} \geq 10^{13}$ years). Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 5s^2$. Ionic radius Cd^{2+} 0.99 Å. Metallic radius 1.489 Å. First ionization potential, 8.99 eV; second, 16.84 eV; third, 38.0 eV. Oxidation potentials $Cd \longrightarrow Cd^{2+} + 2e^-$, 0.402 V; $Cd + 2OH^- \longrightarrow Cd(OH)_2 + 2e^-$, 0.915 V; $Cd + 4CN^- \longrightarrow Cd(CN)_4 + 4e^-$, 0.90 V. Other important physical properties of cadmium are given under **Chemical Elements**.

Although ranking 57th in abundance in the earth's crust (0.15 ppm), cadmium is not encountered alone, but is always associated with zinc. The only known cadmium minerals are greenockite (sulfide) and otavite (carbonate), both minor constituents of sphalerite (zinc oxide) and smithsonite (zinc carbonate), respectively. See also **Greenockite**; **Smithsonite**; and **Sphalerite Blende**.

Production

Two major processes are used for producing cadmium: (1) pyro-hydro-metallurgical and (2) electrolytic. Zinc blende is roasted to eliminate sulfur and to produce a zinc oxide calcine. The latter is the starting material for both processes. In the pyro-hydro-metallurgical process, the zinc oxide calcine is mixed with coal, pelletized, and sintered. This procedure removes volatile elements such as lead, arsenic, and the desired cadmium. From 92–94% of the cadmium is removed in this manner, the vapors being condensed and collected in an electrostatic precipitator. The fumes are leached in H_2SO_4 to which iron sulfate is added to control the arsenic content. The slurry then is oxidized, normally with sodium chlorate, after which it is neutralized with zinc oxide and filtered. The cake goes to a lead smelter, while the filtrate is charged with high-purity zinc dust to form zinc sulfate or zinc carbonate and cadmium sponge. The latter is briquetted to remove excess H_2O and melted under caustic to remove any zinc. The molten metal then is treated with zinc ammonium chloride to remove thallium, after which it is cast into various cadmium metal shapes. The process just described is known as the *melting under caustic process*. In a *distillation process*, regular rather than high-purity zinc is used to make the sponge. Then, after washing and centrifuging to remove excess H_2O, the sponge is charged to a retort. The heating and distillation process is under a reducing atmosphere. Lead and zinc present in the vapors contaminate about the last 15% of the distillate. Thus, a redistillation is required. The cadmium vapors produced are collected and handled as previously described.

Reactions that occur in the foregoing processes are: (Leaching): $CdO + H_2SO_4 \longrightarrow CdSO_4 + H_2O$; (Oxidation): $3As_2O_3 + 2NaClO_3 \longrightarrow 3As_2O_5 + 2NaCl$; and $6FeSO_4 + NaClO_3 + 3H_2SO_4 \longrightarrow 3Fe_2(SO_4)_3 + NaCl + 3H_2O$; (Neutralization): $Fe_2(SO_4)_3 + As_2O_5 + 3ZnO + 8H_2O \longrightarrow 2FeAs(OH)_8 + 3ZnSO_4$; (Cadmium Precipitation): $CdSO_4 + Zn \longrightarrow Cd + ZnSO_4$; (Melting Under Caustic): $Zn + 2NaOH + \frac{1}{2}O_2 \longrightarrow Na_2ZnO_2 + H_2O$.

In the electrolytic process, the calcine first is leached with H_2SO_4. Charging the resultant solution with zinc dust removes the cadmium and other metals that are more electronegative than zinc. The sponge that results is digested in H_2SO_4 and purified of all contaminants except zinc. Nearly pure cadmium sponge is precipitated by the addition of high-purity, lead-free zinc dust. The cadmium sponge then is redigested in spent cadmium electrolyte, after which the cadmium is deposited by electrolysis onto aluminum cathodes. The metal is then stripped from the electrodes, melted, and cast into various shapes. Reactions which occur during the electrolytic process are: (Roasting): $ZnS + 1\frac{1}{2}O \longrightarrow ZnO + SO_2$; (Leaching): $ZnO + H_2SO_4 \longrightarrow ZnSO_4 + H_2O$; (Neutralization): $Fe_2(SO_4)_3 + 3ZnO + 3H_2O \longrightarrow 2Fe(OH)_3 + 3ZnSO_4$; (Cadmium Precipitation): $CdSO_4 + Zn \longrightarrow Cd + ZnSO_4$; (Electrolysis): $CdSO_4 + H_2O \longrightarrow Cd + H_2SO_4 + O_2$.

Industrial specifications normally require that impurities in cadmium metal not exceed the following: zinc, 0.035%; copper, 0.015%; lead, 0.025%; tin, 0.01%; silver, 0.01%; antimony, 0.001%; arsenic, 0.003%; and tellurium, 0.003%. The metal is available in numerous forms. Electroplaters generally prefer balls 2 inches (5 centimeters) in diameter.

Uses

A major use of cadmium is for electroplating steel to improve its corrosion resistance. It is also used in low-melting-point alloys, brazing alloys, bearing alloys, nickel-cadmium batteries, and nuclear control rods, and as an alloying ingredient to copper to improve hardness. Cadmium, unfortunately, is limited in its usefulness because fumes and dusts containing cadmium are quite toxic. Melting and handling conditions that create dust or fumes must be equipped with exhaust ventilation systems. See also specific Cd compounds in this article.

Biological Properties

Over the last several years, concern over the poisonous nature of cadmium, particularly of Cd powder and chips from Cd plating, has increased. For example, cadmium-plated hardware has not been used for food processing equipment for a decade or more. A part of this concern pertains to the incineration of waste materials that may contain cadmium, for fear of introducing Cd particles into the atmosphere. Also, although the quantity of cadmium used in pigments by artists is indeed very small, many artists are adamant concerning possible legislation. One painter has said, "Losing cadmiums would be like a composer losing the use of several keys." As another artist has pointed out, "Van Gogh could not have painted his 'Sunflowers' without cadmium." The jewelry industry also uses cadmium as an ingredient of low-melting silver solders.

In February 1990 the Occupational Safety and Health Administration (U.S.) published a report that summarizes the history of cadmium regulation, studies of health problems, and risk calculations for cancer, kidney damage, and other disorders. This report represents a formal step toward implementation of stricter limits on cadmium exposure in the workplace. Some authorities admit that considerably more research is required.

The battery industry also has been plagued with metal pollution problems. These problems began with lead storage batteries several years ago and was at least partially solved by a lead recycling program based upon manufacturers' recalling "spent" car batteries. This was followed in the 1980s by the grossly reduced quantities of mercury, which is used to coat the electrodes in alkaline batteries. Initially, mercury accounted for about 1% of a battery's weight. By 1993 this has been reduced to 0.025% of battery weight.

In the early 1990s it is estimated that nearly 300 million nickel-cadmium batteries were sold in the United States. A large percentage of these were embedded in a variety of cordless appliances, such as power tools, small vacuum cleaners, and even toothbrushes. It was recently estimated that nearly 2,000 tons of cadmium appeared in the industrial waste stream as the result of equipment "junked" during the mid-1980s. Legislation

directed toward keeping cadmium out of landfills and incinerators already has been passed in Connecticut and Minnesota. Other states considering similar legislation include New Jersey, Vermont, Michigan, California, and Oregon. Battery makers are investigating suitable substitutes for Cd, including nickel–nickel hydride batteries. Metal hydrides, which are porous compounds capable of storing hydrogen, ultimately may suffice for low-power devices (toys, photoflash devices), but presently do not look promising for high-power devices, such as motorized hand tools.

Chemistry and Compounds

In virtually all of its compounds, cadmium exhibits the +2 oxidation state, although compounds of cadmium(I) containing the ion Cd_2^{2+}, have occasionally been reported. Cadmium hydroxide is more basic than zinc hydroxide, and only slightly amphiprotic, requiring very strong alkali to dissolve it, and forming $Cd(OH)_3^-$ or $Cd(OH)_4^{2-}$ depending upon the pH.

Cadmium is found in metallothioneins, which are low-molecular-weight, cysteine-rich proteins that bind metal ions. Metallothioneins and their genes have several potential kinds of physiological activity. See Metallothioneins. Furey et al.(1986) report on a thorough investigation of the crystal structure of Cd, Zn metallothionein.

Cadmium Oxide

[CAS: 1306-19-0]. CdO, formed by burning the metal in air or heating the hydroxide or carbonate, is soluble in acids, ammonia, or ammonium sulfate solution, and is more readily reduced on heating with carbon, carbon monoxide or hydrogen than zinc oxide. Cadmium suboxide, Cd_2O, formed by thermal reduction of cadmium oxalate with carbon monoxide, is believed to be a mixture of CdO and finely divided cadmium. CdO_2 and Cd_4O have been reported. Sodium hydroxide solution precipitates cadmium hydroxide, $Cd(OH)_2$, from solutions of the sulfate or nitrate, but with the chloride the $Cd(OH)_2$ precipitate is mixed with CdOHCl and other hydroxychlorides. $Cd(OH)_2$ exists in two forms, an "active" and an "inactive" one, which have different solubility products. Cadmium(I) hydroxide $Cd_2(OH)_2$, prepared by hydrolysis of Cd_2Cl_2, is, like Cd_2O, believed to be a mixture of the metal and the divalent compound. The Cd_2^{2+} ion is definitely established, however, in such compounds as $Cd_2(AlCl_4)_2$.

Cadmium Halides

These compounds can be prepared by the action of the corresponding hydrohalic acids upon the carbonate; or by direct union of the elements. If bromine water is used, some hydrobromic acid must be added to prevent hydrolysis of the bromide to the oxybromide, CdOHBr.

In general, the cadmium halides show in their crystal structure the relation between polarizing effect and size of anion. The fluoride has the smallest and least polarizable anion of the four and forms a cubic structure, while the more polarizable heavy halides have hexagonal layer structures, increasingly covalent and at increasing distances apart in order down the periodic table. In solution the halides exhibit anomalous thermal and transport properties, due primarily to the presence of complex ions, such as CdI_4^{2-} and $CdBr_4^{2-}$, especially in concentrated solutions or those containing excess halide ions.

Cadmium Sulfide

[CAS: 1306-23-6]. CdS is the most extensively used of cadmium compounds and generally is prepared by precipitation from cadmium salts. The wide range of colors, varying from lemon yellow through the oranges and deep red, coupled with the stability and intensity of these colors, qualify CdS as a most desirable pigment for paints, plastics, and other products. The range of colors of CdS precipitates results from differing conditions in their formulation, including the temperature and acidity of the salt solutions from which they are precipitated. The particular salt, such as nitrate, chloride, sulfate, etc., also affects the resulting color. The rate of addition of hydrogen sulfide to the liquor affects particle size and color of the precipitates. Cadmium sulfide is insoluble in H_2O, is dimorphous, and sublimes at 1,350°C. Several crystalline forms exist. When precipitated from normal H_2SO_4 and HNO_3 solutions, the crystals are cubic. From other media, stable alpha hexagonal and unstable beta cubic forms may be formed, these ranging in specific gravity from 3.9 to 4.5, respectively. Pigment colors are not due to crystal form, but rather derive from the particle size and dispersion of the precipitates. Of total cadmium production, pigments account for 20–25% of the total.

Other cadmium compounds used as pigments in ceramics, glass, and paints include cadmium nitrate, selenide, sulfoselenide, and tungstate. Cadmiopone ($BaSO_4$ plus CdS) ranges from yellow to crimson and is used for coloring plastics and rubber goods. Cadmium stearate, when combined with barium stearate, is widely used as a stabilizer in thermosetting plastics and accounts for well over 20% of the total cadmium produced.

Cadmium Carbonate

[CAS: 513-78-0]. $CdCO_3$, $pK_{sp} = 11.3$, is formed by the hydroxide upon absorption of CO_2, or upon precipitation of a cadmium salt with ammonium carbonate. With alkali carbonates, the oxycarbonates are produced.

Cadmium nitrate tetrahydrate, solubility 215 g/100 ml H_2O at 0°C, is obtained by action of HNO_3 upon the carbonate. It is ionized completely only in solutions weaker than about tenth molar. However, it does not form hydroxy compounds as readily as the zinc salt, requiring the action of NaOH, which in moderate concentration gives $Cd(NO_3)_2 \cdot 3Cd(OH)_2$ and $Cd(NO_3)_2 \cdot Cd(OH)_2$; excess sodium hydroxide precipitates the hydroxide.

Cadmium forms a wide variety of other salts, many by reaction of the metal, oxide, or carbonate with the acids, although some can be obtained only by fusion of the oxides or hydroxides. They include the antimonates (pyro- and meta-), the arsenates (ortho-, meta-, and pyro-, including acid salts as well as normal), the arsenites, the borates ($Cd(BO_2)_2$, $Cd_2B_6O_{11}$, $Cd_3(BO_3)_3$ and $Cd_3B_2O_6$ have been identified), the bromate, the bicarbonate, the chlorate, the chlorite, chromates and dichromates, the cyanide, the ferrate, the iodate, the molybdate, $CdMoO_4$, the nitrate, the perchlorate, various periodates, the permanganate, various phosphates (*ortho*, *meta*, and *para*, including acid salts as well as normal), the selenates and selenites, various silicates, the stannate, the sulfate (which reacts with limited amounts of NaOH or NH_3 solution to give various hydroxy sulfates), the thiosulfate, the titanate, the tungstate, and the uranate.

Cadmium arsenide, nitride, selenide, and telluride are known, the first and third obtainable from the elements, while the nitride is obtained by heating the amide (obtained by reaction of cadmium thiocyanate and potassium amide in liquid NH_3), and the telluride is obtainable by reduction of the tellurate with hydrogen. Cadmium arsenide is used as a semiconductor.

One of the features of the chemistry of cadmium is that it forms a relatively large number of complexes. A number of solid double halides of compositions $MCdX_3$, M_2CdX_4, M_3CdX_5 and M_4CdX_6 where M is an alkali metal and X a halogen are known, the last two probably existing only in the solid state. Conductance studies of solutions indicate the presence of such ions as CdX^+, CdX_3^- and CdX_4^{2-}. The donor ability of oxygen is less toward cadmium than toward zinc, fewer oxygen complexes and organic oxygen-linked complexes being known. Sulfur is a better donor than oxygen; additives of the type $(R_2S)_2 \cdot CdX_2$ are formed from di-alkyl sulfides and cadmium halides. The ready reactions with NH_3, as with amines, give large numbers of complexes; those with ammonia include tetrammines and hexamines, containing $[Cd(NH_3)_4]^{2+}$ and $[Cd(NH_3)_6]^{2+}$, respectively. Ethylenediamine forms 6-coordinate compounds containing $[Cd(en)_3]^{2+}$. Prominent among the carbon donor complexes are the cyanides, principally compounds of $Cd(CN)_4^{2-}$, although $Cd(CN)_3^-$ is also known. Other carbon donor compounds are the organometallic compounds CdR_2, where R may be methyl, ethyl, propyl, butyl, isobutyl, isoamyl, amylthio, phenyl, octylthio, decylthio, and higher organic radicals.

CAFFEINE. See **Alkaloids**.

CAIRNGORM STONE. The name given to the smoky brown variety of quartz, particularly when transparent, from Cairngorm, Scotland, a well-known locality. See also **Quartz**.

CALAVERITE. A gold telluride, $AuTe_2$, associated with quartz in low-temperature veins. A valuable gold ore from Kalgorrlie, Western Australia and the Cripple Creek region of Colorado. The ore occurs in bladed to lath-like monoclinic crystals with striations parallel to the long axis of the crystals. The ore has a metallic luster of brass-yellow to silver-white color, a hardness of 2.5 to 3, a specific gravity of 9.24 to 9.31, and a yellowish to greenish-gray streak.

CALCINATION. The subjection of a substance to a high temperature below its fusion point, often to make the substance friable. Calcination frequently is carried out in long, rotating, cylindrical vessels, known as kilns. Material so treated may (1) lose moisture, e.g., the heating of silicic acid or ferric hydroxide resulting in the formation of silicon oxide or ferric oxide, respectively, (2) lose a volatile constituent, e.g., the heating of limestone (calcium carbonate) resulting in the formation of carbon dioxide gas and calcium oxide residue—destructive distillation of many organic substances is of this type—(3) be oxidized or reduced, e.g., the heating of pyrite (iron disulfide) in air resulting in the formation of sulfur dioxide gas and ferric oxide residue. When the calcination involves oxidation, as in the preceding case, the operation is termed roasting. When heating involves reduction of metals from their ores with separation from the gangue of the liquid metal and slags, the process is termed smelting.

CALCITE. The mineral calcite, carbonate of calcium corresponding to the formula $CaCO_3$, is one of the most widely distributed minerals. Its crystals are hexagonal-rhombohedral although actual calcite rhombohedrons are rare as natural crystals. However, they show a remarkable variety of habit including acute to obtuse rhombohedrons, tabular forms, prisms, or various scalenohedrons. It may be fibrous, granular, lamellar or compact. The cleavage in three directions parallel to rhombohedron is highly perfect; fracture, conchoidal but difficult to obtain; hardness, 3; specific gravity, 2.7; luster, vitreous in crystallized varieties; color, white or colorless through shades of gray, red, yellow, green, blue, violet, brown, or even black when charged with impurities; streak, white; transparent to opaque; it may occasionally show phosphorescence or fluorescence.

Calcite is perhaps best known because of its power to produce strong double refraction of light such that objects viewed through a clear piece of calcite appear doubled in all of their parts. A beautifully transparent variety used for optical purposes comes from Iceland, for that reason is called Iceland spar.

Acute scalenohedral crystals are sometimes referred to as dogtooth spar. Calcite represents the stable form of calcium carbonate; aragonite will go over to calcite at 470°C (878°F). Calcite is a common constituent of sedimentary rocks, as a vein mineral, and as deposits from hot springs and in caves as stalactites and stalagmites.

Localities that produce fine specimens in the United States include the Tri-State area of Missouri, Oklahoma, and Kansas, as well as Wisconsin, Tennessee, and Michigan with inclusions of native copper; several areas in Mexico, notably Charcas and San Luis Potosi; Iceland; Cumberland and Durham regions in England; and at various regions in S.W. Africa, notably Tsumeb. The exceptionally fine sand-calcite crystals from South Dakota and Fontainebleau in France are well known.

CALCIUM. [CAS: 7440-70-2]. Chemical element, symbol Ca, at. no. 20, at. wt. 40.08, periodic table group 2 (alkaline earths), mp 837–841°C, bp 1,484°C, density 1.54 g/cm^3 (single crystal). Elemental calcium has a face-centered cubic crystal structure when at room temperature, transforming to a body-centered cubic structure at 448°C.

Calcium is a silver-white metal, somewhat malleable and ductile; stable in dry air, but in moist air or with water reacts to form calcium hydroxide and hydrogen gas; when heated burns in air to form calcium oxide emitting a brilliant light. Discovered by Davy in 1808.

There are six stable isotopes, ^{40}Ca, ^{42}Ca, ^{43}Ca, ^{44}Ca, ^{46}Ca, and ^{48}Ca, with a predomination of ^{40}Ca. In terms of abundance, calcium ranks fifth among the elements occurring in the earth's crust, with an average of 3.64% calcium in igneous rocks. In terms of content in seawater, the element ranks seventh, with an estimated 1,900,000 tons of calcium per cubic mile (400,000 metric tons per cubic kilometer) of seawater. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$. Ionic radius Ca^{2+} 1.06 Å. Metallic radius 1.874 Å. First ionization potential 6.11 eV; second, 11.82 eV; third, 50.96 eV. Oxidation potentials $Ca \longrightarrow Ca^{2+} + 2e^-$, 2.87 V; $Ca + Ca(OH)_2 + 2e^-$, 3.02 V.

Other important physical properties of calcium are given under **Chemical Elements**.

Calcium occurs generally in rocks, especially limestone (average 42.5% CaO) and igneous rocks; as the important minerals limestone (calcium carbonate, $CaCO_3$), gypsum (calcium sulfate dihydrate, $CaSO_4 \cdot 2H_2O$), phosphorite, phosphate rock (calcium phosphate, $Ca_3(PO_4)_2$), apatite (calcium phosphate-fluoride, $Ca_3(PO_4)_2$ plus CaF_2), fluorite, fluorspar (calcium fluoride, CaF_2); in bones and bone ash as calcium phosphate, and in egg shells and oyster shells as calcium carbonate. See also **Apatite**; **Calcite**; **Fluorite**; and **Gypsum**.

In the United States and Canada, calcium metal is produced by the thermal reduction of lime with aluminum. Before World War II, most elemental calcium was made by electrolysis of fused calcium chloride. In the thermal reduction process, lime and aluminum powder are briquetted and charged into high-temperature alloy retorts, which are maintained at a vacuum of 100 μm or less. Upon heating the charge to 1,200°C, the reaction takes place slowly, releasing Ca vapor. The latter is removed continuously by condensation, thus permitting the reaction to proceed to completion. High-purity lime is required as a starting ingredient if resulting calcium metal of high purity is desired. Aluminum contamination of the resulting calcium is removed by an additional vacuum-distillation step. Other impurities also are reduced by this distillation step.

Uses of Elemental Calcium

The very active chemical nature of calcium accounts for its major uses. Calcium is used in tonnage quantities to improve the physical properties of steel and iron. Tonnage quantities are also used in the production of automotive and industrial batteries. Other major uses include refining of lead, aluminum, thorium, uranium, samarium, and other reactive metals.

Calcium treatment of steel results in improved yields, cleanliness, and mechanical properties. Because it is a very strong deoxidizer and sulfide former, calcium will improve the deoxidation and desulfurization of steel. In addition, it alters the morphology and size of inclusions, reduces internal and surface defects, and reduces macrosegregation. Hydrogen-induced cracking of line pipe steels by high-sulfur fuels is reduced with calcium treatment. Several grades of calcium-treated steel are used in automotive, industrial, and aircraft applications. Oil line pipe, heavy plate, and deep drawing sheet were first treated in Japan. Additional uses have been developed in the United States and Europe.

The high vapor pressure and reactivity of calcium limited its use in steel and iron making prior to the development of injection systems and mold nodularization processes. There are two types of injection systems. One consists of the use of a holding furnace, a sealed vessel, a carrier gas, and a lance through which calcium or calcium compounds are blown into the molten metal. This system is effective for massive desulfurization of large quantities of steel. It is a ladle process. The second type of injection process is wire feeding. A steel-jacketed calcium-core wire is

fed through a delivery system that drives the composite wire below the surface of the liquid metal bath. The steel jacket protects the solid metallic calcium from reacting at the surface and allows it to penetrate deep into the bath. Because the reaction occurs below the surface, high and reproducible calcium recoveries are possible. This process is used in both ladle additions and in tundish additions for continuous casting. It provides shape control, deoxidation, final desulfurization and reduction of macrosegregation.

Ladle and mold processes using calcium ferroalloys are important in the production of nodular iron castings. The principal calcium alloy used is magnesium ferrosilicon. Calcium reduces the reactivity of the alloy: with the molten iron it enhances nucleation and improves morphology. The calcium content of the alloy is proportional to the magnesium content, typically in the range of 15–50% of magnesium content. In ladle or sandwich treatment techniques, pieces of the ferroalloy are placed in a pocket cut in the refractory lining of the ladle and the molten iron is then poured into the ladle. The treated, nodularized iron is then cast from the ladle into molds.

In the mold addition process, a granular form of the alloy is placed in a small reaction chamber in the mold. The nodularization treatment occurs in the mold when the iron is cast, rather than in the ladle. The reaction is contained in the mold, and high recoveries result. The production of nodular iron castings is over three million tons per year.

A calcium lead alloy is used in maintenance-free automotive and industrial batteries. The use of calcium reduces gassing and improves the life of the battery. From 0.1 to 0.5% calcium is alloyed with the lead prior to the fabrication of the battery plates either by casting or through the production of coiled sheet. With calcium present, these lead-acid batteries can be sealed and do not require the service of conventional batteries. The batteries have a higher energy-to-weight ratio. Of the battery market in the United States, over 50 million batteries per year, 40% are maintenance-free types.

Calcium is used in refining battery-grade lead for removing bismuth. Calcium is also used as an electrode material in high-energy thermal batteries.

The production of samarium cobalt magnets requires the use of calcium. The reaction is

$$3\ Sm_2O_3 + 10\ Co_3O_4 + 49\ Ca\ (vapor) \xrightarrow[\Delta]{850-1150^\circ C} 6\ SmCo_5 + 49\ CaO$$

$$0.75\ \text{weight units of Ca} \longrightarrow 1\ \text{weight unit of}\ SmCo_5$$

Samarium cobalt magnets have three to six times greater magnetic energy than alnico magnets.

Calcium serves as a reductant for such reactive metals as zirconium, thorium, vanadium, and uranium. In zirconium reduction, zirconium fluoride is reacted with calcium metal. The high heat of the reaction melts the zirconium. The zirconium ingot resulting is remelted under vacuum for purification. Thorium and uranium oxides are reduced with an excess of calcium in reactors or trays under an atmosphere of argon. The resulting metals are leached with acetic acid to remove the lime.

Calcium is also used in aluminum alloys and as an addition in a magnesium alloy used for etching. An alloy of 80% Ca-20% Mg is used to deoxidize magnesium castings. The metal also is used in the production of calcium pantothenate, a B-complex vitamin.

Chemistry and Compounds

Calcium exhibits a valence state of +2 and is slightly less active than barium and strontium in the same series. Calcium reacts readily with all halogens, oxygen, sulfur, nitrogen, phosphorus, arsenic, antimony, and hydrogen to form the halides, oxide, sulfide, nitride, phosphide, arsenide, antimonide, and hydride. It reacts vigorously with water to form the hydroxide, displacing hydrogen. Calcium oxide (quicklime) adds water readily and with the evolution of much heat (slaked lime) to form the hydroxide. Calcium hydroxide forms a peroxide on treatment with hydrogen peroxide in the cold. Calcium exhibits little tendency to form complexes: the ammines formed with ammonia are unstable, although a solid of composition $Ca(NH_3)^6$ can be isolated from solutions of the metal in liquid ammonia.

Calcium Acetate. [CAS: 62-54-4], $Ca(C_2H_3O_2)_2 \cdot H_2O$, white solid, solubility: at 0°C, 27.2 g; at 40°C, 24.9 g, at 80°C, 25.1 g of anhydrous salt per 100 g saturated solution, formed by reaction of calcium carbonate or hydroxide and acetic acid.

Calcium Aluminates. [CAS: 065997-16-2]. Four in number, have been prepared by high-temperature methods and identified, $3CaO \cdot Al_2O_3$, at 1,535°C, decomposes with partial fusion; $5CaO \cdot Al_2O_3$, mp 1,455°C, $CaO \cdot Al_2O_3$, mp 1,590°C, $3CaO \cdot Al_2O_3$, mp 1,720°C.

Calcium Aluminosilicates. Two in number, have been prepared by high-temperature methods and identified: $2CaO \cdot Al_2O_3 \cdot SiO_2$, gehlinite; $CaO \cdot Al_2O_3 \cdot 2SiO_2$, anorthite.

Calcium Arsenate. [CAS: 7778-44-1]. $Ca_3(AsO_4)_2$, white precipitate, formed by reaction of soluble calcium salt solution and sodium arsenate solution. $pK_{sp} = 18.17$.

Calcium Arsenite. [CAS: 52740-16-6]. $Ca_3(AsO_3)_2$, white precipitate, formed by reaction of soluble calcium salt solution and sodium arsenite solution.

Calcium Borates. Found in nature as the minerals colemanite, $Ca_2B_6O_{11} \cdot 5H_2O$, borocalcite, $CaB_4O_7 \cdot 4H_2O$, and pandermite $Ca_2B_6O_{11} \cdot 3H_2O$. See also **Colemanite**.

Calcium Bromide. [CAS: 7789-41-5]. $CaBr_2 \cdot 6H_2O$, white solid, solubility 1,360 g/100 ml H_2O at 25°C, formed by reaction of calcium carbonate or hydroxide and hydrobromic acid.

Calcium Carbide. [CAS: 75-20-7]. CaC_2, grayish-black solid, reacts with water yielding acetylene gas and calcium hydroxide, formed at electric furnace temperature from calcium oxide and carbon.

Calcium Carbonate. [CAS: 1317-65-3]. $CaCO_3$, found in nature as calcite, Iceland spar, marble, limestone, coral, chalk, shells of mollusks, aragonite. $pK_{sp} = 8.32$. It is (1) readily dissolved by acids forming the corresponding calcium salts, (2) converted to calcium oxide upon heating. Aragonite is an unstable form at room temperature, although no change is observable until heated, when, at 470°C, it is quickly converted into calcite; calcium hydrogen carbonate, calcium bicarbonate, $Ca(HCO_3)$, known only in solution, formed by reaction of calcium carbonate and carbonic acid. See also **Aragonite**; **Calcite**; and **Calcium Carbonate**.

Calcium Chloride. [CAS: 10043-52-4]. $CaCl_2 \cdot 6H_2O$, white solid, solubility 536 g/100 g H_2O at 20°C, absorbs water from moist air, formed by reaction (1) of calcium carbonate or hydroxide and HCl, (2) of calcium hydroxide and ammonium chloride. See also **Calcium Chloride**.

Calcium Chromate. [CAS: 13765-19-0]. $CaCrO_4$, yellow solid, formed by the reaction of chrome ores and calcium oxide heated to a high temperature in a current of air. $pK_{sp} = 3.15$.

Calcium Citrate. $Ca_3(C_6H_5O_7)_2 \cdot 4H_2O$, white solid, solubility: at 18°C 0.085 g/100 g H_2O, formed by reaction of calcium carbonate or hydroxide and citric acid solution.

Calcium Cyanamide. [CAS: 156-62-7]. $CaCN_2$, white solid, formed (1) by heating cyanamide or urea with calcium oxide, sublimes at 1,050°C, (2) by heating calcium carbide at 1,100–1,200°C in a current of nitrogen. Decomposes in water with evolution of NH_3.

Calcium Fluoride. [CAS: 7789-75-5]. CaF_2, white precipitate, formed by reaction of soluble calcium salt solution and sodium fluoride solution. $pK_{sp} = 10.40$. See also **Fluorite**.

Calcium Formate. [CAS: 544-17-2]. $Ca(CHO_2)_2$, white solid, solubility at 0°C 13.90 g, at 40°C 14.56 g, at 80°C 15.22 g of anhydrous salt per 100 g saturated solution, formed by reaction of calcium carbonate or hydroxide and formic acid. Calcium formate, when heated with a calcium salt of a carboxylic acid higher in the series, yields an aldehyde.

Calcium Furoate. $Ca(C_4H_3O \cdot COO)_2$, formed by reaction of calcium carbonate or hydroxide and furoic acid.

Calcium Hydride. [CAS: 7789-78-8]. CaH_2, white solid, reacts with water yielding hydrogen gas and calcium hydroxide; when electrolyzed in fused potassium lithium chloride, hydrogen is liberated at the anode.

Calcium Hypochlorite. [CAS: 7778-54-3]. $CaOCl_2$ or $Ca(ClO)_2 \cdot 4H_2O$, white solid, contains 60%–65% "available chlorine" and sufficient calcium hydroxide to stabilize, formed by reaction of calcium hydroxide and chlorine. Very soluble in water.

Calcium Hypophosphite. [CAS: 7789-79-9]. $Ca(H_2PO_2)_2$, white solid, solubility 15.4 g/100 g H_2O at 25°C, formed (1) by boiling calcium hydroxide suspension in water and yellow phosphorus, (2) by reaction of calcium carbonate or hydroxide and hypophosphorous acid.

Calcium Iodide. [CAS: 10102-68-8]. CaI_2, yellowish-white solid, solubility 66 g/100 g H_2O at 10°C, formed by reaction of calcium carbonate or hydroxide and hydriodic acid. The hexahydrate, $CaI_2 \cdot 6H_2O$, is soluble to the extent of 1.680 g/100 g H_2O at 30°C.

Calcium Lactate. [CAS: 814-80-2]. $Ca(C_3H_5O_3)_2 \cdot 5H_2O$, white solid, solubility at 0°C 3.1 g, at 30°C 7.9 g of anhydrous salt per 100 g H_2O, formed by reaction of calcium carbonate or hydroxide and lactic acid.

Calcium Malate. [CAS: 17482-42-7]. $CaC_4H_4O_5 \cdot 2H_2O$, white solid, solubility at 0°C 0.670 g, at 37.5°C 1.011 g of anhydrous salt per 100 g saturated solution. Formed (1) by reaction of calcium carbonate or hydroxide and malic acid, (2) by precipitation of soluble calcium salt solution and sodium malate solution.

Calcium Nitrate. [CAS: 10124-37-5]. $Ca(NO_3)_2 \cdot 4H_2O$, white solid, solubility 660 g/100 g H_2O at 30°C, formed by reaction of calcium carbonate or hydroxide and HNO_3.

Calcium Oxalate. CaC_2O_4, white precipitate, insoluble in weak acids, but soluble in strong acids, formed by reaction of soluble calcium salt solution and ammonium oxalate solution. Solubility at 18°C 0.0056 g anhydrous salt per liter of saturated solution.

Calcium Oxide. [CAS: 1305-78-8]. CaO (quicklime), white solid, mp 2,570°C, reacts with H_2O to form calcium hydroxide with the evolution of much heat; reacts with H_2O vapor and CO_2 of the atmosphere to form calcium hydroxide and carbonate mixture (slaked lime); formed by heating limestone at high temperature (800°C) and removal of CO_2. This process is conducted industrially in a lime kiln.

Tricalcium Phosphate. $Ca_3(PO_4)_3$, white solid, insoluble in water; reactive with silicon oxide and carbon at electric furnace temperature yielding phosphorus vapor; reactive with H_2SO_4 to form, according to the proportions used, phosphoric acid, or dicalcium hydrogen phosphate, $CaHPO_4$, white solid, insoluble; or calcium dihydrogen phosphate, $Ca(H_2PO_4)_2 \cdot H_2O$, white solid, soluble. $pK_{sp} = 28.70$. See also **Apatite**.

Calcium Silicates. Four have been prepared by high-temperature methods and identified: $3CaO \cdot SiO_2$, prepared by heating the constituents to a temperature below the mp (mp is 1,700°C but substance unstable); $2CaO \cdot SiO_2$, mp 2,080°C, but upon slow cooling changes to forms of different volume; $3CaO \cdot 2SiO_2$, mp 1,475°C; and $CaO \cdot SiO_2$, wollastinite, mp approximately 1,400°C. See also **Clinozoisite**; **Datolite**; **Diopside**; **Feldspar**; **Lawsonite**; **Tremolite**; and **Wollastonite**.

Calcium Sulfate. [CAS: 10101-41-4]. Gypsum, $CaSO_4 \cdot 2H_2O$, plaster of Paris, $CaSO_4 \cdot \frac{1}{2}H_2O$ anhydrite $CaSO_4$, white solid, slightly soluble (about 0.2 g per 100 ml of H_2O), formed by reaction of soluble calcium salt solution with a sulfate solution. pK_{sp} of $CaSO_4 = 4.6_{25}$. See also **Anhydrite**; **Gypsum**; and **Calcium Sulfate**.

Calcium Sulfide. [CAS: 20548-54-3]. CaS, grayish-white solid, reactive with H_2O, formed by reaction of calcium sulfate and carbon at high temperatures. Calcium hydrogen sulfide, $Ca(HS)_2$, formed in solution by saturating calcium hydroxide suspension with $H_2S \cdot pK_{sp}$ of CaS = 7.24.

Calcium Sulfite. [CAS: 10257-55-3]. $CaSO_3 \cdot 2H_2O$, white precipitate, $pK_{sp} = 7.9$, formed by reaction of soluble calcium salt solution and sodium sulfite solution, or by boiling calcium hydrogen sulfite solution; calcium hydrogen sulfite, $Ca(HSO_3)_2$, formed in solution by saturating calcium hydroxide or carbonate suspension with sulfurous acid.

Calcium Tartrate. $CaC_4H_4O_6 \cdot H_2O$, white solid, solubility: at 0°C 0.0875, at 80°C 0.180 g anhydrous salt in 100 ml saturated solution, formed by reaction of calcium carbonate or hydroxide and tartaric acid, or by precipitation of Ca^{2+} with a tartrate solution.

CALCIUM CARBONATE. [CAS: 1317-65-3]. Calcium carbonate, [CAS: 471-34-1]. $CaCO_3$, mol wt 100.09, occurs naturally as the principal constituent of limestone, marble, and chalk. Powdered calcium carbonate is produced by two methods on the industrial scale. It is quarried and ground from naturally occurring deposits and in some cases beneficiated. It is also made by precipitation from dissolved calcium hydroxide and carbon dioxide. The natural ground calcium carbonate and the precipitated material compete industrially based primarily on particle size and the characteristics imparted to a product.

Calcium carbonate is one of the most versatile mineral fillers and is consumed in a wide range of products, including paper, paint, plastics, rubber, textiles, caulks, sealants, and printing inks. High purity grades of both natural and precipitated calcium carbonate meet the requirements of the *Food Chemicals Codex* and the *United States Pharmacopeia* and are used in dentifrices, cosmetics, foods, and pharmaceuticals.

Properties

Calcium carbonate occurs naturally in three crystal structures: calcite, aragonite, and, although rarely, vaterite. Calcite is thermodynamically stable; aragonite is metastable and irreversibly changes to calcite when heated in dry air to about 400°C.

The commercial grades of calcium carbonate from natural sources are either calcite, aragonite, or sedimentary chalk. In most precipitated grades aragonite is the predominant crystal structure. The essential properties of the two common crystal structures are shown in Table 1.

TABLE 1. PROPERTIES OF CALCIUM CARBONATE

Property	Calcite	Aragonite
specific gravity	2.60–2.75	2.92–2.94
hardness, Mohs'	3.0	3.5–4.0
solubility at 18°C, g/100 g H_2O	0.0013	0.0019
melting point, °C	1339[a] dec 900	[b]
index of refraction		
α		1.530
β		1.680
γ		1.685
ω	1.658	
ε	1.486	

[a] At 10.38 MPa (102.5 atm).
[b] Decomposes to calcite at temperatures >400°C

Economic Aspects

The principal U.S. producers of ground calcium carbonate are Columbia River Carbonates, ECC International, Franklin Limestone Company, Genstar Stone Products, Georgia Marble Company, J.M. Huber Corporation, Calcium Carbonates Division, James River Limestone Company, Inc., OMYA Inc. (Pluess-Staufer), and MTI Inc. The principal U.S. producers of precipitated calcium carbonate are Mississippi Lime Company and MTI Inc.

Health and Safety Factors

Calcium carbonate is listed as a food additive and not considered a toxic material. The exposure to dust is regulated and a Threshold Limit Value-Time-Weighted Average (TLV-TWA) of 10 mg/m^3 is set. Both natural ground and precipitated calcium carbonates can contain low levels of impurities that are regulated.

CALCIUM CHLORIDE. Calcium chloride, [CAS: 10043-52-4], $CaCl_2$, is a white, crystalline salt that is very soluble in water. Solutions containing 30-45 wt % $CaCl_2$ are used commercially. Of the alkaline-earth chlorides it is the most soluble in water. It is extremely hygroscopic and liberates large amounts of heat during water absorption and on dissolution. It forms a series of hydrates containing one, two, four, and six moles of water per mole of calcium chloride (Table 1). Another hydrate, $CaCl \cdot 0.33H_2O$, has been identified, mol wt 116.98; 94.8 wt % $CaCl_2$; heat of solution in water to infinite dilution, −71.37 kJ/mol (−17.06 kcal/mol).

Commercial applications of calcium chloride and its hydrates exploit one or more of its properties with regard to aqueous solubility, hygroscopic nature, the heat gained or lost when one hydrated phase changes to another, and the depressed freezing point of the eutectic solution at a composition of about 30% by weight calcium chloride.

Properties

The properties of calcium chloride and its hydrates are summarized in Table 1.

Calcium Chloride Solutions. Because of high solubility in water, calcium chloride is used to obtain solutions having relatively high densities.

Viscosity is an important property of calcium chloride solutions in terms of engineering design and in application of such solutions to flow-through porous media. Data and equations for estimated viscosities of calcium chloride solutions over the temperature range of 20-50°C are available.

Production and Consumption

Significant quantities of calcium chloride are produced in the United States, Canada, Mexico, Germany, Belgium, Sweden, Finland, Norway, and Japan.

In the United States the principal route for making calcium chloride is by the evaporation of underground brines. Additional commercial material is available by the action of hydrochloric acid on limestone.

Uses

Calcium chloride, manufactured for over 100 years, has been used for a variety of purposes. The primary $CaCl_2$ markets have not changed since the 1950s. Significant markets in the United States are for deicing during the winter and roadbed stabilization, and as a dust palliative during the summer. Use as an accelerator in the ready-mix concrete industry is sizable but there is concern about chloride usage because of the possible corrosion of steel in highways and buildings. Calcium chloride is also used in oil and gas well drilling. The size of that market is dependent on the state of the worldwide oil and gas industry.

Food. Food-grade calcium chloride is used in cheese making to aid in rennet coagulation and to replace calcium lost in pasteurization. In the canning industry it is used to firm the skin of fruit such as tomatoes, cucumbers, and jalapenos. It acts as a control in many flocculation, coagulation systems. Food-grade calcium chloride is used in the brewing industry both to control the mineral salt characteristics of the water and as a basic component of certain beers.

Toxicity and Environmental

Above certain levels chloride is toxic to plants and animals. Thus, when considering calcium chloride, potentially large concentrations of calcium ion can be tolerated, but at these concentrations the chloride ion becomes toxic.

Calcium chloride solutions, typically employed at 2-5% concentration, are used as antispasmodics, diuretics, and in the treatment of tetany. Concentrated solutions of calcium chloride cause erythema, exfoliation, ulceration, and scarring of the skin. Injections into the tissue may cause necrosis. If given orally calcium chloride can cause irritation to the gastrointestinal tract unless accompanied by a demulcent. There is no published information on mutagenicity or carcinogenicity caused by calcium ions or calcium chloride. Calcium chloride has been give a toxicity or hazard level of 3. Materials in this classification typically have LD_{50} below 400 mg/kg or an LC_{50} below 100 ppm.

livestock is well established. Although about 99% of the calcium in the bodies of animals is found in bones and teeth, the element is an essential constituent of all living cells.

Various calcium salts and organic compounds fall into this category of dietary supplements and are frequently used in feeds and foods. Some of the more important additives include calcium carbonate, calcium glycerophosphate, calcium phosphate (di- and monobasic), calcium pyrophosphate, calcium sulfate, and calcium pantothenate.

Limestone is frequently used to augment animal feedstuffs. When used, it must be low in fluorine. Calcite limestone is preferred. Calcium is also supplied in the form of crushed oyster shells, marl, gypsum (calcium sulfate), bone meal, and basic slag. In compounding feedstuffs, the specific selection of calcium source is dependent upon the species to be fed. The requirements differ, for example, between cattle, swine, and poultry. The quantity required also varies with the life stage of the animal. For example, laying hens require a much higher percentage of calcium in their diet than starting poultry.

In the mammalian body, calcium is required to insure the integrity and permeability of cell membranes, to regulate nerve and muscle excitability, to help maintain normal muscular contraction, and to assure cardiac rhythmicity. Calcium plays an essential role in several of the enzymatic steps involved in blood coagulation and also activates certain other enzyme-catalyzed reactions not involved in any of the foregoing processes. Calcium is the most important element of bone salt. Together with phosphate and carbonate, calcium confers on bone most of its mechanical and structural properties.

Calcium Metabolism

The aggregate of the various processes by which calcium enters and leaves the body and its various subsystems can be summarized by the term *calcium metabolism*. The principal pathways of calcium metabolism are intake, digestion and absorption, transport within the body to various sites, deposition in and removal from bone, teeth, and other calcified structures, and excretion in urine and stool.

Pathways

The principal pathways involve three subsystems of the body: (1) the oral cavity where ingestion occurs and the gastrointestinal tract where digestion and absorption take place and from which the feces is excreted; (2) the body fluids, including blood, which transport calcium, and the soft tissues and body organs to which calcium is transported and where many of its physiological functions are carried out (some of the organs, like the kidney, the liver, and sweat glands, are also responsible for calcium excretion); and (3) the skeleton, including the teeth, where calcium is deposited in the form of bone salt and from where it is removed (resorbed) after destruction of the bone salt.

Calcium Intake

This varies in different populations and is related to the food supply and to the cultural and dietary patterns of a given population. The intake of a substantial fraction of the world population falls between 400 and 1,100 mg/day, but a range encompassing 95% of all people would undoubtedly be even wider. Most populations derive half or more of their calcium intake from milk and dairy products. Calcium intakes of domestic and laboratory animals are higher than are those of humans. For example, rats typically ingest 250 mg Ca/kg body weight, and cattle 100 mg/kg, whereas humans ingest only 10 mg/kg. Ingestion falls with age in all species. The average percentage concentration of minerals in the lean body mass of vertebrates ranges from 1.1 to 2.2%.

Calcium Absorption

In most animals, including the human body, this occurs mainly in the upper portion of the small intestine. The amount and, therefore, the fraction of calcium absorbed from the gut are a function of intake, age, nutritional status, and health. Generally, the fraction absorbed decreases with age and intake and as the nutritional status improves. The absolute amount absorbed increases with intake and may or may not decrease with age. The mechanisms by which calcium is absorbed are not well understood. Active transport of the ion against an electrochemical gradient seems to be involved, but not all of the calcium appears to be absorbed by ways of this process, because calcium absorption continues under conditions when active transport is severely depressed, as in vitamin D deficiency. Calcium absorption can be enhanced by the administration of large doses of vitamin D and is depressed in vitamin D deficiency. There is uncertainty regarding the effect on calcium absorption of the parathyroid hormone, the major endocrine control of the blood calcium level. Patients with hyperparathyroidism have been shown to have higher than normal absorption and patients with hypoparathyroidism to have lower than normal absorption. Similar effects have been observed in acute animal experiments, but in most of these instances a possible indirect effect has not been excluded.

Effects of Microgravity

Experience to date with humans who have lived under microgravity conditions in spacecraft has indicated possible "demineralization" of bone structure. Research has been difficult because the time spans of exposure have been so short. More must be known, however, as plans for programs requiring living under microgravity conditions for months and years are getting underway. Some analytic marker, which can return a record of changes that have occurred during space travel, is needed. A marker isotope, calcium-48, is now being seriously considered. The isotope is not abundant in nature and must be produced in the laboratory. Researchers contemplate that, by using a laser to excite calcium-48 at its resonance frequency, it will be possible to extract the isotope from samples.

Interrelationship with Phosphorus and Vitamin D

The interdependence of calcium, phosphorus, and vitamin D is exemplary of how synergistic effects can occur from combinations of feed and food components, either with a positive or negative result in the animal body. The relative concentrations (proportions) of each component in such a combination can be quite critical. Much research has gone into these particular interrelationships; much further research is required. The relationship between phosphorus and calcium nutrition has been known since the early 1840s, when Chossat in France first discovered that pigeons develop a poor bone structure when fed diets low in calcium. A few years later, the fundamental relationship of calcium and phosphorus in animal diets was developed by French and German researchers. It was not until 1922, however, with the discovery of vitamin D, that a triangular relationship was observed. See also **Phosphorus**; and **Vitamin D**.

Calcium in Blood Plasma

The concentration of calcium in the blood plasma of most mammals and many vertebrates is quite constant at about 2.5 mM (10 milligrams per 100 milliliters plasma). In the plasma, calcium exists in three forms: (1) as the free ion, (2) bound to proteins, and (3) complexed with organic (e.g., citrate) or inorganic (e.g., phosphate) acids. The free ion accounts for about 47.5% of the plasma calcium; 46% is bound to proteins; and 6.5% is in complexed form. Of the latter, phosphate and citrate account for half.

The mechanism involved in the regulation of the plasma calcium level is not fully understood. The parathyroid glands regulate both level and constancy: when these glands are removed, the plasma level drops and tends to stabilize at about 1.5 mM, but variations in calcium intake may induce fairly wide fluctuations in the plasma level. In the intact organism, wide variations in intake produce essentially no variations in the plasma calcium value, which is stabilized at about 2.5 mM. The equilibrium between bone and plasma is believed to determine the level of the plasma calcium in parathyroidectomized animals, but this reasonable hypothesis requires further experimental support. See also **Blood**. The problem of whether parathyroid regulation is due to a single hormone with hypercalcemic properties or to two hormones, one hypocalcemic, termed calcitonin, the other hypercalcemic, termed parathyroid hormone, continues under investigation.

When the calcium ion concentration is lowered in the fluids bathing nerve axons (fluids which are in very rapid equilibrium with the blood plasma) the electrical resistance of the axon membrane is lowered, there is increased movement of sodium ions to the inside, and the ability of the nerve to return to its normal state following a discharge is slowed. Thus, on the one hand, there is hyperexcitability. But, the ability for synaptic transmission is inhibited because the rate of acetylcholine liberation is a function of the calcium ion concentration. The neuromuscular junction is

affected in a similar fashion; hence, the end plate potential is lowered before the muscle membrane potential and the muscle membrane is in a hyperexcitable state. These events are reversed when the calcium ion concentration is raised above the normal in the blood plasma and in the fluids bathing muscle and nerve. It is for these reasons that hypocalcemia is associated with hyperexcitability and ultimately tetany and hypercalcemia with sluggishness and bradycardia.

Muscular Contraction and Relaxation

The role of calcium in this function is not fully understood. Some researchers have proposed that calcium is the link between the electrical and mechanical events in contraction. It has been shown *in vitro* that when calcium ions are applied locally, muscle fibers can be triggered to contract. It has further been postulated that relaxation of muscle fibers is brought about by an intracellular mechanism for reducing the concentration of calcium ions available to the muscle filaments. Others postulate that contraction occurs because calcium inactivates a relaxing substance, which is released from the sarcoplasmic reticulum in the presence of ATP (adenosine triphosphate).

Bone

This is the most important reservoir of calcium in the animal body. Accounting for the largest portion of the body's calcium, bone calcium also constitutes about 25% (weight) of fat-free, dried bones. Calcium occurs in bone mostly in the form of a complex, apatitic salt, so named for its structural resemblance to a family of calcium phosphates of which hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ is the best-known mineralogical example. Since calcium occurs also as the carbonate, there is discussion as to whether bone salt contains the carbonate as a separate phase, whether some of the surface phosphate in apatite has been substituted for by carbonate, or whether bone mineral is a carbonato-apatite, such as dahlite. It is important to recognize that the crystal lattice of the bone mineral, when first laid down, does not and probably cannot have all possible calcium positions occupied. Whether stability is derived from hydrogen and/or organic bonds to which the mineral may be attached is not fully determined. It has been proposed that bone salt is a lamellar mixture of octocalcium phosphate and hydroxyapatite. This hypothesis has to account for the amount of pyrophosphate formed when bone salt is heated and also for its evolution with age, i.e., the increase with age in the calcification of bone and the corresponding drop in its induced pyrophosphate content, observations for which the apatitic structure can account. The proponents of the octocalcium phosphate hypothesis explain this by showing that octocalcium phosphate breaks down to apatite and anhydrous dicalcium phosphate, which upon further heating give rise to pyrophosphate. Finally, it is postulated that octocalcium phosphate may be present in young and presumably newly formed bone, whereas in older bone an apatitic phosphate admittedly dominates the equilibrium.

Calcium enters and remains in bone as a result of calcification processes that involve two steps: (1) deposition of bone salt of a minimum calcium content and specific gravity, which occurs by way of nucleation, probably an epitactic process on the collagen fibers, with the ground substance (mostly mucopolysaccharides) between the fibers exerting either a positive or an inhibitory effect on the nucleation process; and (2) subsequent further mineralization of the bone mineral, leading to an increase in its calcium content and its specific gravity.

Calcium removal, in contrast, involves destruction of the calcified structure *in toto*. There is no evidence that only particular structures are resorbed, e.g., those with a given degree of mineralization.

The amount of calcium deposited in bone at any moment may be determined from experiments with radioactive calcium. In growing individuals, it exceeds the amount removed by bone destruction. In adults, it is about the same as the amount removed. Such individuals are considered to be in "zero" calcium balance. In older persons, the amount deposited is less than the amount removed.

Calcium's Role in Postmenopausal Women

The effectiveness of calcium supplementation in retarding the rate of bone loss in older, postmenopausal women, continued to be debated in the 1990s. Some studies demonstrated that calcium could reduce the rate of bone loss; other studies were not fully convincing, particularly with regard to slowing bone loss from the spine and hip. Dowson-Hughes and a group of researchers (Tufts University) conducted a double-blind, placebo-controlled, random trial to determine the effect of calcium on bone loss from the spine, femoral neck, and radius in over 300 healthy postmenopausal women. Conclusions: Healthy postmenopausal women whose usual dietary calcium intake is low should increase their calcium intake to 800 mg per day (essentially consistent with most RDAs). In the study calcium citrate maleate was found to be a better source of calcium than calcium carbonate for dietary augmentation.

A 1990 study by Sheikh and Fordtran (Baylor University Medical Center) indicated that there are important differences in the bioavailability of calcium from different calcium-containing compounds. The ability to dissolve a preparation in dilute acid is a major factor that contributes to bioavailability. Currently, the FDA (Food and Drug Administration, U.S.) does not require commercially available products to meet specific dissolution standards.

R.L. Prince and a group of investigators (Sir Charles Gairdner Hospital, Nedlands, Western Australia and King Edward Memorial Hospital, Subiaco, Western Australia) researched the effects of exercise, calcium supplementation, and hormone replacement therapy over a two-year period involving 120 postmenopausal women. General conclusions of the study: "In postmenopausal women with low bone density, bone loss can be slowed or prevented by exercise plus calcium supplementation, or prevented by exercise plus calcium supplementation or estrogen-progesterone replacement. Although the exercise-estrogen regimen was more effective than exercise and calcium supplementation in increasing bone mass, it also caused more side effects.

Preclampsia

During but mainly at the end of pregnancy, a syndrome referred to as *preclampsia* may develop during labor or in the immediate puerperium. The condition is relatively common and poses a danger to mother and baby. With current knowledge, the condition is unpredictable in its onset and progression. Presently, the only known treatment is to terminate the pregnancy.

Although there is no specific diagnostic test, certain abnormalities, including hypertension and proteinuria, may be detected. Zemel et al., as the result of conducting a study of over 50 women during each trimester of pregnancy, have found that an increase in the sensitivity of platelet calcium to arginine vasopressin may be an early predictor of subsequent preclampsia.

Excretion of Calcium

The principal routes of excretion are stool and urine. Calcium in the stool may be considered as made up of unabsorbed food calcium and non-reabsorbed digestive juice calcium. The latter is termed the fecal endogenous calcium. The proportion of fecal endogenous calcium to urinary calcium varies in different species. It is approximately 1:1 in humans and 10:1 in the rat and in cattle. The calcium in the urine may have a dual origin—calcium that was filtered at the glomerulus and failed to get reabsorbed along the length of the nephron, and calcium that may have originated from trans-tubular movement in certain regions of the nephron. The amount of calcium that may be lost in sweat can be large, but there is no convincing evidence that sweat is a habitual route of significant loss.

Natural Availability of Calcium

The soils of humid regions are commonly low in calcium; thus, ground limestone usually is applied to add the element, reduce the toxicity of aluminum and manganese, and correct soil acidity. The soils of dry areas are frequently rich in calcium. There is little evidence to indicate a strong relationship between human nutrition and calcium excesses or deficiencies in the soil. Even with farm livestock, most calcium deficiencies are not related to levels of available calcium in the soil. The reason for this anomaly is evident when one examines some of the controls over the movement of calcium in the food chain.

At the step in the food chain when calcium moves from the soil to the plant, controls based upon the genetic nature of the plant are very important.

Because of these controls, certain plant species always accumulate fairly high concentrations of calcium; while other plants accumulate rather low concentrations. Among the forage crops, red clover grown, for example, on the low-calcium soils of the northeastern United States, contains more calcium than grasses grown on the high-calcium soils of the western United States. Among the food crops, snap beans and peas normally contain about three to five times as much calcium as corn (maize) and tomatoes. Thus, the level of calcium in the diets of people or of animals depends more on what kinds of plants are included in the diet than it does on the supply of available calcium in the soil where these plants are grown.

Adding limestone to soils to correct soil acidity and to supplement available calcium will, of course, indirectly affect human and calcium nutrition, but this is a difficult quantity to measure.

CALCIUM SULFATE. [CAS: 10101-11-4]. Calcium sulfate, $CaSO_4$, in mineral form is commonly called and occurs abundantly in many areas of the world. In natural deposits, the main form is the dihydrate. Some anhydrite is also present in most areas, although to a lesser extent. Mineral composition can be found in Table 1. The hemihydrate is normally produced by heat conversion of the dihydrate from which $\frac{3}{2}H_2O$ is removed as vapor. The resulting powder is also known as plaster of Paris. Stucco has the greatest commercial significance of these materials. It is the primary constituent used to fabricate products and in formulated plasters used in job or shop-site applications.

About 23×10^6 t of gypsum are consumed annually. About 80% is processed into the commercially usable hemihydrate. Uses of gypsum are in fabricated or formulated building materials, Portland cement set regulation, and agricultural soil conditioning.

Properties

Table 2 lists the physical properties of calcium sulfate.

TABLE 1. GYPSUM FORMS AND COMPOSITION

Common name	Molecular formula	Composition, wt % CaO	SO_3	Combined H_2O
anhydrite	$CaSO_4$	41.2	58.8	
gypsum	$CaSO_4 \cdot 2H_2O$	32.6	46.5	20.9
stucco	$CaSO_4 \cdot \frac{1}{2}H_2O$	38.6	55.2	6.2

TABLE 2. PHYSICAL PROPERTIES OF CALCIUM SULFATE

Property	Dihydrate	Hemihydrate	Anhydrite
mol wt	172.17	145.15	136.14
transition point, °C	128[a] 163[b]	163[b]	
mp[c] °C	1450	1450	1450
specific gravity	2.32		2.96
solubility at 25°C, g/100 g H_2O	0.24	0.30	0.20
hardness, Mohs'	1.5–2.0		3.0–3.5

[a] Hemihydrate is formed.
[b] Anhydrous material is formed.
[c] Compound decomposes.

Sources

The natural, or mineral, form of gypsum is most widely extracted by mining or quarrying and used commercially.

Gypsum is also obtained as a by-product of various chemical processes. The main sources are from processes involving scrubbing gases evolved in burning fuels that contain sulfur, and the chemical synthesis of chemicals, such as sulfuric acid, phosphoric acid, titanium dioxide, citric acid, and organic polymers.

Decomposition Thermodynamics

The thermodynamic properties of gypsum decomposition, which involve two distinct steps, have been the subject of much theoretical and practical study. Two forms of the hemihydrate, α and β, have been identified.

$$CaSO_4 \cdot 2H_2O \xrightarrow{\Delta} CaSO_4 \cdot \frac{1}{2}H_2O + 1\frac{1}{2}H_2O$$

$$CaSO_4 \cdot \frac{1}{2}H_2O \xrightarrow{\Delta} CaSO_4 + \frac{1}{2}H_2O$$

Manufacture

Natural Gypsum. Gypsum rock from the mine or quarry is crushed and sized to meet the requirements of future processing or removed for direct marketing of the dihydrate as a cement retarder. Once subjected to a secondary crusher, calcining, and drying, the product is fine-ground. Fine-ground dihydrate is commonly called land plaster, regardless of its intended use. The degree of fine grinding is dictated by the ultimate use. The majority of fine-ground dihydrate is used as feed to calcination processes for conversion to hemihydrate.

β-Hemihydrate. The dehydration of gypsum, commonly referred to as calcination in the gypsum industry, is used to prepare hemihydrate, or anhydrite. Kettle calcination continues to be the most commonly used method of producing β-hemihydrate.

α-Hemihydrate. Three processing methods are used for the production of α-hemihydrate. One, developed in the 1930s, involves charging lump gypsum rock 1.3–5 cm in size into a vertical retort, sealing it, and applying steam at a pressure of 117 kPa (17 psi) and a temperature of about 123°C. After calcination under these conditions for 5–7 h the hot moist rock is quickly dried and pulverized.

Another method, first reported in the 1950s, has lower water demand. The dihydrate is heated in a water solution containing a metallic salt such as $CaCl_2$ at pressures not exceeding atmospheric. A third method, developed in 1967, prepares very low water-demand α-hemihydrate by autoclaving powdered gypsum in a slurry. A crystal-modifying substance such as succinic acid or malic acid is added to the slurry in the autoclave to produce large squat crystals.

Anhydrite. In addition to kettle calcination, soluble anhydrite is commercially manufactured in a variety of forms, from fine powders to granules 4.76 mm (4 mesh) in size, by low temperature dehydration of gypsum.

Production and Trade

Crude gypsum is the principal form of calcium sulfate shipped in international trade, although the 1980s saw an increase in the volume of fabricated products moved across international borders. See also **Gypsum.**

CALICHE (Nitrate). The gravel, rock, soil, or alluvium cemented with soluble salts of sodium in the nitrate deposits of the Atacama Desert of northern Chile and Peru. The material contains from 14 to 25% sodium nitrate, 2 to 3% potassium nitrate, and up to 1% sodium iodate, plus some sodium chloride, sulfate, and borate. At one time, this was an important natural fertilizer.

CALIFORNIUM. [CAS: 7440-71-3]. Chemical element, symbol Cf, at. no. 98, at. wt. 251 (mass number of the most stable isotope), radioactive metal of the *Actinide* series, also one of the *Transuranium* elements. All isotopes of californium are radioactive; all must be produced synthetically. See also **Radioactivity**. The isotope ^{245}Cf was first produced by S.G. Thompson, K. Street, Jr., A. Ghiorso, and G.T. Seaborg at the University of California at Berkeley in 1950 by bombarding microgram quantities of ^{242}Cm with helium ions. The reaction: ^{242}Cm (α, n) $\rightarrow$ ^{245}Cf. The isotope has a half-life of 44 min. A number of other isotopes of Cf have been made, one of which, ^{254}Cf, half-life 55 days, is of interest because it decays predominantly by spontaneous fission. The longest-lived isotope is ^{251}Cf ($t_{1/2}$ = about 700 yrs), the next is ^{249}Cf ($t_{1/2} = 470$ yrs). Except for ^{250}Cf ($t_{1/2} = 10$ yrs), and ^{252}Cf ($t_{1/2} = 2.2$ yrs), all other isotopes have half-lives less than one year. Several other isotopes (246, 248, 249, 250, 252) also decay by spontaneous fission, but with fission half-lives much longer than the half-lives for alpha-decay. Californium is considered to occur in its compounds only in the tripositive state.

Studied through the use of tracer quantities, the chemical properties of californium indicate that its chemical properties are analogous to those of the tripositive actinides and lanthanides, showing the fluoride and the oxalate to be insoluble in acid solution, and the halides, perchlorate, nitrate, sulfate and sulfide to be soluble.

Probable electronic configuration:

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^{10} 6s^2 6p^6 7s^2$$

Ionic radius: Cf^{3+} 0.98 Å.

In 1960, Cunningham and Wallmann isolated 0.3 microgram of californium (as californium-249) oxychloride. The best isotope for the study of californium is ^{249}Cf, which can be isolated in pure form through its beta particle-emitting parent, ^{249}Bk.

Californium-252 is an intense neutron source. One gram emits 2.4×10^{12} neutrons per second. This isotope shows promise for applications in neutron activation analysis, neutron radiography, and as a portable source for field use in mineral prospecting and oil well logging.

CALORESCENCE. A term designating the production of visible light by means of energy derived from invisible radiation of frequencies below the visible range. Tyndall found it possible to raise a piece of blackened platinum foil to a red heat by focusing upon it infrared radiation from an arc or from the sun, the visible wavelengths having been filtered out. It is to be noted that the transformation is indirect, the light being produced by heat and not by any direct stepping up of the infrared frequency. A somewhat analogous phenomenon is the production of visible sparks or the glowing of a fine platinum wire in a resonant circuit energized by long-wave Hertzian radiation.

CALORIMETRY. Calorimetry is one of the oldest reported scientific measurement techniques. Calorimetry is derived from the Latin calor meaning heat, and the Greek metry meaning to measure. All calorimetric techniques are based on the measurement of heat that may be generated (exothermic process) or consumed (endothermic process) by a sample or system. The approaches to measuring such heat transfers are numerous. Since calorimetry's advent in the late 18th century, a large assortment of techniques has been developed. Initially calorimetric techniques were based on simple temperature measurement methods. More recently, advances in electronics and control have added a new dimension to calorimetry, enabling users to collect data and maintain samples under conditions that were previously unattainable.

Any process that results in heat being generated and/or exchanged with the environment is a candidate for a calorimetric study. As a result, it is not surprising to discover that calorimetry has a very broad range of applicability, with examples ranging from characterizing the heating value of fuel materials to drug design in the pharmaceutical industry, to quality control of process streams in the chemical industry, and the study of metabolic rates in biological systems.

Traditionally, calorimeters have been classified according to the degree of heat transfer occurring between the reacting system and its surroundings. At one extreme, the calorimeter is isolated as fully as possible from its surroundings so that heat transfer is minimized. Work added or energy converted by a chemical process causes a change in temperature of the calorimeter and its contents. For an exothermic reaction, the ideal situation is approximated by heating the jacket that surrounds the calorimeter in order to nullify the temperature differential between the calorimeter cell and its surroundings during a test. This type of calorimeter is known as an adiabiatic calorimeter.

The second extreme case uses a good, systematic path for heat to flow between the calorimeter system and its surroundings. In this type of calorimeter, there is no net change in temperature between the calorimeter cell and its surroundings. In this conduction type or isothermal calorimeter, the transfer of heat from the calorimeter to the surroundings is typically measured by integrating the voltage output of a thermoelectric transducer situated in the heat flow path between the calorimeter and a heat sink. Another variation of this type of calorimeter operates on the heat compensation principle. Either Joule heating or Peltier cooling compensation of the reaction enthalpy achieves isothermal conditions.

An important variation of the adiabatic principle is isoperibol calorimetry. Well-defined heat leaks, minimized by efficient calorimeter construction and experiment design, are compensated for by calculation and/or extrapolation. The isoperibol design holds the temperature of the immediate environment surrounding the calorimeter constant. The word isoperibol literally means "constant temperature environment."

Calorimetry is used to determine the thermodynamic properties of materials as well as to measure the thermal effects associated with physical and chemical processes. These properties are valuable, for example, in choosing practical manufacturing techniques in the chemical process industries, optimizing yields of reaction products, making energy balances, and as diagnostic or analysis tools. Calorimetry is also used to determine the important properties of complex or poorly defined materials. One example of this is in determining the heating value of fuels such as coal and coke, petroleum products and gaseous fuels. In recent years, the heating value of incinerated waste materials and other refuse-derived fuels have become important. The calorimetry of hazardous and explosive materials has direct relevance to the transport and safe handling of chemicals.

Interest in the use of calorimetry as a routine diagnostic or analysis tool has gained significant momentum only in the last 50 years. This interest has lead to the development of popular procedures such as differential thermal analysis (DTA) and differential scanning calorimetry (DSC). A wide variety of solution calorimetric techniques exist today. These techniques include thermometric titration, injection and flow enthalpimetry. The major growth of commercial instrumentation for calorimetry has occurred to address applications in routine analysis and the rapid characterization of materials.

The following discussion will use an oxygen combustion calorimeter to help illustrate some of the basic concepts of calorimetry. One of the fundamental characteristics of any fuel is the amount of energy released as it is burned. This value is referred to as the heat of combustion or the calorific value of the fuel. This value is usually expressed in British thermal units per pound (Btu/lb), calories per gram (cal/g), or megajoules per kilogram (MJ/kg). The heat of combustion of fuels is routinely determined in order to establish the price of the fuel as well as to serve as a basis for calculating the overall efficiency of a power-generating facility or engine.

To determine the heat of combustion of a fuel, a representative sample (typically one gram) is burned in a high-pressure oxygen atmosphere within a metal "bomb" or pressure vessel. The energy released by this combustion is adsorbed by the calorimeter and results in a temperature rise. The heat of combustion of the sample is the product of the temperature rise and the predetermined energy equivalent or calibration factor for the instrument. Burning a sample with a known heat of combustion and recording the temperature rise of the calorimeter determines the energy equivalent of the calorimeter. This factor is usually expressed as the amount of heat necessary to raise the calorimeter one degree Celsius. Benzoic acid is used almost exclusively as a reference material for fuel calorimetry because it is nonhydroscopic and is readily available in a very pure form.

Any oxygen bomb calorimeter consists of four essential parts: (1) a bomb or vessel in which the sample is burned; (2) a bucket or container which holds the bomb as well as a precisely measured quantity of water to absorb the heat released from the bomb and a stirring device to aid in achieving rapid thermal equilibrium; (3) a jacket for protecting the bucket from transient thermal stresses; and (4) a thermometer for measuring temperature changes within the bucket. The cross section of a simple calorimeter is shown in Fig. 1.

The bomb consists of a strong, thick-walled, metal vessel that can be opened for inserting the sample, for cleaning, and for recovering the products of combustion. Valves are provided for filling the bomb with oxygen and releasing the residual gases after the test is complete. Electrodes to carry the ignition current to a fuse wire that ignites the sample are also provided. Pressures up to 100 bar are developed during the combustion. As a result, most bombs are constructed to safely withstand pressures of at least double this value.

The calorimeter bucket contains the bomb plus a sufficient quantity of water to completely immerse the bomb in order to absorb the heat released from the combustion. A stirrer is used in the bucket to facilitate bringing the bucket and its contents to thermal equilibrium.

The jacket that contains the bucket with its bomb provides a thermal shield to control the heat transfer between the calorimeter bucket and its surroundings. In an isoperibol calorimeter, it is not necessary to prevent this transfer, as long as a means of precisely determining the amount of heat transferred during the determination can be established.

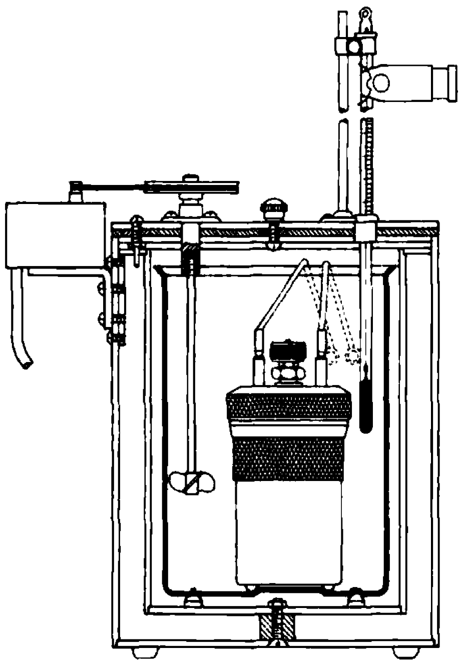

Fig. 1. Cross-section of plain jacket oxygen bomb calorimeter. (*Parr Instrument Co.*)

The calorimetric thermometer measures temperature changes within the calorimeter bucket. It must be able to provide excellent resolution and repeatability. High single-point accuracy is not required since it is the change in temperature that is important in fuel calorimetry. Mercurial thermometers, platinum resistance thermometers, quartz oscillators, and thermistor systems have all been successfully used as calorimetric thermometers.

The American Society for Testing and Materials (ASTM) has developed a series of standard test methods for both solid and liquid fuels in oxygen bomb calorimeters. Advanced combustion calorimeters are capable of performing 8 to 10 tests per hour with a precision of 0.1%.

Calorimeters of Historical and Special Interest

Around 1760 Black realized that heat applied to melting ice facilitates the transition from the solid to the liquid state at a constant temperature. For the first time, the distinction between the concepts of temperature and heat was made. The mass of ice that melted, multiplied by the heat of fusion, gives the quantity of heat. Others, including Bunsen, Lavoisier, and Laplace, devised calorimeters based upon this principle involving a phase transition. The heat capacity of solids and liquids, as well as combustion heats and the production of heat by animals were measured with these calorimeters.

A steam calorimeter was perfected by J. Joly (1886) and used for the accurate determination of specific heats of solids, liquids, and gases. In principle this apparatus consists of a balance, with the specimen hung from one pan and surrounded by an enclosure that can be flooded with steam. The mass of moisture condensing on the specimen, multiplied by the heat of vaporization of water, gives the quantity of heat imparted to the specimen.

The Nernst calorimeter is a calorimeter for the measurement of specific heat capacities at low temperatures. The sample to be measured is suspended in a glass or metal envelope that can be evacuated. The sample is heated by means of a platinum wire located in a bore inside the sample. The wire also serves as a resistance thermometer. The specific heat capacity is determined by recording the temperature rise in the sample for a given delivery of energy.

Differential scanning calorimetry (DSC) is a technique determining the variation in the heat flow given out or taken in by a sample when it undergoes temperature scanning in a controlled atmosphere. Any transformation taking place in a material during the temperature scan is accompanied by an exchange of heat. DSC enables the temperature of this transformation to be determined and the heat from it to be quantified. The DSC is used to measure specific heat capacity and heats of transition as well as to detect the temperature of phase changes and melting points.

Gas Calorimeters

There are three basic classifications: (1) total calorific value types, (2) net calorific value types, and (3) inferential types. Net calorific value is less than the total calorific value by an amount equal to the latent heat of vaporization of the water formed during combustion. A net calorific value instrument uses a means that give results more nearly related to the net value. Thus, these types are affected by gas composition and must be calibrated for the gas to be tested. Inferential-type instruments depend upon such characteristics as flame appearance, maximum flame temperature, specific gravity, or gas analysis as indicative of the calorific value.

CALORIZING. Production of a protective coating of iron-aluminum alloy on iron or steel. The articles are ordinarily coated by heating to a high temperature in a closed container packed with powdered aluminum. Other processes include impregnation at high temperature with an aluminum chloride vapor and spraying with molten aluminum from a spray gun and then heating to a high temperature. When the aluminum coating is held at high temperatures, an iron-aluminum alloy forms which is resistant to oxidation and corrosion by hot combustion gases, especially those containing sulfur compounds which are particularly corrosive to bare iron or steel.

Steel sheets are aluminized by a hot-dip process similar to galvanizing. The principal applications for such a product are furnaces and ovens, automobile mufflers, and other equipment requiring heat and corrosion resistance. When a sheet which has been coated with aluminum by a hot-dip process is exposed to a temperature over 1,000°F (538°C), the aluminum forms an iron-aluminum alloy which is heat- and corrosion-resistant.

CALVIN, MELVIN (1911–1997). An American chemist who won the Nobel prize for chemistry in 1961. Muck of his work involved the study of photosynthesis, biophysics, and application of physics and chemistry of molecules to some of the basic problems of biology. His doctorate was from the University of Minnesota. He did postgraduate work in England and at Northwestern University and the University of Notre Dame.

CAMPHOR *(Cinnamonum camphora; Lauraceae).* A crystalline compound occurring in various parts of the wood and leaves of the camphor tree, a large evergreen tree with light green leaves growing in many warm regions of southeastern Asia, notably Taiwan. Camphor, $C_{10}H_{16}O_7$, is a white solid, mp 179°C, bp 209°C, of a characteristic pleasant odor, insoluble in H_2O, soluble in alcohol or ether. Camphor may be produced synthetically by converting pinene into bornyl chloride with HCl, thence to isobornyl acetate, thence to isoborneol, and finally oxidizing borneol to camphor. Camphor has found use in medicines, insecticides and moth preventives. Earlier uses included the manufacture of plastics and lacquers.

As reported by American Forests, a champion camphor tree growing in Darby Florida was selected in 1992. Dimensions of the tree: circumference (at $4\frac{1}{2}$ feet; 1.4 meters above ground level) = 422 inches (1070 centimeters); height = 67 feet (20.4 meters); spread = 103 feet (31.4 meters).

CANCER (Drugs). See **Chemotherapeutics, Anticancer**.

CANCRINITE. The mineral cancrinite is a complex hydrous silicate (see also **Silicon**) corresponding approximately to the formula $(Na, K, Ca)_{6-8}(Al, Si)_{12}O_{24}(SO_4, CO_3, Cl)_{1-2} \cdot nH_2O$. It is hexagonal, with prismatic cleavage; hardness, 5–6; specific gravity, 2.42–2.50; color, white to gray or may be greenish, bluish, yellow, or flesh red; colorless streak; luster, subvitreous to greasy; transparent to translucent. Cancrinite is found only in the nephelite-syenites and related rock types and is commonly associated with sodalite. It is believed to be in part primary, having crystallized direct from the magma, and in part secondary as a result of alteration of nephelite by solutions of calcium carbonate. It is found in the Ilmen Mountains of the former U.S.S.R., in Rumania, in Norway, in Canada in Hastings County, Ontario, and in the United States in Kennebec County, Maine. This mineral was named for Count Georg Cancrin, a Russian statesman who died in 1845.

CANNIZZARO REACTION. Base catalyzed dismutation of aromatic aldehydes or aliphatic aldehydes with no α-hydrogen into the corresponding acids and alcohols. When the aldehydes are not identical, the reaction is called the "crossed Cannizzaro reaction."

CANNIZZARO, STANISLAO (1826–1910). Born in Italy, he extended the research of Avogadro on the molecular concentration of gases and thus was able to prove the distinction between atoms and molecules. His investigations of atomic weights helped to helped to make possible the discovery of the periodic law by Mendeleyev. His research in organic chemistry led to the establishment of the Cannizzaro reaction involving the oxidation reduction of an aldehyde in the presence of concentrated alkali.

CAPILLARITY. The name given to a class of phenomena, of which the elevating or depression of liquids in fine tubes is representative. When the interface between a liquid and a gas, or between two liquids, is intercepted by a solid surface, an equilibrium is established at the junction among the forces acting along the three surfaces of contact. For example, let a plate of solid S be dipped into a liquid L having gas G above it. See Fig. 1. A molecule at the junction O is acted upon by the adhesive attraction P, by the forces which give rise to the three surface tensions along the interfaces OH, OE, and OD, and by the reaction R of the plate S against which it is drawn by the adhesion. (Its weight may be considered negligible.) The flexible interface OH adjusts itself so that these forces come into equilibrium; unless, indeed, one of them, E, exceeds the sum of D and C, in which case the liquid "creeps" indefinitely along the surface as oil does over a glass or tin container. The equilibrium polygon at the right is labeled in each case to correspond with the figure representing the surfaces. The "angle of contact" α, between the liquid surface at O and the solid surface OD, is determined by the aforesaid forces acting at O. For most liquids against glass it is acute; for mercury against glass it is obtuse. See Fig. 2. In special cases it may be 90°, and in others it reduces to zero.

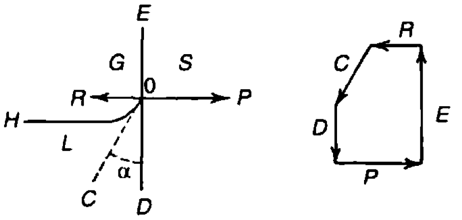

Fig. 1. Capillary force, large adhesion

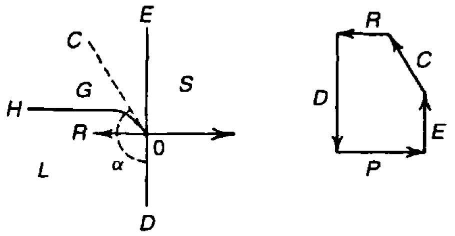

Fig. 2. Capillary force, small adhesion

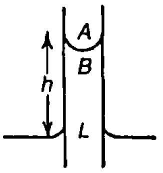

Fig. 3. Rise of liquid in capillary tube

If the interface between two media *A* and *B* (Fig. 3) is curved, *A* being on the concave side, the pressure in *A* is greater than in *B* on account of the surface tension; much as the pressure inside a rubber balloon is greater than outside. We can now understand why water rises in a capillary tube. In order to secure equilibrium, the liquid must rise until the pressure inside the surface at *B*, plus the pressure due to gravity at depth *h*, makes the pressure at *L* equal to that at the surface level outside; that is, to the atmospheric pressure. Similar reasoning applies to the depression of mercury in a glass tube. For a circular tube of internal radius *r*, the distance *h* to which capillarity will elevate (or depress) a liquid of density ρ and surface tension *T* (against air) is readily shown to be

$$h = \frac{2T\cos\alpha}{r\rho g}$$

where *g* is gravity. See also **Electrocapillarity**.

CAPILLARY. 1. Hair-like, especially in application to fine tubes. 2. A minute thin-walled blood vessel intervening between the arteries and veins. 3. A cylindrical space of small radius, or a tube containing such a space. The numerous uses of such tubes has given rise to a number of derived terms. Thus, the capillary correction is a correction applied to mercury barometers, widebore thermometers, etc., for the effect of capillarity on the height of the column. Capillary pressure is a pressure due to capillary force. See also **Capillarity**.

Capillary rise is the elevation of liquid in a capillary tube above the general level. Capillary separation is the separation of gases by flow through a porous medium. In a theory of this process based on the concept of momentum transfer, the actual porous medium is treated as equivalent to a bundle of parallel capillary tubes.

CAPRIC ACID. [CAS: 334-48-5]. Also called decanoic, decoic, and decyclic acid, formula $CH_3(CH_2)_8COOH$. The acid occurs as a glyceride in natural oils. Usual form is white crystals having an unpleasant odor. Soluble in most organic solvents and dilute nitric acid; insoluble in water. Specific gravity 0.8858 (40°C); mp 32.5°C; bp 270°C. Combustible. A component of some edible vegetable oils. See also **Vegetable Oils (Edible)**. Capric acid is derived from the fractional distillation of coconut oil fatty acids. The acid is used in esters for perfumes; fruit flavors; a base for wetting agents; as an intermediate in organic synthesis; plasticizer; resins; and used in food-grade additives.

CAPROIC ACID. [CAS: 142-62-1]. Also called hexanoic, hexylic, or hexoic acid, formula $CH_3(CH_2)_4COOH$. Present in milk fats to extent of about 2%. Also a constituent of some edible vegetable oils. See also **Vegetable Oils (Edible)**. The acid is oily, colorless or slightly yellow, and liquid at room temperature. Odor is that of Limburger cheese. Soluble in alcohol and ether; slightly soluble in water. Specific gravity 0.9276 (20.4°C); mp −4.0°C; bp 205°C. Combustible. Caproic acid is derived from the crude fermentation of butyric acid; or by fractional distillation of natural fatty acids. Used in various flavorings; manufacture of rubber chemicals; varnish dryers; resins; pharmaceuticals.

CAPROLACTAM. [CAS: 105-60-2]. $NH(CH_2)_5CO$, formula weight 112.15, liquid ingredient used in the manufacture of type 6 nylon. See also **Fibers**. Several hundred million pounds of the compound are produced annually. There are a number of proprietary processes for caprolactam production.

In one process, the chargestock is nitration-grade toluene, air, hydrogen, anhydrous NH_3, and H_2SO_4. The toluene is oxidized to yield a 30% solution of benzoic acid, plus intermediates and byproducts. Pure benzoic acid, after fractionation, is hydrogenated with a palladium catalyst in stirred reactors operated at about 170°C under a pressure of 10 atmospheres. The resultant product, cyclohexanecarboxylic acid, is mixed with H_2SO_4 and then reacted with nitrosylsulfuric acid to yield caprolactam. The nitrosylsulfuric acid is produced by absorbing mixed nitrogen oxides N_2O_3 in H_2SO_4: $N_2O_3 + H_2SO_4 \longrightarrow SO_3 + 2NOHSO_4$. The resulting acid solution is neutralized with NH_3 to yield $(NH_4)_2SO_4$ and a layer of crude caprolactam which is further purified.

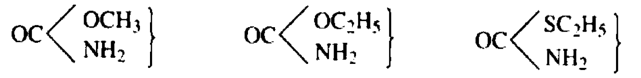
A later process utilizes a photochemical reaction in which cyclohexane is converted into cyclohexanone oxime hydrochloride.

The yield of cyclohexanone is estimated at about 86% by weight. Then, in a Beckmann rearrangement, the cyclohexanone oxime hydrochloride is converted to ε-caprolactam:

$$C_6H_{10}NOH \cdot 2\,HCl \xrightarrow{H_2SO_4} \underbrace{CH_2-(CH_2)_4-C{=}O}_{NH} + 2\,HCl$$

CARAT. See **Diamond**.

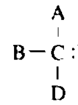
CARBAMATES. Derivatives of the hypothetical carbamic acid, H_2NCOOH, which does not exist. The ethyl derivative urethane is prepared by heating urea in alcohol under pressure, by the reaction $H_2NC(=O)NH_2 + C_2H_5OH \longrightarrow H_2NCOOC_2H_5 + NH_3$. The structures of representative carbamates are shown below:



Methyl carbamate   Methyl carbamate (urethane)   Thiourethane

CARBAMIC ACID. See **Herbicides**; **Insecticide**.

CARBANION. An ion of the general formula



where A, B and D are substituent groups. Their importance in elucidating the mechanism of organic reactions is because a considerable proportion of all organic reactions involve carbanions, as others do carbonium ions and carbon free radicals (including carbene radicals). Many carbanion reactions involve removal of a proton from a carboxylic acid to form a carbanion. Many electrophilic substitution reactions involve carbanions. Carbanions are strong bases or nucleophiles. Many electrophilic substitution reactions that have carbanion intermediates are base-catalyzed since the basic reagent produces the basic carbanion. Because of the negative charge on carbanions, their structures are affected by cations, by attached substituents and particularly by the solvent.

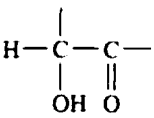
CARBENE. The name quite generally used for the methylene radical,: CH_2. It is formed during a number of reactions. Thus the flash photochemical decomposition of ketene ($CH_2{=}C{=}O$) has been shown to proceed in two stages. The first yields carbon monoxide and $:CH_2$, the latter then reacting with more ketene to form ethylene and carbon monoxide. Carbene reacts by insertion into a C−H bond to form a $C-CH_3$ bond. Thus carbene generated from ketene reacts with propane to form *n*-butane and isobutane. Carbene generated by pyrolysis of diazomethane reacts with diethyl ether to form ethylpropyl ether and ethylisopropyl ether.

Substituted carbenes are also known: chloroform reacts with potassium *t*-butoxide to form dichlorocarbene:CCl_2, which adds to double or triple carbon-carbon bonds to form cyclopropane derivatives.

CARBIDES. A binary solid compound of carbon and another element. The most familiar carbides are those of calcium, tungsten, silicon, boron, and iron (cementite). Two factors have an important bearing on the properties of carbides: (1) the difference in electronegativity between carbon and the second element, and (2) whether the second element is a transition metal. Saltlike carbides of alkali metals are obtained by reaction with acetylene. Those obtained from silver, copper, and mercury salts are explosive. See also **Carbon**; and **Iron Metals, Alloys, and Steels**.

CARBOCYCLIC COMPOUNDS. See **Organic Chemistry**.

CARBOHYDRATES. These are compounds of carbon, hydrogen, and oxygen that contain the saccharose grouping (below), or its first reaction product, and in which the ratio of hydrogen to oxygen is the same as in water.



Carbohydrates are the most abundant class of organic compounds, representing about three-fourths of the dry weight of all vegetation. Carbohydrates are also widely distributed in animals and lower life forms. These compounds comprise one of the three major components (others are protein and fat) of the human diet, and indeed that of most other animals. In a nutrition-conscious era, advocates for both more and fewer carbohydrate calories in the human diet can be found.

Classification of Carbohydrates

Because carbohydrates as components of foods and feedstuffs are not limited to just a few specific classes or types, but essentially run the gamut of the carbohydrate spectrum, it is in order here to review briefly the organization of carbohydrate chemistry, with some examples from the various classes. See also entry on **Organic Chemistry**.

Elementary Terminology

A term synonymous with carbohydrate is *saccharide* (sometimes *saccharose*). When referring to saccharides, the basic molecular formula is considered to be $C_6H_{12}O_6$. Compounds with this general formula, such as glucose, mannose, and galactose, are known as *monosaccharides* because they contain one $C_6H_{12}O_6$. A *disaccharide*, as typified by sucrose, lactose, and maltose, has the general molecular formula, $C_{12}H_{22}O_{11}$ and may be considered as containing two $C_6H_{12}O_6$ groupings that have been joined by one atom of oxygen, with the elimination of one molecule of water. Similarly, the *trisaccharides*, such as raffinose, have the molecular formula, $C_{18}H_{32}O_{16}$. Any larger molecules of the $C_x(H_2O)_y$ configuration are termed *polysaccharides*, and include the starches, celluloses, dextrin, and glycogen. See also **Starch**. An *oligosachharide* is a carbohydrate containing from two up to ten simple sugars linked together (e.g., sucrose, composed of dextrose and fructose). Beyond ten, the term *polysaccharide* is used. Gums and mucilages are complex carbohydrates. See also **Gums and Mucilages**.

Both the terms carbohydrate and saccharide are significant only by way of classifying these compounds, because neither term appears in whole or in part in any of the widely used names of these compounds. About the only point of nomenclature enjoyed in common by several of the saccharides is the termination *-ose*, as found, for example, in cellulose, dextrose, sucrose, and glucose. Any saccharides having the structure of an aldehyde is termed as *aldose*; any saccharide with the structure of a ketone is termed a *ketose*. For those saccharides that contain 4–6 carbons, the number of carbons forms a nomenclature base, as a *tetrose*, $C_4H_8O_4$, a *pentose*, $C_5H_{10}O_5$, and a *hexose*, $C_6H_{12}O_6$.

To be consistent with the relationship between a mono- and a disaccharide, some authorities do not term a tetrose or a pentose a monosaccharide. By combining the *ald-* and *ket-* prefixes, certain compounds then may be called aldohexoses, such as glucose and galactose, or ketohexoses, such as fructose and sorbose.

The mono-, di-, and trisaccharides are also commonly termed *sugars*. A sugar generally is considered to possess the properties of a crystalline solid with a relatively low melting point (below 150°C), of being soluble in water, and of possessing a sweet taste. Thus, the common names of several saccharides incorporate the term sugar, preceded by the common raw source of the substance, as glucose (grape sugar), sucrose (cane or beet sugar), maltose (malt sugar), and lactose (milk sugar). The crosscurrents of the nomenclature employed for the carbohydrates will be evident from Table 1.

Important Carbohydrates in Foods and Biological Systems

The properties of several carbohydrates that are of particular importance in foods and biological systems are described in the following paragraphs.

Glucose. This may be considered the key carbohydrate. It is the leading member of the aldohexose group, and is formed as one of the products or the only product when the following carbohydrates are hydrolyzed, sucrose, lactose, maltose, cellulose, glycogen. In many of its properties and its structural forms, it is representative of the sugars, and it is therefore discussed in detail here. Glucose is a colorless solid ($C_6H_{12}O_6$), less sweet than sucrose, soluble in water from which it may be crystallized $C_6H_{12}O_6$ H_2O. Glucose reacts (1) with alkaline cupric salt solution (Fehling's solution or Benedict's solution) to form cuprous oxide, (2) with ammonio-silver salt solution (Tollens' solution) to form finely divided or mirror film of silver, (3) with phenylhydrazine in acetic acid, to form glucose phenylhydrazone $CH_2OH(CHOH)_4CH{:}NNHC_6H_5$, white solid, melting point alpha 159–160°C, beta 140–141°C, with excess phenylhydrazine to form glucosazone

$$CH_2OH(CHOH)_3C : (NNHC_6H_5) \cdot CH : NNHC_6H_5$$

yellow solid, melting point 205°C decom., (4) with acetic anhydride, to form glucose pentacetate $C_5H_6(OOCCH_3)_5CHO$, melting point alpha 112 to 113°C, beta 131 to 134°C, (5) with sodium amalgam, to form sorbitol $CH_2OH(CHOH)_4CH_2OH$, (6) with hydriodic acid, to form 2-iodo-normal-hexane $CH_3(CH_2)_3CHICH_3$, (7) with sodium hydroxide solution, to form yellowish-brown solutions upon warming, (8) with calcium hydroxide solution, to form calcium glucosate $CH_2OH\ (CHOH)_4COCa(OH)$, slightly soluble solid from which glucose is recoverable by action of carbon dioxide (calcium carbonate formed simultaneously). Strontium hydroxide and barium hydroxide react similarly. Any of these three reactions may be utilized to recover glucose, with the limitation that barium soluble compounds are poisonous, (9) with hydroxylamine hydrochloride, to form glucoseoxime $CH_2OH(CHOH)_4CH{:}NOH$, melting point 138°C, (10) with hydrocyanic acid, to form glucosecyanhydrin

$$CH_2OH(CHOH)_4CHOHCN,$$

(11) by oxidation, to yield with bromine gluconic acid $CH_2OH(CHOH)_4$ COOH, and with nitric acid saccharic acid $COOH(CHOH)_4COOH$, (12) with alpha-naphthol dissolved in chloroform and then forming a layer of concentrated sulfuric acid beneath the mixture, to form a red coloration at the junction of the two liquid layers (Molisch's test for carbohydrates). Upon standing, the color changes to purple. (13) With methyl alcohol in the presence of hydrogen chloride, to form methyl glucoside (methyl ether of glucose). See also **Glycosides**.

If a sample of glucose is recrystallized from water, it is found that a freshly prepared aqueous solution of this sample has a specific rotation of +113°, and upon standing, the value steadily changes to +52° and remains there. On the other hand, if a sample of the same glucose is recrystallized from pyridine, a freshly prepared aqueous solution has a specific rotation of +19°, which steadily increases upon standing and levels off at a constant value of +52°. This changing of optical rotation with time is referred to as mutarotation. The fact that the two portions of glucose when recrystallized from different solvents mutarotate and stop at the same position suggests the formation of some equilibrium mixture.

To explain this situation, it must be recognized that glucose contains an aldehyde (–CHO) group and four alcohol groups (–OH). These two kinds of groups can react to form a hemiacetal just as if they were present in different molecules. See Fig. 1.

Glucose and fructose are present in sweet fruits, such as grapes and figs, and in honey. These two are the only hexoses found in nature in the free state. Glucose is normally present in human urine to the extent of about 0.1%, but in the case of those suffering from diabetes glucose is excreted in large amounts. Glucose is formed, as previously mentioned, by the reaction of polysaccharides and water, the reaction with starch in the

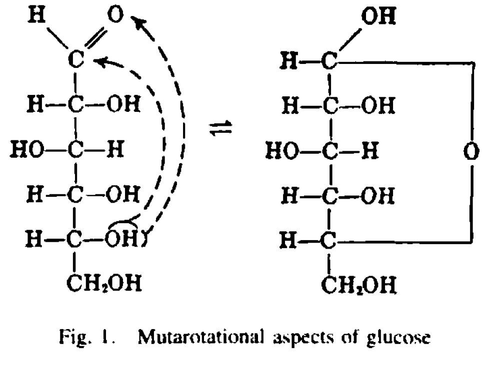


Fig. 1. Mutarotational aspects of glucose

TABLE 1. CLASSES OF CARBOHYDRATES (with examples)

Monosaccharides (sugars):

crystalline solids, soluble in water, sweet taste; those that occur in nature are hydrolyzed by certain enzymes.

Tetrose, $C_4H_8O_4$

1. Erythrose

Pentoses, $C_5H_{10}O_5$

2. Arabinose
   By boiling gum arabic, cherry gum, corn pith, elder pith with dilute sulfuric acid.
3. Xylose
   By boiling substances mentioned under arabinose above.
4. Ribose
5. Lyxose

Hexoses, $C_6H_{12}O_6$

Aldohexoses

6. Glucose, dextrose ("grape sugar"), melting point 146°C (anhyjeniferdrous).
   With the enzyme zymase (of yeast) yields ethyl alcohol plus carbon dioxide. Specific rotatory power—see glucose below.
7. Galactose
   Specific rotatory power +83.9°.
8. Mannose
   Specific rotatory power +14.1°.
9. Glucose
10. Idose
11. Talose
12. Altrose
13. Allose

Ketohexoses

14. Fructose, levulose ("fruit sugar"), melting point 95°C. Specific rotatory power −88.5°.
15. Sorbose
16. Tagatose

Disaccharides (sugars), $C_{12}H_{22}O_{11}$: crystalline solids, soluble in water, sweet taste.

17. Sucrose ("cane sugar," "beet sugar"), melting point 170–186°C (decomposes). With the enzyme invertase, yields glucose plus fructose. Specific rotatory power +66.4°.
18. Lactose ("milk sugar"), melting point 202°C (anhydrous). With the enzyme lactase yields glucose plus galactose. Specific rotatory power +52.4°.
19. Maltose ("malt sugar"), melting point of $C_{12}H_{22}O_{11} \bullet H_2O$: 100°C. With the enzyme maltase yields glucose plus glucose. Specific rotatory power +138.5°.
20. Melibiose
    With enzymes or dilute acid yields glucose plus galactose.
21. Cellobiose
    With the enzymes maltase, or cellase, yields glucose plus glucose.
22. Trehalose

Trisaccharide, $C_{18}H_{32}O_{16}$: crystalline solid, soluble in water, tasteless.

23. Raffinose, melitose, melting point 118°C (anhydrous). With the enzyme invertase, yields fructose plus melibiose. With the enzyme emulsin, yields sucrose plus galactose.

Polysaccharides (non-sugars), $(C_6H_{10}O_5)_n$: noncrystalline solids, insoluble in water, tasteless.

24. Starches
    With the enzyme diastase yield maltose.
25. Celluloses
    With hydrochloric acid, heated, yield glucose.
    With acetic anhydride plus concentrated sulfuric acid, yield cellobiose.
26. Dextrin
    With the enzyme diastase yields maltose.
    With the enzyme maltase or with acids yields glucose.
27. Inulin, melting point 178°C (decom.) $(C_6H_{10}O_5)_n$.
    With the enzyme inulase (but not with diastase) yields fructose.
28. Glycogen, melting point 240°C.
    With the enzyme diastase (or ptyalin), yields glucose plus maltose.
29. Pentosans

presence of very dilute hydrochloric acid serving as the industrial source (the hydrochloric acid acts as a catalyzer, and the small percentage present is later neutralized to form sodium chloride). The solution is evaporated to a syrup or to crystallization, and is used in the manufacture of sweets, and (usually) alcohol, and in foods. The reaction of glucosides with water, by enzymes or acids, produces glucose as one of the products. With sodium hydroxide, under carefully defined conditions, glucose forms lactic acid. Glucose is used as food and for the production of alcohol (wines) from fruit juices. Glucose may be detected by formation of glucosazone, and determination of its melting point.

Industrial process for converting starch into dextrose (glucose) are described under **Starch**.

Fructose. This sugar is present with glucose in sweet fruits and honey, and may be obtained free by reaction of insulin of dahlia tubers or artichokes with water, and with glucose by reaction of sucrose with water, the product being known as invert sugar. Fructose differs from glucose in structure in being a pentahydroxy-2-ketone,

$$CH_2OH(CHOH)_3COCH_2OH$$

instead of aldehyde. The specific rotary power of fructose is $-88.5°$. Fructose forms the same identical osazone as glucose, and sorbitol plus mannitol by reduction. Fructose may be used as sugar by diabetic patients to advantage instead of glucose or sucrose. Fructose is detected by the violet color its alkaline solution gives with meta-dinitrobenzene.

Sucrose. This is a colorless solid which when heated melts at 170–186°C, and upon cooling forms barley sugar, which gradually crystallizes. Upon heating above the melting point, it forms caramel, a brown liquid, with decomposition. Caramel is used in confectionery, and in coloring beverages and foods. At higher temperatures decomposition into gaseous and tarry substances occurs, finally leaving a residue of carbon ("sugar charcoal"). Other sugars behave similarly. Sugars are also carbonized by concentration sulfuric acid. Sucrose is very soluble in water, and is obtained from solution by crystallization, usually by vacuum evaporation. The solution has a specific rotatory power of $+66.4°$, does not exhibit mutarotation, but is converted by acids or invertase into invert sugar (glucose plus fructose), specific rotatory power $-19.7°$. Sucrose forms with calcium hydroxide calcium sucrosate, a 1% solution of sugar dissolves about 18 times as much calcium hydroxide as does pure water. This behavior is utilized to recover sugar from solutions, as in the case of glucose, and also to determine free calcium oxide in burnt lime, due to the reactivity of calcium hydroxide and non-reactivity of calcium carbonate. Sucrose is nonreactive with dilute sodium hydroxide, with phenylhydrazine, with ammonio-silver salt solution, but, when inverted to glucose plus fructose, these reactions may be obtained. Sucrose forms with acetic anhydride sucrose octaacetate. The suggested structural formula is as shown in Fig. 2. Sucrose is an important food preservative, food flavor, and a raw material for confectionery and for industrial alcohol.

Sucrose is extensively distributed in the seeds and leaves of plants, and is the most abundant of the sugars. The commercial sources of sucrose are the stems of sugar-cane (11 to 16% sucrose, average 13%), the root of the sugar-beet (average 16% sucrose, selection having raised the sucrose content from 5% to a maximum of 20%), the sap of the sugar maple, and the stems of sorghum-cane. Sucrose is pressed from the stems of sugar cane or sorghum cane, and extracted with the water from the sliced roots of sugar beets. The solutions are purified, evaporated and crystallized to such a degree that commercial sucrose is practically chemically pure (about 99.8% sucrose). The purity of sugar and the concentration or strength of sugar solutions is determined by the rotatory power of the solution, and the special polariscope usually used is called a saccharimeter. Sucrose is reduced with Fehling's solution only after inversion. See also **Sugar**.

The sugar content of some common fruits have been reported by Kulisch:

	SUCROSE	HEXOSES
Apple	1.0–5.4	7.0–13.0
Apricot	6.0	2.7
Banana, ripe	5.0	10.0
Pineapple	11.3	2.0
Strawberry	6.3	5.0

Lactose. This sugar is obtained from the residual water solution (whey) of milk after removal of fat and casein for making butter and cheese. Milk contains about 4.5% of lactose. Lactose forms hard gritty crystals ("sand sugar") $C_{12}H_{22}O_{11} \cdot H_2O$, loses water at 140°C, melting point 202°C (anhydrous) with decomposition; is less sweet than sucrose, reduces ammoniocupric salt solution, ammoniosilver salt solution, forms osazone, melting point 200°C, turns yellow when warmed with sodium hydroxide solution. Lactose is the source of galactose, and undergoes, with the proper enzymes, fermentation into lactic acid and butyric acid.

Maltose. This sugar is found in soybean, and is produced by the action of the enzyme diastase of germinated barley (malt) on starch at 50°C, and is thus an intermediate product in the transformation of starch into alcohol. Maltose $C_{12}H_{22}O_{11} \cdot H_2O$, melting point 100°C, when rapidly heated, may be crystallized from the concentrated malt syrup after removal of proteins and insoluble material. Maltose reduces ammonio-cupric salt solution, and forms osazone.

Starch. This is a white powder, odorless and tasteless, insoluble in cold water, forming an emulsion ("starch paste") or gel with hot water, the consistency of which depends upon the ratio of starch to water used. When boiled starch emulsion is cooled and treated with a solution of iodine in alcohol or potassium iodide, a blue coloration is produced, which is a sensitive and characteristic test. The blue color is associated with the adsorption of iodine on the surface of the starch, and disappears in the presence of alkalis. When boiled with dilute acid, starch is first changed into a soluble gummy mixture known as dextrin, and finally into glucose. When starch, either alone or in the presence of a slight amount of nitric acid, is heated to 120° to 200°C, dextrin is formed; at higher temperatures starch behaves similarly to sucrose. With concentrated nitric acid, starch forms esters, similar to cellulose nitrates. By the action of the enzyme diastase, starch is converted into maltose, which, with the enzyme maltase, yields glucose. Starch is nonreactive with ammonio-cupric salt solution, and with phenylhydrazine. See also **Starch**.

Dextrin. This is a white-to-yellow solid, forming an adhesive with water, nonreactive with ammonio-cupric salt solution, reactive with iodine in alcohol or potassium iodide, usually forming red, brown, or blue color. Formed when starch is (1) heated to 120° to 200°C either alone or in the

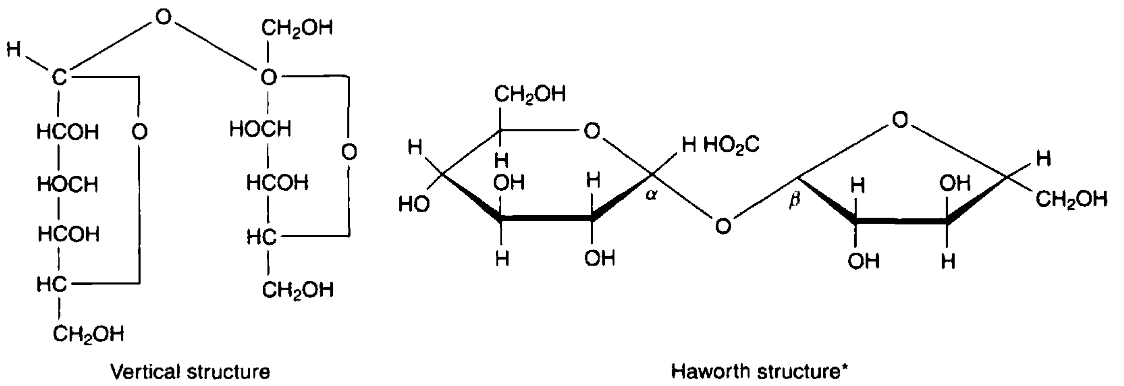

Fig. 2. Direction of angular momentum vector is perpendicular to plane formed by radial vector **r** and momentum vector **p**.

presence of a slight amount of nitric acid. Dextrin is formed when bread is toasted and is present in well-baked bread crust, and on the surface of starched goods that have been ironed hot. Dextrin is used in adhesives.

Inulin. This is a white solid, soluble in warm water, specific rotatory power −40°, with iodine in alcohol or potassium iodide gives yellow color. Inulin is present in tubers of dahlia to the extent of about 10%. Inulin reacts with water in the presence of the enzyme inulase or of acids to form fructose. The enzyme diastase does not produce this change.

Glycogen. Also known as *animal starch*, this is a white solid, soluble in water, specific rotatory power +197°, with iodine in alcohol or potassium iodide solution, forming brown color. Glycogen is found as reserve carbohydrates in the animal body, more particularly in the liver. Horse flesh, oysters and beef are sources of glycogen.

Pentosans. These compounds are polysaccharides which may be considered as anhydrides of pentose sugars, after the manner of the hexosans, sucrose, starch, from glucose, fructose. When pentosans or pentoses are heated with hydrochloric or sulfuric acid, furfural $C_4H_3O \cdot CHO$ is formed, and addition of aniline produces a red color. Pentosans are present in gummy carbohydrates, in bran of wheat seed, and in woods.

By means of the cyanohydrin reaction, higher sugars of the heptose, octose, and nonose types have been prepared. A monosaccharide such as an aldohexose may be converted into the next lower monosaccharide, such as an aldopentose, by oxidation to the acid, which corresponds to the aldohexose, then treating the calcium salt solution of this acid with a solution of ferrous acetate plus hydrogen peroxide. Carbon dioxide is evolved and aldopentose formed.

For a description of cellulose, see **Cellulose**.

Carbohydrate Metabolism

Carbohydrates are utilized by the cells as a source of energy and as precursors for the manufacture of many of their structural and metabolic components. In the mammal, for example, D-glucose is the carbohydrate primarily used for this purpose. certain microorganisms, in contrast, can grow on a medium containing some other hexose or a pentose as the principal source of carbon. Green plants obtain their carbohydrates by photosynthesis, while animals receive most of their carbohydrates by ingestion and digestion. See also **Photosynthesis**.

The complete oxidation of glucose to carbon dioxide and water yields 689 kcal of heat per mole of glucose. When this oxidation occurs in a cell, the energy is not all dissipated as heat. Some of the evolved energy is conserved in biochemically utilizable form of "high-energy" phosphates, such as adenosine triphosphate (ATP) and guanosine triphosphate (GTP). In addition to enzymes concerned with energy metabolism, there are enzymes in biological systems which catalyze the transformation of glucose into various carbohydrates, fatty acids, steroids, amino acids, nucleic acid components, and other necessary biochemical substances. The entire network of reactions involving compounds that interconvert carbohydrates constitutes *carbohydrate metabolism*. By convention, some reactions involving compounds which are not carbohydrates, but which are derived from them, may also be included in this area of metabolism.

Anaerobic Oxidation of Glucose. Historically, the first system of carbohydrate metabolism to be studied was the conversion by yeast of glucose to alcohol (fermentation) according to the equation: $C_6H_{12}O_6 2CH_3CH_2OH + 2CO_2$. The biochemical process is complex, involving the successive catalytic actions of 12 enzymes and known as the *Embden-Meyerhof pathway*. This series of reactions is summarized in the entry on **Glycolysis**.

In order for the cell to carry out a "controlled" oxidation of D-glucose and conserve some of the energy derived from the process, it is first necessary to add phosphate to the hexose with the expenditure of energy. The necessary energy and the phosphate per se is supplied by ATP in two separate reactions of the system. Since each molecule of glucose can yield two molecules of triose phosphate for oxidation, the conversion of glucose to pyruvic acid nets two molecules of ATP per molecule of hexose utilized.

Approximately 30% of the evolved energy is conserved as ATP, but only about 8% of the total energy in glucose is made available in this anaerobic oxidation of glucose to pyruvic acid. Since nicotinamide adenine dinucleotide (NAD^+), also called diphosphoryidine nucleotide (DPN^+), which is involved in the oxidation of glyceraldehyde-3-phosphate, is present in the cell in small quantities only, this coenzyme must constantly be regenerated for the oxidative process to continue. This regeneration is accomplished by the reduction of *acetaldehyde* to *ethanol*. Since oxygen plays no role in this process, the system can obviously proceed anaerobically. In fact, the presence of oxygen decreases the net disappearance of glucose (*Pasteur effect*).

Fermentation occurs in many microorganisms, but not all organisms reoxidize the reduced nicotinamide adenine dinucleotide (NADH) through the formation of ethanol. In certain organisms, for example, *pyruvic acid* is converted to *acetoin*, which is then reduced with NADH to 2,3-butylene glycol. In other organisms and in animal tissues, NADH is oxidized in the reduction of *pyruvic acid* to *lactic acid*. In insects, and possibly in some animal tissues, the reduction of *dihydroxyacetone phosphate* to *alpha-glycerol phosphate* may serve to regenerate NAD^+. The conversion of glucose to lactic acid in animal tissues is termed *glycolysis*. This term arose from the initial understanding that this process was markedly different from the microbial fermentation process. Fermentation and glycolysis are now known to differ primarily in the further anaerobic utilization of pyruvic acid.

Aerobic Oxidation of Pyruvic Acid. Pyruvic acid can be oxidized completely to carbon dioxide and water in a cyclic enzymatic system known as the *Krebs citric acid cycle*, or the *tricarboxylic acid cycle (TCA cycle)*. In this system, a two-carbon unit in the form of acetyl coenzyme A (acetyl = CoA), derived from the NAD^+ mediated oxidative decarboxylation of pyruvic acid in the presence of coenzyme A, is condensed with oxalacetic acid to form citric acid. This tricarboxylic acid is then converted back to oxalacetic acid in a stepwise manner with the formation of $2CO_2$ and $2H_2O$. In addition to this formation of CO_2, one reduced nicotinamide adenine dinucleotide phosphate (NADPH), two NADH, one reduced flavin, and one GTP arise per two-carbon unit oxidized in the cycle. Since in the aerobic oxidation of the reduced flavin and the reduced nicotinamide adenine nucleotides, ATP is formed, the oxidation of a molecule of "acetate" results in the conservation of energy in the form of 12 molecules of triphosphate. In the complete oxidation of glucose through glycolysis and the citric acid cycle, about 40% of the energy originally present in the glucose can be retained as triphosphate. The ubiquitous distribution of this cycle in nature suggests that the citric acid cycle is a major energy-yielding pathway in biological systems.

Certain microorganisms have a modification of this cycle in which isocitric acid is cleaved to succinic acid and glyoxylic acid. The latter acid is condensed with acetyl-CoA to form malic acid. In this modification (the *glyoxylic acid cycle*), oxalsuccinic acid and alpha-ketoglutaric acid are not involved. This is sometimes referred to as the "glyoxylate shunt" pathway.

Since in the citric acid cycle there is no net production of its intermediates, mechanisms must be available for their continual production. In the absence of a supply of oxalacetic acid, "acetate" cannot enter the cycle. Intermediates for the cycle can arise from the carboxylation of pyruvic acid with CO_2 (e.g., to form malic acid), the addition of CO_2 to phosphenolpyruvic acid to yield oxalacetic acid, the formation of succinic acid from propionic acid plus CO_2, and the conversion of glutamic acid and aspartic acid to alpha-ketoglutaric acid and oxalacetic acid, respectively. See Fig. 3.

The utilization of carbohydrate intermediates for the biosynthesis of amino acids, fatty acids, steroids, etc. occurs at various stages of the cycle and its related reactions. See Fig. 4. See also **Coenzymes**.

Other Carbohydrate Interconversions. Two systems, as shown in Fig. 5, are available for the synthesis of ribose-5-phosphate, a precursor of the pentose moiety of ribonucleic acid, ATP, and other substances. The formation of ribose-5-phosphate from glucose-6-phosphate by formation and decarboxylation of 6-phosphogluconic acid and isomerization of the resulting ribulose-5-phosphate is termed the *hexose monophosphate oxidative pathway*. The scheme, together with the system involving the enzymes *transketolase* and *transaldolase* (which also can synthesize pentose) that act to form hexose phosphate from pentose phosphate, is called the *pentose phosphate cycle*. This cycle represents an alternative pathway to glycolysis for the formation of triose phosphate from glucose-6-phosphate. The relative importance of the two pathways seems to be different among the various organisms and tissues.

In a certain group of bacteria, still another pathway (*Entner-Doudoroff pathway*) for the utilization of glucose has been studied. Here glucose-6-phosphate is oxidized to 6-phosphogluconic acid which is dehydrated to 2-keto-3-deoxy-6-phosphogluconic acid. This substance is then split to pyruvic acid and glyceraldehyde-3-phosphate (which also can be converted to pyruvic acid).

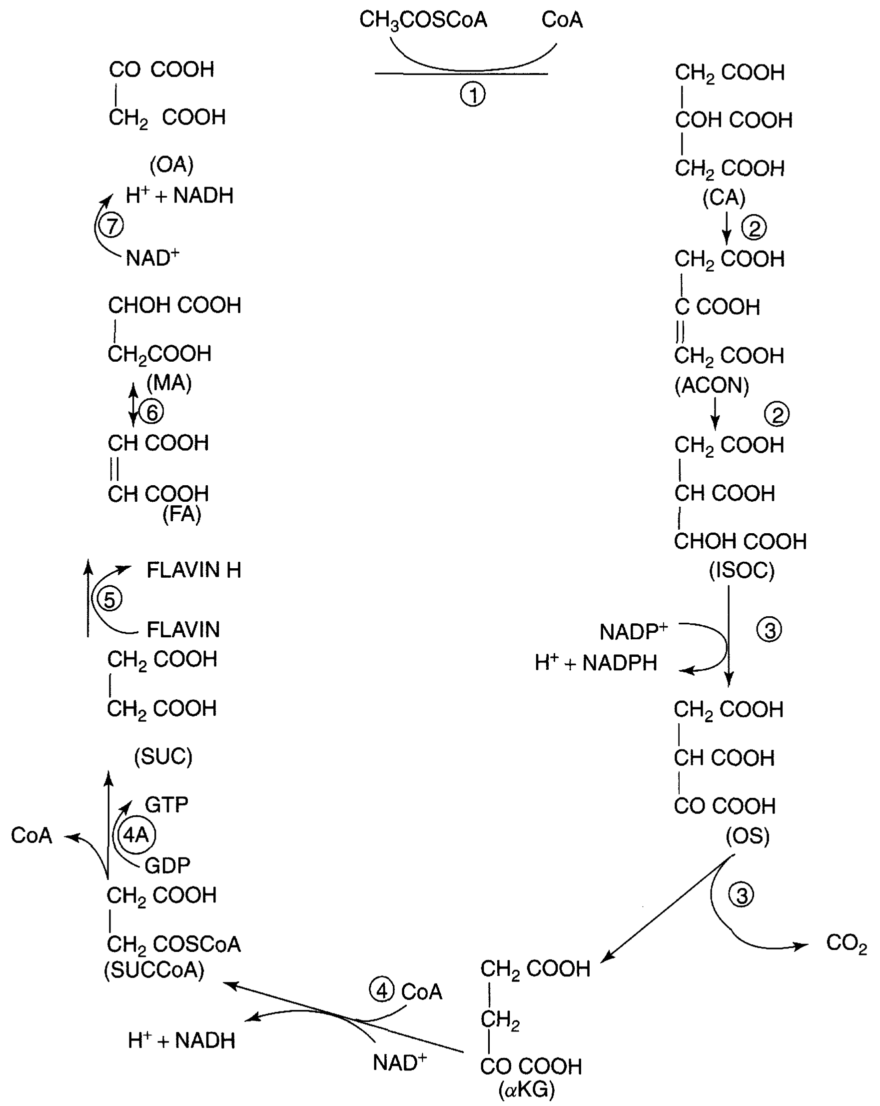

Fig. 3. Krebs citric acid cycle. *Enzymes involved*: (1) Condensing enzyme; (2) aconitase; (3) isocitric acid; (4) α-ketoglutaric acid dehydrogenase; (4) α-succinic acid thiokinase; (5) succinic acid dehydrogenase; (6) fumarase; (7) malaic acid dehydrogenase. *Abbreviations*: CA = citric acid; ACOM = *cis*-aconitic acid; KG = α-ketoglutaric acid; SIC = succinic acid; FA = fumaric acid; MA = malic acid; OA = oxalacetic acid

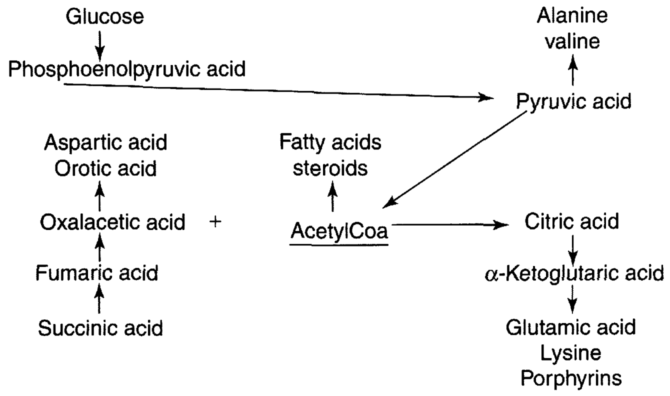

Fig. 4. Representative conversions of carbohydrates to other substances

The formation of deoxyribose, the pentose moiety of deoxyribonucleic acid, can occur directly from ribose while the latter is in the form of a nucleotide diphosphate. Deoxyribose-5-phosphate can also be formed by condensation of acetaldehyde and glyceraldehyde-3-phosphate.

Transglycosylation. An enzymatic process, transglycosylation, plays an important role in carbohydrate metabolism. Figure 6 represents the formation of the disaccharide, sucrose, as an example of this mechanism. In the upper reaction of Fig. 6, glucose-1-phosphate is the glycosyl donor and fructose is the acceptor. In the lower reaction, the sugar nucleotide, uridine diphosphoglucose (UDP-glucose) is the glycosyl donor. With UDP-glucose as donor and glucose-6-phosphate as acceptor, trehalose-6-phosphate may be formed. Polysaccharides may also be formed by this process. The donor residues provided by sugar nucleotides are added to preexisting polysaccharide chains (known as "primers") acting as glycosyl acceptors. In the formation of glycogen, for example, UDP-glucose donates the glucose moiety which is added to the end of a previously synthesized chain by a 1,4-linkage, thereby lengthening the chain by one glucose unit.

Digestion, Absorption and Storage of Carbohydrates

In the mammal, complex polysaccharides which are susceptible to such treatment, are hydrolyzed by successive exposure to the amylase of the saliva, the acid of the stomach, and the disaccharidases (e.g., maltase, invertase, amylase, etc.) by exposure to juices of the small intestine. The last mechanism is very important. Absorption of the resulting monosaccharides occurs primarily in the upper part of the small intestine, from which the sugars are carried to the liver by the portal system. The absorption across the intestinal mucosa occurs by a combination of active transport and diffusion. For glucose, the active transport mechanism appears to involve phosphorylation. The details are not yet fully understood. Agents which inhibit respiration (e.g., azide, fluoracetic acid, etc.) and phosphorylation (e.g., phlorizin), and those which uncouple oxidation from phosphorylation (e.g., dinitrophenol) interfere with the absorption of glucose. See also **Phosphorylation (Oxidative)**. Once the various monosaccharides pass through the mucosa, interconversion of the other

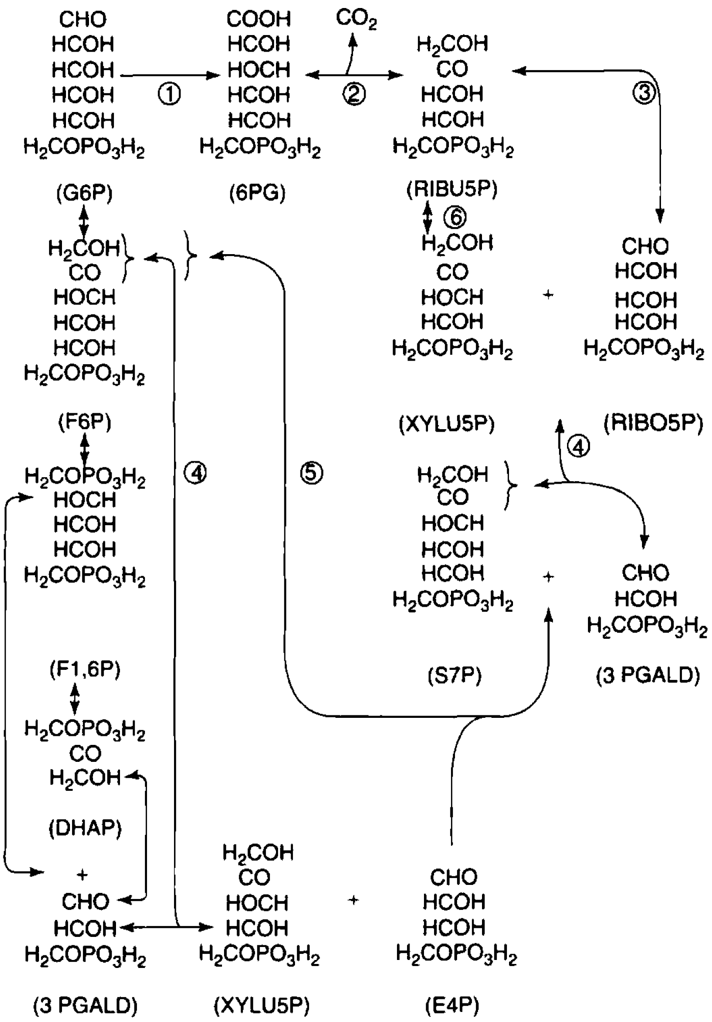

Fig. 5. Pentose phosphate cycle. *Enzymes involved*: (1) Glucose-6-phosphate dehydrogenase; (2) 6-phosphogluconic acid dehydrogenase; (3) pentose phosphate isomerase; (4) transketolase; (5) transaldolase; (6) pentose phosphate epi merase. *Abbreviations*: G6P = glucose-6-phosphate; 6PG = 6-phospho gluconic acid; RIBIUP = ribulose-5-phosphate; 3PGALD = glyceraldehyde-3-phosphate; E4P = erythrose-4-phosphate; F1,6P = fructose-1-6-diphosphate; DHAP = dihydroxyacetone phosphate; F6P = fructose-6-phosphate. Enzymes not named are those of glycolysis. $NADP^+$ is reduced in reactions (1) and (2)

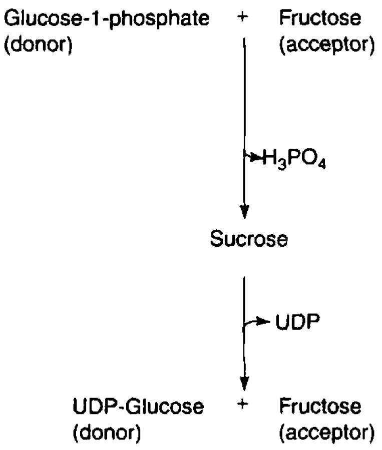

Fig. 6. Examples of transglycosylation

sugars to glucose can begin, although the liver is probably the chief site for such conversions. Even though many organs and tissues store carbohydrates as glycogen for their own use, the liver provides the main source of glucose for all tissues, through conversion of its glycogen (and other substances) to glucose-6-phosphate, hydrolysis of this ester by the specific liver glucose-6-phosphatase, and transport of the free glucose in the bloodstream throughout the body.

A common cause of *osmotic diarrhea* is the ingestion of carbohydrates that a person cannot digest. Retention of a disaccharide, such as lactose or sucrose, within the intestinal lumen occurs because of the absence of the appropriate disaccharidase at the intestinal surface membrane. Unless they are converted to monosaccharides, these sugars cannot be transported. Their retention in the lumen can cause a significant diarrheal water loss per day. As an added complication, bacteria in the lower small intestine and colon may catabolize the 12-carbon sugars to 3-carbon fragments, further aggravating the osmotic effect. Infants and very young children usually have sufficient lactase and sucrase, but there is a tendency among some people to become lactase deficient between the ages of 3 and 14 years. Once such a condition is fully recognized, the ingestion of milk and other dairy products should be eliminated. It should be pointed out, however, that the so-called *irritable bowel syndrome* is attributable to lactase deficiency in a relatively small percentage of cases. Carbohydrates that can cause diarrhea in some persons include: lactose and sucrose, already mentioned; stachyose and raffinose, contained in many legumes; mannitol and sorbitol, contained in artificial sweeteners (which contain sugar alcohols); glucose and galactose, present in all dietary sugars; and lactulose, contained in nondietary disaccharides as parts of certain medications.

Endocrine Influences. A number of hormones are known to influence carbohydrate metabolism in the mammal. Insulin seems to increase oxidation of glucose, lipogenesis, and glycogenesis. Its primary mode of action may be to facilitate the entry of glucose into the cell.

Vitamin Influences. The involvement of NAD^+ and $NADP^+$ in many carbohydrate reactions explains the importance of nicotinamide in carbohydrate metabolism. Thiamine, in the form of thiamine pyrophosphate (cocarboxylase), is the cofactor necessary in the decarboxylation of pyruvic acid, in the *trans*-ketolase-catalyzed reactions of the pentose phosphate cycle, and in the decarboxylation of alpha-ketoglutaric acid in the citric acid cycle, among other reactions. Biotin is a bound cofactor in the fixation of carbon dioxide to form oxalacetic acid from pyruvic acid. Pantothenic acid is a part of the CoA molecule. There are separate alphabetical entries in this volume on the various specific vitamins as well as a review entry on **Vitamin**.

Photosynthesis. The formation of carbohydrates in green plants by the process of photosynthesis is described in the entry on **Photosynthesis**. The synthetic mechanism involves the addition of carbon dioxide to ribulose-1,5-diphosphate and the subsequent formation of two molecules of 3-phosphoglyceric acid which are reduced to glyceraldehyde-3-phosphate. The triose phosphates are utilized to again from ribulose-5-phosphates by enzymes of the pentose phosphate cycle. Phosphorylation of ribulose-5-phosphate with ATP regenerates ribulose-1,5-diphosphate to accept another molecule of carbon dioxide. See also **Phosphorylation (Photosynthetic)**.

Carbohydrates in Foods

Sugar is discussed in several entries in this volume, including **Fiber (Dietary)**; **Gums and Mucilages**; and **Sugar**.

Statistics on the carbohydrate content of diets of various peoples throughout the world have not been very reliable because of the scores of variables involved, the great difficulties in establishing reliable sampling procedures, lack of past records, among other factors. One summary, for example, that breaks down food energy from protein, fat, and carbohydrates shows a downward trend for carbohydrates in the American diet—from 56% in 1911 to 46% in the mid-1970s. These figures were based upon U.S. Department of Agriculture statistics of food disappearance at the retail level, but they do not take into consideration food spoilage, cooking waste, plate waste, and other factors that affect actual consumption. Since protein remained quite constant at 11–12% throughout this time span, the drop in carbohydrates was made up by an increase in fats—from 32% in 1911 to 42% in the mid-1970s. In another study, of the 46% carbohydrate energy intake as of 1977, 24% is attributed to sugar and 22% to complex carbohydrates. In a controversial U.S. government study that attempted to set new dietary goals for the nation, it was suggested that the traditional 12% protein be retained, but that fat be reduced from 42% and carbohydrates upped to 58%, but with a major difference, namely, cutting the sugar portion of carbohydrates from 24% to 15%. Thus, the dietary goal would require 40–45% complex carbohydrates in the diet. It has been suggested that to achieve the projected carbohydrate goals, there would

have to be a 66% increase in the consumption of grain products; a 25% increase of vegetables and fruit; and a 50% reduction in sugar and sweets.

Even though much visibility had been given by the various news media to the dietary role of sugar, it was obvious that, as of the late 20th Century, a great deal of fundamental research remained to be done to prove or disprove many conclusions, often conflicting and confusing, in order to establish reliable dietary guidance in this area.

CARBON. [CAS: 7440-44-0]. Chemical element symbol C, at. no. 6, at. wt. 12.011, periodic table group 14, mp 3,550°C (approximate), bp 4,289°C (approximate), density 3.52 g/cm^3 (diamond at 20°C), 2.25 g/cm^3 (graphite at 20°C). The specific gravity of amorphous carbon at 20°C ranges from 1.8 to 2.1. There are two stable isotopes of the element, ^{12}C and ^{13}C, and four known radioactive isotopes, ^{10}C, ^{11}C, ^{14}C, and ^{15}C. Because the half-life (about 5,760 years) of ^{14}C has been established, this isotope is useful for dating ancient documents and materials.

The first ionization potential of carbon is 11.264 eV; Second, 24.28 eV; third, 47.7 eV. Other important physical characters of carbon are given in article on **Chemical Elements**.

Traditionally, the principal forms of carbon have (1) *diamond*, with its tetrahedral arrangement of atoms; (2) *graphite*, whose structure resembles layers of chicken wire; and sometimes (3) *amorphous*, a poorly defined grouping of carbons. This latter classification was chosen more out of convenience than grounded scientifically. However, by recent consensus, a third form of carbon is now officially recognized: *fullerene*, of which the C_{60} so-called *buckminsterfullerene* or "buckyball" is the most thoroughly investigated example of its class.

Diamond, the hardest of natural materials, consists of a lattice of carbon atoms arranged in a tetrahedral structure at equal distances apart (1.544 Å) and bonded by electron pairs in localized molecular orbitals formed by overlapping of the sp^3 hybrids. See article on **Diamond**.

Graphite, a very soft material, consists of carbon atoms arranged in laminar sheets, 3.40 Å apart and composed of carbon atoms in hexagonal arrangement 1.42 Å apart. Each atom is bonded to three others in its sheet by electron pairs in localized molecular orbitals formed by overlapping of the sp^2 hybrids. The remaining p-electrons form a mobile system of nonlocalized pi bonds that permit electrical conductivity between the lamina. See also **Graphite**.

The familiar carbon blacks are formed by such methods as combustion of carbon-containing materials with sufficient oxygen. These carbons are found to have x-ray diffraction patterns that are suggestive of graphite, but with more diffuse rings, thus indicating a much lower degree of crystallinity. When carbon black is heated, its diffraction pattern develops new rings indicative of a structure more like that of graphite. When so heated, the properties of the carbons as absorbent materials deteriorate. See also **Carbon Black and Coal**.

Because of the comparatively recent demonstration of the geometry of C_{60} and cousins of both lower and higher carbon atom content, this giant molecule is ushering in a new concept to the chemistry of carbon and organic chemistry. This discovery, which later may have profound implications for practical industrial and scientific usage, provides insights into other scientific fields, such as astrochemistry, and serves as a source of yet unknown chemical derivatives; it has been likened by some scientists to the first practical suggestion by Kekulè (1825) on the structure of the benzene ring. The carbon atoms in Kekulè's design have dangling bonds which usually are accommodated by hydrogen. In contrast the three-dimensional configuration of C_{60} has exactly 60 carbon atoms in a single molecule that is inert, in the absence of dangling bonds. The molecule, however, appears to tolerate the insertion of certain ions and thus may make possible large numbers of derivatives.

Traditional Carbon Chemistry

The probable importance to high-temperature behavior of the $-C\equiv C-$ triple bond, most familiarly encountered in acetylene, was proposed in the late 1960s. The essence of the proposal is that high-temperature carbon forms are made up of chains of triple-bonded carbon atoms, termed *carbynes*. See Fig. 1. It will be noted that at high temperatures, a single bond in the structure may break. This shifts an electron into each of the adjacent double bonds, forming a triple bond. Completion of the process transforms the sheet of atoms into a chain of carbynes. The chains can be variously stacked. In 1973, at least five such forms had been reported. Researchers in 1977 reported that the transformation from the carbyne form to graphite involves a reaction between acetylene-like molecules (acting rapidly and exothermically), whereas the reverse reaction (breaking of single bonds) can be expected to be a much slower process. Thus, the conventional carbon phase diagram may be deficient because it does not

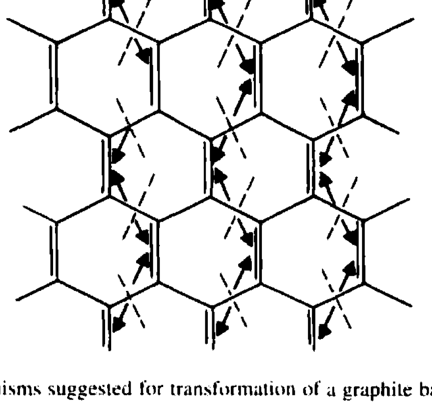

Fig. 1. Mechanisms suggested for transformation of a graphite basal plane sheet of atoms into carbyne chains

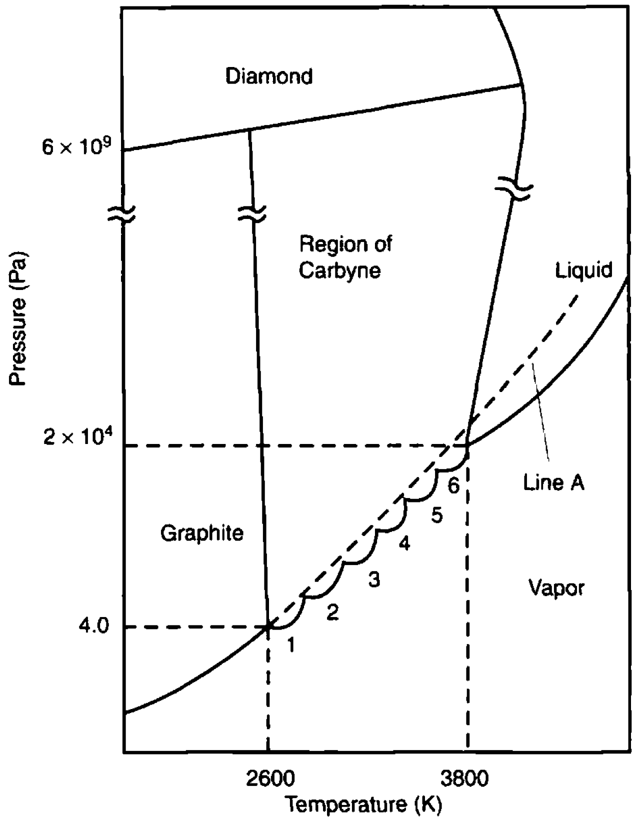

Fig. 2. Carbon phase diagram (suggested by Whittaker) to accommodate region of carbyne. Dashed line A is vapor pressure graphite would have if it were the stable form above 2600 K. Whittaker notes: (1) graphite is not stable above 2600 K at any pressure; (2) the solid-liquid-vapor triple point occurs at 3800 K and 2 ×

consider the carbyne forms. One scientist pointed this out because it had been difficult to reconcile high-pressure results with the low-pressure data available on the vapor pressure of carbon. See Fig. 2.

Research pertaining to carbynes, in way, was a prelude to further molecular carbon research and the now well-known buckyball.

Carbon Compounds

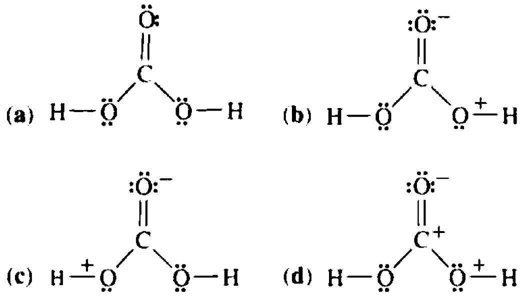
With the exception of hydrogen, carbon forms more compounds than any of the other chemical elements. Traditionally, carbon compounds fall into two fundamental classes: (1) *inorganic* compounds and (2) *organic* compounds.

The main subclasses of inorganic carbon compounds include:

1. The *carbon oxides*, notably CO (carbon monoxide) and CO_2 (carbon dioxide).
2. The *carbonates* $-CO_3$, which occur widely in nature—minerals, rocks, ores, and mineral waters—and include such compounds as Na_2CO_3, $CaCO_3$ (limestone), $MgCO_3$ (magnesite), $MgCa(CO_3)_2$ (dolomite), etc.
3. Some carbon-sulfur compounds, such as CS_2 (carbon disulfide), the thiocyanides, and thiocyanates −CNS, such as HCNS (thiocyanic acid), $Pb(CNS)_2$ (lead thiocyanate), etc.
4. The *carbides*, such as Na_2C_2, Cu_2C_2, WC, ZrC, etc.
5. The *carbonyls* −CO, such as $Cr(CO)_6$, $Fe(CO)_5$, $Ni(CO)_4$, etc.
6. The *halides*, such as CCl_4 (carbon tetrachloride), CBr_4, etc.

The subclasses of organic compounds comprise the realm of organic chemistry and are described under **Organic Chemistry**. There are several subclasses of organic compounds that include oxygen along with hydrogen and carbon in their structure—e.g., acid anhydrides, alcohols, aldehydes, carbohydrates, carboxylic acids, esters, ethers, fatty acids, furans, ketones, lactides, lactones, phenols, quinones, and terpenes. Some of the main subclasses of nitrogen-bearing organic compounds include the amides, amines, amino acids, anilides, azo and diazo compounds, carbamates, cyanamides, hydrazines, polypeptides, proteins, purines, pyridines, pyrroles, quaternary ammonium compounds, semicarbazones, ureas, and ureides. The addition of the halogens to the structure yields chlorine organics, brominated compounds, fluorocarbons, etc. Most of the metals combine with carbon compounds to form organometallics. Sulfur-bearing organics include the sulfonic acids, sulfonyls, sulfones, thioalcohols, thioaldehydes, sulfoxides, etc. Silicones are silicon-bearing carbon compounds. See also **Chlorinated Organics**.

Carbides. As might be expected from its position in the periodic table, carbon forms binary compounds with the metals in which it exhibits a negative valence, and binary compounds with the non-metals in which it exhibits a positive valence. A convenient classification of the binary compounds of carbon is into ionic or salt-like carbides, intermediate carbides, interstitial carbides, and covalent binary carbon compounds.



The ionic or salt-like carbides are formed directly from the elements, or from metallic oxides and carbon, carbon monoxide, or hydrocarbons. This last reaction is reversible, and this group of carbides may be further subdivided into acetylides, e.g., Li_2C_2, Na_2C_2, K_2C_2, Rb_2C_2, Cs_2C_2, Cu_2C_2, Ag_2C_2, Au_2C_2, BeC_2, Mg_2C_2, CaC_2, SrC_2, BaC_2, ZrC_2, CdC_2, Al_2C_6, Ce_2C_6, and ThC_4: methanides, e.g., Be_2C and Al_4C_3; and the allylides, primarily magnesium allylide, Mg_2C_3, according to the hydrocarbon or the principal hydrocarbon formed upon hydrolysis. By the term intermediate carbides is meant compounds intermediate in character between the ionic carbides and the interstitial carbides. The intermediate carbides, such as Cr_3C_2, Mn_3C, Fe_3C, Co_3C, and Ni_3C are similar to the ionic carbides in that they react with water or dilute acids to give hydrocarbons, and they resemble the interstitial carbides in their electrical conductivity, opacity, and metallic luster. The interstitial carbides have these properties, and are uniformly chemically inert. They include those having cubic close-packed structures, such as TiC, ZrC, HfC, VC, NbC, TaC, MoC, and WC, and those having hexagonal close-packed structures such as V_2C, Mo_2C, and W_2C. In both, the carbon atoms occupy interstitial positions in the crystal lattices of the metals, giving hardness, high melting points, and chemical inertness, as well as electrical conductivity with a positive temperature coefficient and metallic luster. The covalent binary compounds of carbon range in character from hard, chemically inert solids, such as silicon carbide, SiC, to volatile liquids, such as carbon disulfide and carbon tetrachloride, CS_2 and CCl_4, and even to gases such as carbon tetrafluoride, carbon dioxide and methane, CF_4, CO_2 and CH_4, varying in thermal stability. With several of these elements carbon forms a series of compounds, or as with hydrogen, a number of series of hydrocarbons, consisting of both compounds based upon chains and branched chains of carbon atoms, variously saturated (i.e., joined by single, double, or triple bonds), and also of ring connected carbon atoms, with or without side chains, with varying degrees of saturation, and capable of replacement of the hydrogen atoms with other atoms or radicals.

Carbonates. Carbonic acid H_2CO_3 is present to the extent of 0.27% of the total CO_2 present in the solution that is formed by dissolving CO_2 in H_2O at room temperature. The CO_2 may be expelled fully upon boiling. The solution reacts with alkalis to form carbonates, e.g., sodium carbonate, sodium hydrogen carbonate, calcium carbonate, calcium hydrogen carbonate. The acid ionization constant usually cited for carbonic acid (4.2×10^{-7}) is actually for the equilibrium $CO_2(aq) + H_2O \longleftrightarrow H^+ + HCO_3^-$. The true ionization constant, i.e., for the equilibrium $H_2CO_3 \longleftrightarrow H^+ + HCO_3^-$ is about 1.5×10^{-4}. The carbonate ion is a resonance hybrid of the three structures shown *a*, *b*, and *c* as well as structures of the type *d* which give a partial ionic character to bonds. This resonance is somewhat inhibited in the acid and its esters, but is complete, or much more nearly complete, in many other derivatives and in the

carbonate ion. Esters of both metacarbonic, $(RO)_2CO$, and orthocarbonic acid, $(RO)_4C$, are known. The esters also exhibit resonance.

Metallic carbonates are (1) soluble in H_2O, e.g., sodium carbonate, potassium carbonate, ammonium carbonate (2) insoluble in H_2O and excess alkali carbonate, e.g., calcium carbonate, strontium carbonate, barium carbonate, magnesium carbonate, ferrous carbonate (3) insoluble in H_2O but soluble in excess alkali carbonate forming carbonate complexes, e.g., compounds of uranium and ytterbium $U(CO_3)_2$, UO_2CO_3, $Yb_2(CO_3)_3$. Metallic bicarbonates are known in solution and on warming are converted into ordinary or normal carbonates, e.g., bicarbonates of sodium, potassium, calcium, barium. These are preferably named as "hydrogen carbonates," e.g., $NaHCO_3$ = sodium hydrogen carbonate. Basic carbonates are important in such cases as lead ("white lead"), zinc, magnesium, and copper. Carbonates of very weak bases, such as aluminum, iron(III), and chromium(III), are now known.

The carbonates are found in nature as the carbonates, calcite, iceland spar, limestone and various forms of impure calcium carbonate $CaCO_3$, as magnesite (magnesium carbonate, $MgCO_3$), as dolomite (various compositions of calcium and magnesium carbonates), as witherite $SrCO_3$, as strontianite $SrCO_3$, as azurite and malachite (various compositions of cupric hydroxycarbonates), in various natural waters as carbonic acid, calcium and magnesium hydrogen carbonates, in blood, as sodium hydrogen carbonate.

Many esters of carbonic acid are known, e.g., diethyl carbonate, ethyl ester of metacarbonic acid, $(C_2H_5O)_2CO$, made by reaction of ethyl alcohol and carbonyl chloride; dimethyl carbonate, $(CH_3O)_2CO$; methyl ethyl carbonate, $(CH_3O)CO(OC_2H_5)$; dipropyl carbonate, $(C_3H_7O)_2CO$; tetraethyl carbonate, ethyl ester of orthocarbonic acid, $(C_2H_5O)_4C$, bp 158°C.

Peroxycarbonic acid exists only in its compounds. Alkali peroxycarbonates are obtained by electrolysis of concentrated solutions of the carbonates, the anodic reaction being written as

$$2CO_3^{2-} \longrightarrow C_2O_6^{2-} + 2\epsilon^-$$

The peroxycarbonates are relatively stable only in concentrated alkaline solutions. On dilution they decompose to give the bicarbonate and hydrogen peroxide

$$Na_2C_2O_6 + 2H_2O \longrightarrow 2NaHCO_3 + H_2O_2$$

when acidified, the peroxycarbonate ion gives, correspondingly, CO_2 and hydrogen peroxide

$$C_2O_6^{2-} + 2H^+ \longrightarrow 2CO_2 + H_2O_2$$

Carbonyls. The metal carbonyls are strongly covalent in character, as shown by their volatility, their solubility in many nonpolar solvents, and their insolubility in polar solvents. They also behave in many reactions like mixtures of carbon monoxide, CO, and the metal. Those of group 6b elements, $Cr(CO)_6$, $Mo(CO)_6$, and $W(CO)_6$ are more stable and less reactive than the others, especially those of group 8 elements. Group 7b carbonyls are $Mn_2(CO)_{10}$, $Tc_2(CO)_{10}$, and $Re_2(CO)_{10}$, while group 8 elements form $Fe(CO)_5$, $Fe_2(CO)_9$, $Fe_3(CO)_{12}$, $Co_2(CO)_8$, $Co_4(CO)_{12}$, $Ni(CO)_4$, $Ru(CO)_5$, $Ru_2(CO)_9$, $Ru_3(CO)_{12}$, $Rh_2(CO)_8$, $Rh_3(CO)_9$, (and multiples), $Rh_4(CO)_{14}$, (and multiples), $Os(CO)_5$, $Os_2(CO)_9$, $Ir_2(CO)_8$, and $Ir_3(CO)_9$ (and multiples). The carbonyls form a wide variety of addition compounds; they are dissolved in alcoholic potassium hydroxide or other strong alkalies to form hydrides which are acids, and can be used to form a wide variety of more complex compounds. Although $H_2Fe(CO)_4$ is a moderately weak acid, $pK_1 = 4.44$, $pK_2 = 14.0$, $HCo(CO)_4$ appears to be comparable with HCl in acidity. The carbonyl compounds have zero charge number on the metal. The mononuclear carbonyls are spin-paired complexes, and are formed only by metals having even atomic numbers. However, metals having odd atomic numbers can form carbonyl compounds with other atoms or radicals, as exemplified by the nitrosyl compound of cobalt carbonyl, $Co(CO)_3NO$, where the $-NO$ radical contributes the electron necessary to complete the 3*d* level of the cobalt atom. More than one NO group may occur in a metal carbonyl, as, for example, in $Fe(CO)_2(NO)_2$. This is isostructural with $Co(CO)_3NO$ and $Ni(CO)_4$.

Halides. The four tetrahalides of carbon are symmetrical, planar compounds, with the general property of marked stability to chemical reactions, although the tetraiodide undergoes slow hydrolysis in contact with water to form iodoform and iodine. It also decomposes under the action of light and heat. The stability of these four compounds decreases in order of descending periodic table position. Their properties are given below:

	NAME	FORMULA	MP	BP
Carbon tetrafluoride	CF_4	−184°C		−128°C
Carbon tetrachloride	CCl_4	−23.0°		−76.8°
Carbon tetrabromide	CBr_4	{α48.48, β90.18}		−189.5°
Carbon tetraiodide	CI_4	171° dec		

The same relation of reactivity and stability to periodic position is exhibited by such other carbon halides as hexachloroethane $CCl_3 \cdot CCl_3$ and hexabromoethane, $Br_3 \cdot CBr_3$, as well as by hexachloroethylene, $CCl_2 = CCl_2$ and hexabromoethylene, $CBr_2 = CBr_2$. Carbon also forms halides containing more than one halogen. See also **Carbon Tetrachloride**.

It is well established that hydrogen forms more than one covalent binary compound with carbon. Fluorine behaves similarly. Thus, fluorine forms CF_4, C_2F_4, C_2F_6, C_3F_8 and many higher homologs, as well as the definitely interstitial compound $(CF)_n$. The other halogens form some similar compounds, although to more limited extent, and various polyhalogen compounds have been prepared. They exhibit the maximum covalency of four and are therefore inert to hydrolysis and most other low temperature chemical reactions.

Carbon Oxides. See also **Carbon Dioxide**; **Carbon Monoxide**; and **Carbon Suboxide**.

The Fullerenes

The less-than-scientific ring ascribed to the comparatively recent discovery of a third form of carbon, the *fullerenes*, is reminiscent of *flavors* used a few years ago to describe the various kinds of quarks in the field of high-energy physics. The technical literature on fullerenes, as of early 1994, features such terms as bucky-ball, buckminsterfullerene, buckytube, carbon cage, dopey ball, hairy ball, Russian doll, et al., some of which terms are synonymous; others have specific connotations. Considered as an entity, fullerene chemistry constitutes a major breakthrough in the science of physics and chemistry of materials at the molecular level.

The absence of a formal nomenclature at this juncture is accompanied by a somewhat fuzzy chronology pertaining to the discovery and early research on the fullerenes. However, the isolation and confirmation of the C_{60} all-carbon molecule sans any dangling bonds, as first conjectured in 1985, was pivotal to subsequent research.

Setting the Stage for Carbon 60 Research. The pathways that ultimately led to the geometric visualization of the C_{60} molecule were several and varied.

(1) A growing interest in cluster configurations extends back to the 1950s. The sophistication of instrumentation for investigating once exotic substances has improved many times over during recent years, and numerous schemes of molecular geometry have been proposed. Thus, in retrospect, the efforts made to visualize the structure of the C_{60} molecule were not exclusively of a pioneering bent.

(2) For many years, astrophysicists have been interested in the role of carbon molecules, both as building blocks and as photofragments of carbonaceous materials. As early as 1972, *polyyne* chain molecules $(\cdots C \equiv C-C \equiv C-C \equiv C \cdots)$ were proposed as being present in interstellar space and in the atmospheres of carbon stars. This material, in the form of HC_5N was prepared in the laboratory and later was found, by way of radio astronomy, to exist in space. The structural geometry of the compound, however, could not be explained satisfactorily.

(3) Over a number of years, researchers engaged in the study of carbon (fuel) combustion reactions sought a better understanding of such reactions at the molecular level and, in particular, those processes that produced soot (carbon particles). Thus, carbon particles became a major target of their research. Because of concerns with air pollution, efforts were made to make carbon particle determination an exact science.

Carbon Sixty Research Chronology

In 1984, scientists (Rohlfing, Cox, and Caldor at Exxon Research and Engineering) created clusters of carbon (soot) by the laser vaporization of a carbon target rod in connection with a supersonic nozzle. By means of mass spectroscopy, the researchers determined the relative abundance of the carbon clusters produced. Small, 20- to 40-atom clusters of carbon were expected inasmuch as these had been produced a number of times by earlier investigators working on the soot problem. In such experiments, an interesting but unexplained question always arose—Why were only even-numbered carbon clusters produced in the complete absence of odd-numbered clusters? See Fig. 3.

In 1985, similar experiments were conducted at Rice University. In a 1988 paper, Curl and Smalley (Rice University) outlined their experiments with carbon cluster beams, essentially using the cluster-generating apparatus previously described by the Exxon researchers. Initially, this experimentation was motivated by an interest that had been shown by the astrophysicist, Kroto (University of Sussex), who had been modeling the formation of carbon molecules in circumstellar shells. As a consequence, the Rice University team concentrated its studies on the smaller (2- to 30-atom) carbon clusters. As pointed out in the Curl-Smalley paper, the objective was to "determine if some or all of the species had the same form as the long linear carbon chains known to be abundant in interstellar space."

Over time, the research interests of the Rice University team and of Kroto were directed increasingly to developing a suitable structural explanation of the even-numbered carbon clusters and, notably, of the C_{60} molecule.

It has been reported that, over a period of at least several months, Kroto and the Rice University team had formed a sort of research camaraderie, which developed out of their common interests in learning more about the structure of C_{60}. There are, however, some differences in opinion as to how the buckyball was visualized initially.

In a 1988 article, Kroto observed, "Initially, cluster reactions were probed which showed that C_n ($n > 30$) clusters did indeed react with H and N to form polyynes, which had been detected in space, a result satisfyingly consistent with the idea of a stellar source of interstellar chains. The larger clusters were totally inert, and as the experiments progressed, it became impossible to ignore the antics of the C_{60} peak which varied from relative insignificance to total dominance, depending on the clustering conditions.

"After much discussion we conjectured that the bizarre behavior, particularly of the dominance of C_{60}, could be the result of stabilization by closure of a graphite net into a hollow chicken-wire cage similar to the geodesic domes of Buckminster Fuller.[1] Such closure would eliminate all 20 or so reactive edge bonds of a 60-atom sheet. This led to the realization that there was a most elegant and, at the time, overwhelming solution—the *truncated icosahedron cage*." See Fig. 4.

"The structure necessitated the throwing of all caution to the wind (the Greek icosahedron) and it was proposed immediately by Kroto, Heath, O'Brien, Curl, and Smalley: *Nature*, **318**, 162 (1987). After all, it was surely too perfect a solution to be wrong. We named C_{60} after Buckminster Fuller, which has turned out to be a highly appropriate name."

The diagram (Fig. 5) shows a full accounting of the 60 carbon atoms that fully close the cage without any dangling bonds. Because the molecule resembles a soccer ball, it has been called the "buckyball."

Smalley's description of how the geometry of C_{60} was revealed varies somewhat from Kroto's accounting. This is explained partially by Philip Yam (reference listed), who writes in a short biography of Smalley, "Neither individual probably would have discovered buckyballs had they not collaborated, and both agree that it was a serendipitous finding." Ironically, it is interesting to note that David Jones (writing under the pseudonym, Daedalus) previously had proposed such cages as early as 1982.

Ensuing Fullerene Research

In the 1990s, fullerene research continued apace. Hundreds of new papers appeared each quarter pertaining to the properties of C_{60} and its cousins, and the prospects for developing new materials based upon this new dimension of carbon chemistry. (A sampling list of additional reading is given at the end of this article.)

Researchers J.M. Hawkins, et al. (University of California, Berkeley), for example, studied infrared, Raman, ^{13}C nuclear magnetic resonance, and photoelectron spectra of C_{60}, and found the data to be consistent with

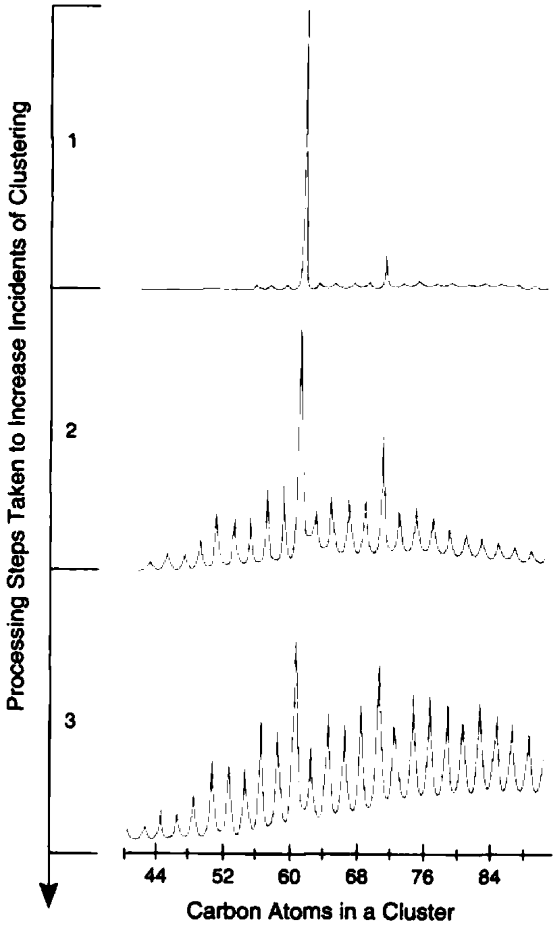


Fig. 3. Reasonable facsimiles of mass spectra produced by laser vaporization of carbon in a supersonic beam, indicating three stages in the process for increasing the extent of clustering. Experiment was carried out by Rohlfing, Cox, and Kaldor (Exxon Research and Engineering). Original diagrams were featured in *Nature* (1985)

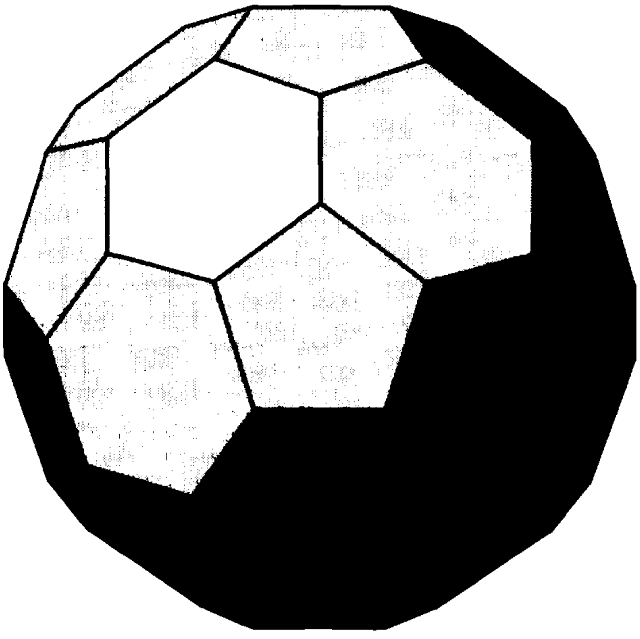

Fig. 4. Frontal view of truncated icosahedral structure of C_{60} cluster

[1] Architect, Buckminster Fuller, probably is most famous for his design of the United States exhibit building for the 1967 Exposition in Montreal.

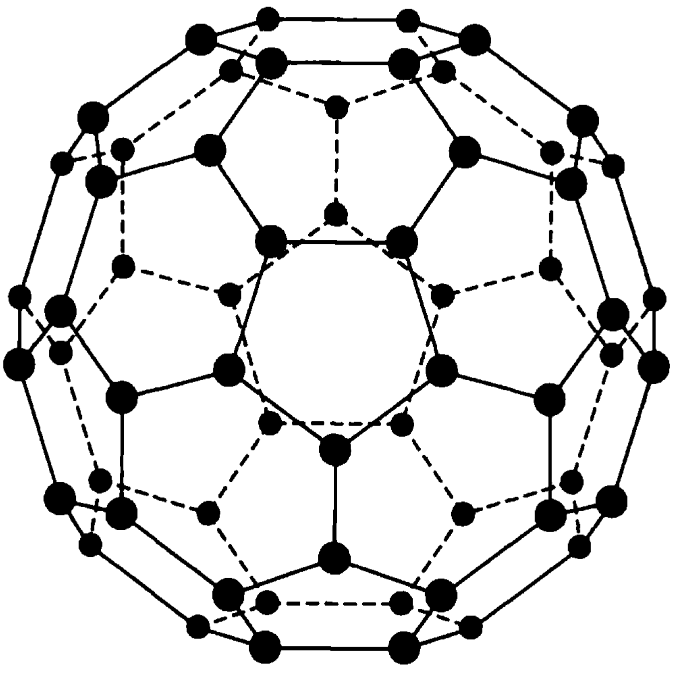

Fig. 5. C_{60} shown as transparent to indicate all sixty carbon atoms

icosahedral symmetry and thus highly supportive of the original proposed structure. However, the researchers did not strictly prove the soccer ball framework or provide atomic positions through the studies of spectra. Therefore, the investigators added an osmyl unit to C_{60} in order to break its pseudospherical symmetry and give an ordered crystal. The crystal structure of this derivative, C_{60} (OsO_4) (4-*tert*-butylpyridine$)_2$, revealed atomic positions within the carbon cluster, thus essentially confirming the soccer ball framework.

Scientists Y.Z. Li, R.E. Smalley, et al. (Rice University) have used scanning tunneling microscopy to study monolayer and multilayer structures of C_{60}. Detailed studies of potassium incorporation in crystalline C_{60} show highly ordered structures in the K_3C_{60} metallic state, but disordered nonmetallic structures for high potassium concentrations.

Researcher R.C. Haddon (AT&T Bell Laboratories) reports that there seems to be no doubt that the C_{60} molecule is highly electronegative, but that recent research has characterized C_{60} as that of an electron-deficient polyalkene without significant delocalization. Fullerenes are without boundary conditions; just as in an ideal graphite sheet, there are no peripheral atoms to serve as sites of preferred activity. "Without curvature, the fullerenes would be no more reactive than an ideal graphite sheet. The chemistry of the fullerenes is best described as that of a class of strained and continuous aromatic molecules. C_{60} is of ambiguous magnetic properties but with the reactivity of a continuous aromatic molecule moderated only by the tremendous strain inherent in the spheroidal structure."

J.E. Fischer and a team of researchers (University of Pennsylvania) report, "The recent discovery of an efficient synthesis of C_{60} and C_{70}... has facilitated the study of a new class of molecular crystals ('fullerites') based on these molecules ('fullerenes')." In the Fischer reference listed, a study of the compressibility of solid C_{60} is described.

In the S. Chakravarty (University of California, Los Angeles) et al. reference, "A theory of the electronic properties of doped fullerenes is proposed in which electronic correlation effects, within single fullerene molecules play a central role and qualitative predictions are made, which, if verified, would support this hypothesis. Depending on the effective intra-fullerene electron-electron repulsion and the interfullerene hopping amplitudes (which would depend on the dopant species, among other things), the calculations indicate the possibilities of singlet superconductivity and ferromagnetism."

As described by V.P. Dravid (Northwestern University) et al., "Transmission electron microscopy (TEM) observations of graphite tubules (*buckytubes*) and their derivatives have revealed not only the previously reported buckytube geometrics but also additional shapes of the buckytube derivatives. Detailed cross-sectional TEM images reveal the cylindrical cross section of buckytubes and the growth pattern of buckytubes as well as their derivatives.... Based on the TEM observations, it is proposed that buckytubes act as precursors to closed-shell fullerene (buckyball) formation."

The NEC Corporation, when examining deposits of soot on a carbon electrode used for generating fullerenes, found miniscule (up to a micron long) fibers which were tiled in hexagonal arrays. The arrays appear to tightly bind the carbon atoms and terminate in faceted, conical caps. The fibers immediately were referred to as "buckytubes." Iijama observes, "It (buckytube) could be the strongest fiber that can exist. Its strength flows from the nature of carbon-carbon bonds, on the one hand, and the nearly flawless structure of the tubular crystals, on the other." A scientist at the Massachusetts Institute of Technology has observed, "Buckyfibers have very few defects and so in that sense are better than graphite."

Materials engineers are becoming very interested in buckytubes because they may perform better than graphite in carbon-carbon composite materials, as currently used in aircraft.

Fullerenes in nature have been reported by a team of scientists, including P.R. Buseck (Arizona State University). High-resolution transmission electron microscopy images of poorly graphitized material in carbon-rich (coaly) rock, taken from an area near Karelia, Russia, are similar to those produced by synthetic fullerenes. The presence of C_{60} and C_{70} was confirmed by mass spectrometry. Needless to say, the finding was a surprise because the natural conditions for producing the fullerenes differ so much from the high-temperature processes of the laboratory. This finding may contribute in some way to future fullerene research.

CARBONADO. The mineral carbonado is an opaque massive black variety of diamond, often crystalline to granular or compact and without cleavage. In thin splinters it appears greenish-black by transmitted light. It is found chiefly in Bahia, Brazil. Carbonado is used for rock-drilling apparatus.

Carbonado also is known as *black diamond*.

CARBONATE. A compound resulting from the reaction of either a metal or an organic compound with carbonic acid. The reaction with a metal yields a salt (calcium carbonate) and that with an aliphatic or aromatic compound forms an ester, e.g., diethylcarbonate, diphenyl carbonate. The latter are liquids used as solvents and in synthesizing polycarbonate resins. See also **Carbon**.

CARBON BLACK. [CAS: 1333-86-4]. Finely divided carbonaceous pigments of a wide variety are termed carbon blacks. Over 90% of the carbon black manufactured is consumed as reinforcing and compounding agents for rubber, mainly for motor vehicle and aircraft tires. Most users of tires do not realize that the effective use of these agents extends the life of a tire in normal usage by eight to ten times. The addition of as little as 1 to 2% carbon black to plastics greatly minimizes the effects of sunlight in degrading the materials. Most carbon blacks are derived from the pyrolysis of hydrocarbon gases and oils. The permanent and penetratingly deep black coloration obtainable with carbon blacks also makes the materials attractive for paints, inks, protective coatings, and as colorants for paper and plastics.

Two properties of carbon blacks are most significant for commercial applications: (1) particle size and (2) surface area. The particle sizes range from 100 to 5,000 micrometers. Surface areas will range from 6 to 1,100 m^2/g of material. Under electron microscopic examination, the carbon particles appear as rough spheres, usually as clusters of spheres rather than as individual spheres. The clustering characteristics stem from both chemical and physical bonding forces. Classically, the arrangement of the carbon particles may be likened to hexagonal nets of carbon atoms, which are *paracrystalline* in nature. The particle size and surface area characteristics essentially are at the microscopic level-hence control over carbon black production is exacting. In terms of coloration, for example, the human eye can resolve 260 shades of blackness. The blackest of commercially produced carbon particles will have a diameter of about 100 micrometers. The grayest particle will have a diameter of about 5,000 micrometers. The blackness characteristic sometimes is referred to as *masstone* (mass-tone). The particles with the smaller diameters and hence greater surface area exhibit the highest masstone.

Lampblacks have been made for many centuries. Early methods involved the burning of petroleum-like substances or coal-tar residues with a minimum of air, thus producing large amounts of unoxidized carbon particles. The earlier settling chambers in which the particles collected have been replaced by cyclones, bag filters, or electrical precipitators. Modern installations use oil furnaces to create the particles.

Channel or *impingement carbons* are produced from burning natural gas (sometimes containing oil vapors) in many hundreds of small burners. The flames from the burners impinge upon flat surfaces called channels. The carbon deposits are periodically removed by scraping into a collector. The burning equipment is contained within a large burner house, which has means for carefully regulating bottom and top drafting of air.

Thermal blacks also are derived from natural gas, but by thermal decomposition completely in the absence of air. Large furnaces first are preheated to a temperature ranging from 1,100–1,650°C. When the checkerwork is at the proper temperature, natural gas is bled into the furnace, whereupon the gas decomposes into carbon and hydrogen. This is a batch process, requiring pairs of furnaces, one furnace preheating, while the other furnace is decomposing the gas feed. Frequently, the hydrogen byproduct is recycled as fuel to heat the furnaces. Where very fine thermal blacks are produced, the byproduct hydrogen is used as a diluent for the gas feed.

Furnace carbons also are derived from natural gas, but in a process in which a slight excess of air is introduced to support combustion. The hydrocarbon feedstock or liquid oil is injected into the furnace at a location where the so-called blast-flame gases are circulating at their greatest velocity. Injection of the feed at this point causes an instant high rise in temperature, which results in practically instantaneous decomposition of the feed into carbon black. For coarse particles, the oil/air ratio is greater, furnace gas velocities are lower, and residence time in the furnace is longer. There is a wide range of furnace carbon particle sizes. The very fine particles go into tire treads, whereas the coarser particles are used in tire carcasses.

Acetylene black is derived from feeding acetylene into high-temperature retorts whereupon the acetylene dissociates into carbon and hydrogen. This reaction is exothermic (other carbon black processes are endothermic). Temperature control of the furnace is effected by throttling the acetylene feed.

CARBON COMPOUNDS. See **Organic Chemistry**.

CARBON DATING. See **Radioactivity**.

CARBON DIOXIDE. [CAS: 124-38-9]. CO_2, formula weight 44.01, colorless, odorless, nontoxic gas at standard conditions. High concentrations of the gas do cause stupefaction and suffocation because of the displacement of ample oxygen for breathing. Density 1.9769 g/l (0°C, 760 torr), sp gr 1.53 (air = 1.00), mp −56.6°C (5.2 atmospheres), solid CO_2 sublimes at −79°C (760 torr), critical pressure 73 atmospheres, critical temperature 31°C. Carbon dioxide is soluble in H_2O (approximately 1 volume CO_2 in 1 volume H_2O at 15°C, 760 torr), soluble in alcohol, and is rapidly absorbed by most alkaline solutions. The solubility of CO_2 in H_2O for various pressures and temperatures is given in Table 1.

Carbon dioxide plays several roles: (1) as a *raw material* for several processes, as in the Solvay process for the manufacture of sodium bicarbonate and sodium carbonate, (2) as a *byproduct* from many processes, notably as a product of combustion of fossil fuels, (3) as an *ingredient* of products, for example, carbonated beverages, (4) as a *product* for direct consumption, for example, CO_2 fire extinguishers and dry ice refrigerants, and (5) as a *pollutant* of the atmosphere. Carbon dioxide is useful in all three of its physical phases-gas, liquid, and solid. Although not toxic, the presence of CO_2 in the atmosphere disturbs the environmental energy balance. The latter aspects of CO_2 are discussed under **Pollution (Air)**. Normally, CO_2 is present in the air at sea level to the extent of about 0.05% by weight.

Transportation Uses

Solid carbon dioxide (dry ice) is an effective refrigerant for transportation uses. Refrigeration of moving vehicles may be derived from (1) mechanical systems which, of course, require a continuous input of energy, (2) water ice and ice-salt mixes which require water (often briny) removal, and are corrosive and subject to algae formations, and (3) dry ice, the end-product of which is simply gaseous CO_2, which is easily removed. To maintain a cool temperature in a railroad refrigerator car for a trip between California and New York, about 1,000 pounds (~454 kg) of dry ice would be required. To maintain the same conditions with water ice and salt would require 10,000 pounds of ice.

Specially designed rail cars have replaced on-board diesel-powered refrigeration units, with a CO_2 injection system and ceiling-mounted bunker. These bunkers carry sufficient quantities of dry ice snow to provide sufficient refrigeration for long trips. There are similar applications where perishables are moved by truck. Particularly in truck shipments, CO_2 systems not only refrigerate the cargo, but the inert atmosphere (CO_2 in gaseous phase) retards bacterial growth and thus prevents spoilage. The system is widely used for local route deliveries where frequent and lengthy door openings are needed. Automatic temperature controllers are used. Airlines, hotels, and restaurants keep prepared foods fresh during transport by dispensing CO_2 snow into the bunker portion of customized food service carts.

TABLE 1. SOLUBILITY OF CARBON DIOXIDE IN WATER

Pressure	Parts (Weight) CO_2 Soluble in 100 Parts Water				
(atmospheres)	18°C	35°C	50°C	75°C	100°C
25	3.7	2.6	1.9	1.4	1.1
50	6.3	4.4	4.0	2.5	2.0
75	6.7	5.5	4.5	3.4	2.8
100	6.8	5.8	5.1	4.1	3.5
200	—	6.3	5.8	5.3	5.1
300	7.4	—	6.2	5.8	5.7
400	7.8	7.1	6.6	6.3	6.4
700	—	—	7.6	7.4	7.6

Fire-Fighting Uses

The fact that CO_2 is heavier than air makes it particularly effective for fighting fires in low places, such as pipe trenches and hard-to-reach low corners and basements, where the CO_2 tends to roll under the air required to maintain combustion. Both manually and automatically controlled CO_2 fire-fighting systems are available. These can be actuated by heat-sensitive systems—just as a conventional water-sprinkling system. CO_2 is effective for fires involving electrical and electronic gear because, if a fire is not fully out-of-hand, the CO_2 often can quickly quench the fire source without leaving any residual damage, as often is the disastrous consequences of using water or sand.

Food Industry Uses

Large quantities of CO_2 are used in food processing, ranging over a wide variety of cooling and freezing operations. A number of freezer designs have been developed, including tunnel, cabinet, spiral, flighted, and drum designs. For example, wide usage of CO_2 in the baking industry includes chilling pneumatically conveyed dry ingredients, such as flour and powdered sugar, to controlling the temperature of dough during the mixing process.

Carbon dioxide is used for carbonating soft drinks. The wine industry also uses CO_2 to add effervescence to sparkling burgundies, rose wines, and some champagne.

The use of CO_2 atmosphere systems in greenhouses has been found to increase plant growth. During winter months, heating costs are markedly reduced and crop yields are increased.

Oil Production Enhancement

For a number of years, depending upon the geopolitics of crude oil production, considerable interest has been shown in the use of carbon dioxide for increasing the recovery of oil from old wells. In the United States alone, it is estimated that there are more than 300 billion barrels of oil left in known formations, which are incapable of recovery through the use of traditional recovery enhancement techniques, such as steam flooding and the use of surfactants. Supercritical fluid carbon dioxide is an impressive solvent for fats and hydrocarbons. The problems of geological formations underground and their varying characteristics (permeability, etc.) present difficulties as with past methods, but it has been established that the dense fluid CO_2 will contribute to recovery wherever it contacts oil. Consequently, some major oil firms already have expended large sums to ready pipelines and other facilities for bringing CO_2 to oil fields as, for example, those in the Permian basin of western Texas and New Mexico. Although carbon dioxide has been a useful material for other purposes, oil recovery usage may require the gas in huge quantities not heretofore contemplated. The target, of course, is to capture the needed CO_2 mainly from wastes to the atmosphere, as from power plants. Although authorities still consider oil recovery as a long-range goal, the short-term pace is affected by the fluctuating price of crude oil on world markets. More detail concerning the use of supercritical CO_2 for this purpose is given in entry on **Petroleum**.

Sources of Commercial Carbon Dioxide

Although carbon dioxide must be generated on site for some processes, there is a trend toward CO_2 recovery where it is a major reaction byproduct and, in the past, vented to the atmosphere. For example, very large quantities of CO_2 are generated by various fermentation processes and in cement production. If the CO_2 must be removed from stack gases because of pollution control regulations, it is only one more step to purify the gas and sell it, usually in compressed liquid form. There are, of course, several economic tradeoffs that must be considered. Where the gas is recovered, it usually is first absorbed in sodium or potassium carbonate solutions, followed by steam-heating the solutions to free a reasonably pure CO_2. The last step is compression of the gas into steel cylinders. The ethanolamines also are excellent absorbents of CO_2.

Carbon Dioxide in Biological Systems

Carbon dioxide, which is a byproduct of the metabolic activity of all cells, is one of the most important chemical regulators in the human body. It can be said that human life without carbon dioxide would be impossible. In less specialized forms of life, carbon dioxide is essentially a waste product. In the more highly developed animals, such as humans, the gas

is used to regulate the activity of the heart, the blood vessels, and the respiratory system.

As mentioned, CO_2 is normally present in air at sea level at about 0.05% (weight). A poorly ventilated room may contain as much as 1% (volume). Concentrations of the gas from about 0.1–1% (volume) induce languor and headaches; concentrations of 8–10% (volume) bring about death by asphyxiation. High concentrations of the gas are toxic. See also **Basal Metabolism**.

As a general rule, the respiration of individual cells decreases as the concentration of carbon dioxide in the medium increases. Fish show a lessened capacity to extract oxygen from their environment with increasing amounts of carbon dioxide present. On the other hand, many invertebrates show marked increases in respiratory rate (or ventilation) with increased amounts of the gas in their surroundings.

Photosynthetic and autotrophic bacteria reduce carbon dioxide, which is assimilated into complex molecules for use in synthesizing various cellular constituents. The gas is apparently assimilated, at least to a small extent, by the heterotrophic bacteria. Certainly it is required for any growth in these forms. Many pathogenic bacteria required increased carbon dioxide tension for growth immediately after they are isolated from the body. The production of hemolysins and like substances is greatly enhanced by adding 10–20% of CO_2 in the air that comes in contact with the cultures.

The oxygen dissociation curve for blood is shifted to the right when the partial pressure of carbon dioxide is increased. This is referred to as the "Bohr Effect." It means that for a given partial pressure of oxygen, hemoglobin holds less oxygen at high concentration of carbon dioxide than at a lower concentration. It is evident, then, that the production of carbon dioxide by actively metabolizing tissues favors the release of oxygen from the blood to the cells where it is urgently needed. Moreover, at the alveolar surfaces in the lungs, the blood is losing carbon dioxide rapidly, which loss favors the combination of oxygen with hemoglobin. In males, the average amount of CO_2 in the alveolar air is about 5.5% (volume); during the breathing cycle, this concentration varies only slightly. In females and children, somewhat lower mean values obtain.

In every 100 milliliters of arterial blood, there is a total of 48 milliliters of free and combined CO_2. In venous blood of resting humans, there is about 5 milliliters more than this. Only about 1/20 of the carbon dioxide is uncombined, a fact which indicates that there is a specialized mechanism, aside from simple solution, for the transport of CO_2 in the blood.

About 20% of the CO_2 in the blood is carried in combination with hemoglobin as *carbaminohemoglobin*. The balance of the combined carbon dioxide is carried as bicarbonate. A CO_2 dissociation curve for blood can be prepared just as for oxygen, but the shape is not the same as for the latter. As the partial pressure of CO_2 in the air increases, the amount in the blood increases; the increase is practically linear in the higher ranges. Oxygen exerts a negative effect on the amount of CO_2 which can be taken up by the blood.

In working muscles large amounts of CO_2 are produced. This causes local vasodilation. The diffusion of some of the CO_2 into the bloodstream slightly raises the concentration there. It circulates through the body and the capillaries of the vasoconstrictor center, where it excites the cells of the center, resulting in an increase of constrictor discharges. Regarding the stimulating effect of CO_2 on cardiac output, it is evident that a most effective mechanism exists for increasing circulation through active muscles: more blood is pumped by the heart per minute, and the arterial pressure is increased by the general vasoconstriction; blood is forced from the inactive regions, under increased pressure, through the widely dilated vessels of the active muscles.

The partial pressure of CO_2 is important in connection with a number of physiological problems. For example, respiratory acidosis is the result of an abnormally high $p \ldots CO_2$. The value of arterial pCO_2 varies directly with changes in the metabolic production of CO_2 and indirectly with the amount of alveolar ventilation. The problem is more commonly the result of decreased alveolar ventilation caused by abnormally low CO_2 excretion by the lungs (alveolar *hypo*ventilation).

On the other hand, primary respiratory alkalosis occurs as a result of alveolar *hyper*ventilation. This condition is associated with a number of pulmonary diseases, but also may appear during pregnancy, liver disease, and salicylate intoxication, among others. The sequence of events proceeds along these lines: (1) Ventilation removes CO_2 faster than the gas is produced by metabolism, causing a decrease in pCO_2 in the blood and body fluids, including a reduction of venous pCO_2. This reduces the gradient for excretion of CO_2 by the lungs. (2) Pulmonary excretion and metabolic production ultimately balance out at a lower pCO_2 level for all body fluids. (3) The lower pCO_2 level causes a lower carbonic acid concentration and consequently an increase in pH. The latter is relative to the reduced level of pCO_2, but the pH change also alters bicarbonate concentration. The steplike process is quite complex. See also **Blood**.

Narcosis due to CO_2 is characterized by mental disturbances which may range from confusion, mania, or drowsiness to deep coma, headache, sweating, muscle twitching, increased intracranial pressure, pounding pulse, low blood pressure, hypothermia, and sometimes papilloedema. The basic mechanisms by which carbon dioxide induces narcosis is probably through interference with the intracellular enzyme systems, which are all sensitive to pH changes.

See also **Photosynthesis**.

Carbon Dioxide and Enzymes

Dr. Harland Wood (Case Western Reserve University) has made major contributions to the understanding of carbon dioxide cycles and enzyme reactions within living organisms. While investigating the process of bacterial fermentation, Wood discovered that some heterotrophic organisms (non-plant forms that require organic compounds for growth) can use carbon dioxide along with organic compounds to build essential compounds. This was in 1935, when it was considered that only plants could use carbon dioxide and that, in heterotrophs, carbon dioxide was a waste product. Wood also researched the role of carbon dioxide in the metabolism of carbohydrates, fats, and amino acids by forming the required intermediate compounds. In 1985 Wood found that certain bacteria produce organic compounds entirely from carbon dioxide by a pathway that differs from that of photosynthesis. Certain parts of the cycle involving use of carbon dioxide and hydrogen were found to exist within many organisms.

Wood also has worked with transcarboxylase, a complex, biotin-containing enzyme important in the use of carbon dioxide within heterotrophs. As of the early 1990s this pathway had not been fully delineated.

CARBON DISULFIDE. [CAS: 75-15-0]. Carbon disulfide (carbon bisulfide, dithiocarbonic anhydride), CS_2, is a toxic, dense liquid of high volatility and flammability. It is an important industrial chemical and its properties are well established. Low concentrations of carbon disulfide naturally discharge into the atmosphere from certain soils, and carbon disulfide has been detected in mustard oil, volcanic gases, and crude petroleum. Carbon disulfide is an unintentional by-product of many combustion and high temperature industrial processes where sulfur compounds are present.

Commercial uses grew rapidly from about 1929 to 1970, when the principal applications included manufacturing viscose rayon fibers,

cellophane, carbon tetrachloride, flotation aids, rubber vulcanization accelerators, fungicides, and pesticides. Production of carbon disulfide in the United States has declined in recent years. Other chemical fibers and films, as well as environmental and toxicity considerations related to carbon tetrachloride, have had significant impact on the demand for carbon disulfide. Worldwide annual production capacity in 1991 was approximately 1.3 million tons, with actual production estimated at about one million metric tons.

Physical Properties

Pure carbon disulfide is a clear, colorless liquid with a delicate, ether-like odor. Carbon disulfide is slightly miscible with water, but it is a good solvent for many organic compounds. Thermodynamic constants, vapor pressure, spectral transmission, and other properties of carbon disulfide have been determined. Principal properties are listed in Table 1.

Carbon disulfide is completely miscible with many hydrocarbons, alcohols, and chlorinated hydrocarbons. Phosphorus and sulfur are very soluble in carbon disulfide.

Chemical Properties

The low flash point temperature of −30°C at atmospheric pressure and wide flammability range of carbon disulfide deserve special attention. The flash point is lowered if the pressure is decreased or the oxygen content enriched. The flammability limits or explosive ranges depend on conditions of temperature, pressure, and geometry of the enclosure. Flammability limits of 1.06–50.0 vol % carbon disulfide in air are reported for upward propagation and 1.91–35.0 vol % for downward propagation in a 75-mm diameter glass tube.

Carbon disulfide chemistry is thoroughly described in several publications which include many references.

Manufacture

The earliest method for manufacturing carbon disulfide involved synthesis from the elements by reaction of sulfur and carbon as hardwood charcoal in externally heated retorts. Safety concerns, short lives of the retorts, and low production capacities led to the development of an electric furnace process, also based on reaction of sulfur and charcoal. The commercial use of hydrocarbons as the source of carbon was developed in the 1950s, and it was still the predominate process worldwide in 1991. That route, using methane and sulfur as the feedstock, provides high capacity in an economical, continuous unit.

Potential Processes. Sulfur vapor reacts with other hydrocarbon gases, such as acetylene or ethylene, to form carbon disulfide. Light gas oil was reported to be successful on a semiworks scale. In the reaction with hydrocarbons or carbon, pyrites can be the sulfur source. With methane and iron pyrite the reaction products are carbon disulfide, hydrogen sulfide, and iron or iron sulfide. Pyrite can be reduced with carbon monoxide to produce carbon disulfide.

TABLE 1. PROPERTIES OF CARBON DISULFIDE

Property	Values
General	
melting point, K	161.11
latent heat of fusion, kJ/kg[a]	57.7
boiling point at 101.3 kPa[b], °C	46.25
flash point at 101.3 kPa[b], °C	−30
ignition temperature in air, °C

[a] To convert J to cal, divide by 4.184.
[b] To convert kPa to atm, divide by 101.3.

Toxicology, Health, and Safety Factors

Care must be exercised in handling carbon disulfide because of both health concerns and the danger of fire or explosions. Occupational exposure potentially may involve as many as 20,000 workers in the United States. Ingestion is rare, but a 10 mL dose can prove fatal. Contact usually occurs by inhalation of vapor. However, vapor and liquid can be absorbed through intact skin and poisoning may occur by the dermal route. Repeated contact of liquid carbon disulfide with the skin can cause inflammation and cracking because carbon disulfide removes protective waxes and oils. Extended skin contact results in blistering and possibly second- and third-degree burns. Precautions should be taken to avoid breathing of vapors or mists that may contain carbon disulfide. Contact with skin or eyes should also be avoided, and adequate safety gear should be worn, including goggles, impervious gloves, and appropriate clothing.

The odor threshold of carbon disulfide is about 1 ppm in air but varies widely depending on individual sensitivity and purity of the carbon disulfide. However, using the sense of smell to detect excessive concentrations of carbon disulfide is unreliable because of the frequent co-presence of hydrogen sulfide that dulls the olfactory sense.

Immediate effects of overexposure to carbon disulfide vapors range from headache, dizziness, nausea, and vomiting to life-threatening convulsions, unconsciousness, and respiratory paralysis. For an exposure time of 30 min, 1150 ppm carbon disulfide in air results in serious symptoms, 3210 ppm is dangerous to life, and 4815 ppm is fatal. Prolonged and repeated exposure to carbon disulfide vapor can affect both the central and peripheral nervous systems. In recent years, previously unrecognized and more subtle toxic effects of repeated lower level exposures became evident. This led OSHA in 1989 to reduce permissible concentration limits to 4 ppm (12 mg/m^3) maximum time-weighted average for 8-h exposure and 12 ppm (36 mg/m^3) maximum for 15-min short-term exposure. Analysis of urine specimens for carbon disulfide metabolites by an iodine-azide test and other methods can indicate overexposure.

Health hazards linked to carbon disulfide are extensively covered in the literature. Also available are epidemiological studies, general reviews containing many references, and a Material Safety Data Sheet.

Uses

United States consumption of carbon disulfide totaled about 108,000 t in 1990 according to SRI International, with the following distribution by end use application: 46,000 t for rayon; 33,000 t for carbon tetrachloride; 12,000 t for rubber; 5,000 t for cellophane; and 12,000 t for agricultural and miscellaneous uses. During 1991 the carbon tetrachloride application disappeared entirely, thereby reducing the annualized carbon disulfide usage to an estimated 75,000 t. Net exports are around 6,000 t, and are expected to increase in the future.

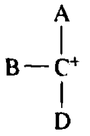
CARBON GROUP (The). The elements of group 14 of the periodic classification sometimes are referred to as the Carbon Group. In order of increasing atomic number, they are carbon, silicon, germanium, tin, and lead. The elements of this group are characterized by the presence of four electrons in an outer shell. The similarities of chemical behavior among the elements of this group are less striking than that for some of the other groups, e.g., the close parallels of the alkali metals or alkaline earths. However, as more knowledge is gained of silicon, including the element's ability to form "carbon-like" chains with alternating silicon and

oxygen atoms, to polymerize, and to form silicones, silanes, etc., the similarity of silicon and carbon emerges more sharply. The semiconductor properties of silicon and germanium in this group are striking, but such properties are not limited to elements in this group. Although some of the elements of the group have valences in addition to +4, all do have the +4 valence in common. Unlike the alkali metals or alkaline earths, for example, the elements of the carbon group are not so similar chemically that they comprise a separate group in classical qualitative chemical analysis separations.

CARBONITRIDING. A surface hardening process for steels involving the introduction of carbon and nitrogen into steels by heating in a suitable atmosphere containing various combinations of hydrocarbons, ammonia, and carbon monoxide followed by a quenching to harden the case.

CARBONIZATION (Coal). See **Coal**.

CARBONIUM ION. An ion of the general formula

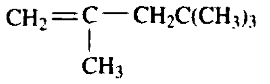


where A, B and D are substituent groups. It is important in elucidating the mechanism of organic reactions because a considerable proportion of all organic reactions involve carbonium ions, as others do carbanions and carbon free radicals (including carbene radicals). Nucleophilic substitution at saturated carbon atoms includes most of carbonium ion chemistry. Carbonium ions are usually powerful acids or electrophiles, and thus many nucleophilic substitution reactions that involve carbonium ions are acid-catalyzed. For example, the tertiary-butyl carbonium ion offers a clear understanding of the probable course of the conversion of isobutylene to its dimers and trimers.

$$(CH_3)_2C{=}CH_2 + H^+ \longrightarrow (CH_3)_3C^+$$

$$(CH_3)_3C^+ + (CH_3)_2C{=}CH_2 \rightleftharpoons (CH_3)_2C{-}CH_2C(CH_3)_3$$

The larger carbonium ion thus formed cannot continue to exist, but may depolymerize, unite with the catalyst, or stabilize itself by the attraction of an electron pair from a carbon atom adjacent to the electronically deficient carbon (C^+) with its proton. This establishes a double bond involving the formerly deficient atom. Thus a proton is expelled to the catalyst or attracted to the catalyst. If this takes place with one of the methyl groups, the product



is If the methylene group is involved, the product is $(CH_3)_2C{=}CHC(CH_3)_3$.

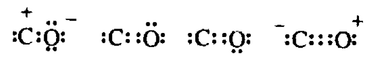
CARBON MONOXIDE. [CAS: 630-08-0]. CO, formula weight 28.01, colorless, odorless, very toxic gas at standard conditions, density 1.2504 g/l (0°C, 760 torr), sp gr 0.968 (air = 1.000), mp −207°C, bp −192°C, critical temperature −139°C, critical pressure 35 atmospheres. Carbon monoxide is virtually insoluble in H_2O (0.0044 part CO in 100 parts H_2O at 50°C). The gas is soluble in alcohol or solutions of cupric chloride. Because carbon monoxide has an affinity for blood hemoglobin that is 300 times that of oxygen, exposure to the gas greatly reduces or fully hinders the ability of hemoglobin to carry oxygen throughout the body, causing death in excessive concentrations. Engines and stoves in poorly ventilated areas are especially hazardous.

Carbon monoxide plays several roles: (1) as a raw material for chemical processes (a) particularly as an effective reducing agent in various metal smelting operations, (b) in the manufacture of formates: $CO + NaOH \longrightarrow HCOONa$, (c) in the production of carbonyls, such as $Ni(CO)_4$ and $Fe(CO)_5$, which are useful intermediate compounds in the separation of certain metals, (d) in combination with chlorine to form $COCl_2$ (phosgene), (e) as an ingredient of several synthesis gases, as for the production of methanol and ammonia; (2) as a *fuel* where CO is a major ingredient of such artificial fuels as coal gas, producer gas, blast-furnace gas, and water gas; (3) as a byproduct of numerous chemical reactions, notably combustion processes where there is insufficient oxygen for complete combustion—the fumes from internal-combustion engines may contain in excess of 7% CO, and (4) as a dangerous air pollutant, particularly in industrial areas and where there are high concentrations of automotive vehicles and aircraft. The latter aspects of CO are discussed under **Pollution (Air)**

Summary of Chemical Reactivity

Chemically, carbon monoxide is (1) reactive with oxygen to form CO_2 accompanied by a transparent blue flame and the evolution of heat, but the fuel value is low (320 Btu per ft^3), (2) reactive with chlorine, forming carbonyl chloride $COCl_2$ in the presence of light and a catalyzer, (3) reactive with sulfur vapor at a red heat, forming carbonyl sulfide COS, (4) reactive with hydrogen, forming methyl alcohol, CH_3OH or methane CH_4 in the presence of a catalyzer, (5) reactive with nickel (also iron, cobalt, molybdenum, ruthenium, rhodium, osmium, and iridium) to form nickel carbonyl, $Ni(CO)_4$ (and carbonyls of the other metals named), (6) reactive with fused NaOH, forming sodium formate, HCOONa, (7) reactive with cuprous salt dissolved in either ammonia solution or concentrated HCl, which solutions are utilized in the estimation of carbon monoxide in mixtures of gases, e.g., flue gases of combustion, coal gas, exhaust gases of internal combustion engines, (8) reactive with iodine pentoxide at 150°C. For the reaction of carbon monoxide with oxygen to form CO_2 finely divided iron or palladium wire is used as a catalyzer; for the reaction of carbon monoxide with H_2O vapor to form CO_2 plus hydrogen ("water gas reaction") important studies have been made of the conditions; and for the reaction of CO_2 plus carbon (hot) similar important studies have been made (at 675°C, 50% CO_2 plus 50% CO; at 900°C, 5% CO_2 plus 95% CO). The reaction of carbon plus oxygen at such a temperature as produces carbon monoxide (say 900°C, 95% CO plus 5% CO_2) and *evolves heat*; while the reaction of carbon plus CO_2, producing carbon monoxide at the same temperature *absorbs heat*. Accordingly it is possible to arrange the oxygen (free or as air) and CO_2 supply ratio in such a way that the desired temperature may be continuously maintained. The reduction of CO_2 by iron forms carbon monoxide plus ferrous oxide.

In valence bond terms, carbon monoxide is considered as a resonance compound with the structures



In molecular orbital terms the CO molecule is described as $CO(KK(z\sigma)^2(y\sigma)^2(x\sigma)^2(w\pi)^4)$, one $(z\sigma)$ pair being formed from the oxygen $2s$ electrons, and one $(y\sigma)$ pair held by the carbon sp hybrid. This $(y\sigma)^2$ pair offsets the dipole moment of the π electrons, and also accounts for the readiness with which the CO molecule coordinates with metals to form the carbonyls.

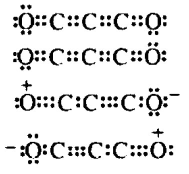
CARBON SUBOXIDE. C_3O_2, formula weight 68.03, colorless, toxic, gas at room temperature, very unpleasant odor, sp gr 2.10 (air = 1.00), 1.24 (liquid at −87°C), mp −107°C, bp 7°C (760 torr), burns with a blue smoky flame, producing CO_2. When condensed to liquid, the oxide slowly changes at ordinary temperature to a dark red solid, soluble in water to a red solution. Reacts with water to form malonic acid, with hydrogen chloride to form malonyl chloride, with ammonia to form malonamide. Made by heating malonic acid or its ester at 300°C under diminished pressure, and separation from simultaneously formed carbon dioxide and ethylene by condensation and fractional distillation.

Carbon suboxide has a linear structure, probably a resonance of four structures of which the last two below probably make a smaller contribution to the normal state of the molecule than the first two.



CARBON TETRACHLORIDE. [CAS: 56-23-5]. CCl_4, formula weight 82.82, heavy, colorless, nonflammable, noncombustible liquid, mp −23°C, bp 76.75°C, sp gr 1.588 (25°C/25°C), vapor density 5.32 (air = 1.00), critical temperature 283.2°C, critical pressure 661 atmospheres, solubility 0.08 g in 100 g H_2O, odor threshold 80 ppm. Dry carbon tetrachloride is noncorrosive to common metals except aluminum. When wet, CCl_4 hydrolyzes and is corrosive to iron, copper, nickel, and alloys containing those elements. About 90% of all CCl_4 manufactured goes into the production of chlorofluorocarbons:

$$2CCl_4 + 3HF \xrightarrow{\text{catalyst}} CCl_2F_2 + CCl_3F + 3HCl.$$

Carbon tetrachloride was first made by chlorinating chloroform (1839). Later, CCl_4 was made by chlorinating carbon disulfide, CS_2, in the first commercial process, developed by Müller and Dubois (1893). Large-scale production commenced in the early 1900s at which time carbon tetrachloride became a popular metal-degreasing solvent, dry-cleaning fluid, fabric-spotting fluid, grain fumigant, and fire extinguishing fluid. In many of these uses, it has now been displaced by other less toxic chlorinated hydrocarbons. The carbon disulfide process consists of: (1) $3C + 6S \longrightarrow 3CS_2$; (2) $2CS_2 + 6Cl_2 \longrightarrow 2CCl_4 + 2S_2Cl_2$; (3) $CS_2 + 2S_2Cl_2 \longrightarrow CCl_4 + 6S$. The reaction must be carried out in a lead-lined reactor in a solution of CCl_4 at 30°C in the presence of iron filings as catalyst. The chlorination of methane is now the principal production route to CCl_4: $CH_4 + Cl_2 \longrightarrow CH_3Cl + CH_2Cl_2 + CHCl_3 + CCl_4 + HCl$ + excess CH_4. The reaction is carried out in the liquid phase at about 35°C. Ultraviolet light is used as a catalyst. The same reaction can be carried out at 475°C without catalyst. The unreacted methane and partially chlorinated products are recycled to control the yield of CCl_4.

Toxicity. The experimental exposure of laboratory animals to the vapors of CCl_4 has shown it to be very toxic by inhalation at concentrations easily obtainable at ambient temperatures. An overexposure to carbon tetrachloride has been known to cause acute but temporary loss of renal function.

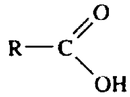
CARBONYLS. See **Carbon**.

CARBONYLS (Chlorinated). See **Chlorinated Organics**.

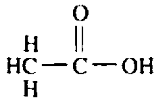
CARBORANE. A crystalline compound composed of boron, carbon, and hydrogen. It can be synthesized in various ways, chiefly by the reaction of a borane (penta-or deca-) with acetylene, either at high temperature in the gas phase or in the presence of a Lewis base. Alkylated derivatives have been prepared. Carboranes have different structural and chemical characteristics and should not be confused with hydrocarbon derivatives or boron hydrides. The predominant structures are the cage type, the nest type, and the web type, these terms being descriptive of the arrangement of atoms in the crystals. Active research on cargorane chemistry has been conducted under sponsorship of the U.S. Office of Naval Research. http://www.onr.navy.mil/

CARBORUNDUM. See **Silicon**.

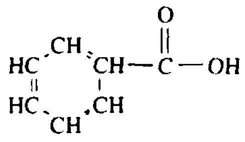
CARBOXYLIC ACIDS. The general formula for a carboxylic acid is



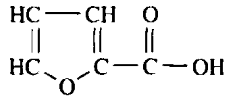
In terms of structure, a carboxylic acid may be aliphatic, carbocyclic, or heterocyclic:



Aliphatic acetic acid

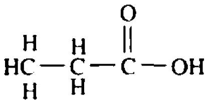


Carbocyclic or aromatic benzoic acid



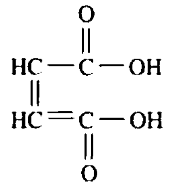
Heterocyclic pyromucic or furoic acid

Or, a carboxylic acid may be classified in terms of the number of carboxyl (−COOH) groups which it contains. If one carboxyl group, it is designated as *mono*carboxylic; if two groups, as *di*carboxylic; if three groups, as *tri*carboxylic; and if four groups, as *tetra*carboxylic:



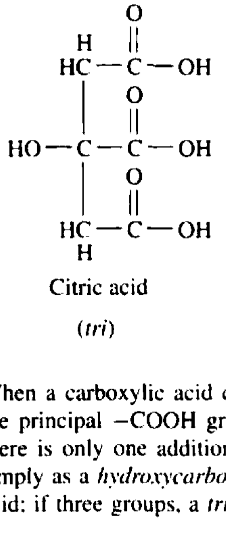
Propionic acid

(*mono*)



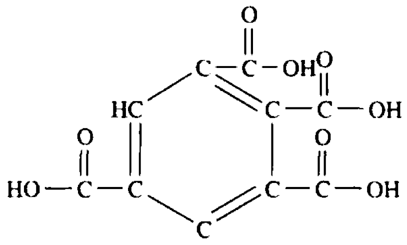
Maleic acid or *cis*-ethylene dicarboxylic acid

(*di*)



Citric acid

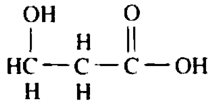
(*tri*)



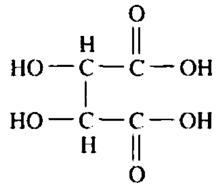
1,2,3,5-Benzenetetracarboxylic acid or mellophanic acid

(*tetra*)

When a carboxylic acid contains a hydroxyl group in addition to that of the principal −COOH grouping, the term *hydroxy* is sometimes used. If there is only one additional hydroxyl group, the acid may be designated simply as a *hydroxycarboxylic* acid; if two groups, a *di*hydroxycarboxylic acid; if three groups, a *tri*hydroxycarboxylic acid.



Hydracrylic acid or β-hydroxypropionic acid
A hydroxymono-carboxylic acid

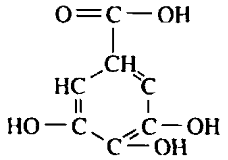


Tartaric acid
A dihydroxycarboxylic acid

A carboxylic acid may be classified in accordance with the number of available hydrogens for salt formation. If only one hydrogen is available, the acid is *monobasic*; if two hydrogens are available, the acid is *dibasic*; if three or more hydrogens are available, the acid is *polybasic*.

A carboxylic acid also may be classified from the standpoint of other groups it contains. An *aldehydic* carboxylic acid contains the CHO group. An example is glyoxalic acid, CHO · COOH. An *amino* carboxylic acid contains the NH_2 group. An example is carbamic or amino-formic acid, NH_2COOH. A *ketonic* carboxylic acid contains the CO group. An example is benzoylacetic acid, $C_6H_5 \cdot CO \cdot CH_2 \cdot COOH$. In the case of a *phenolic* carboxylic acid, the acid is structurally derived from benzoic acid, with

uniting of the OH group with a carbon of the nucleus.



Gallic or pyrogallol carboxylic acid
or 3,4,5-trihydroxybenzoic acid
A trihydroxymonocarboxylic acid

There are several homologous series of carboxylic acids, including:

$C_nH_{2n}O_2$	Saturated monobasic fatty acids
$C_nH_{2n-2}O_2$	Unsaturated monobasic fatty acids
$C_nH_{2n-4}O_2$	Propioloic acid series
$C_nH_{2n}(COOH)_2$	Dicarboxylic acids, where $n = 0$ for oxalic acid
$C_nH_{2n}(OH)(COOH)$	Hydroxymonocarboxylic acids, where $n = 0$ for carbonic acid

Fatty Acids

The simplest or lowest member of the fatty acid series is formic acid, HCOOH, followed by acetic acid, CH_3COOH, propionic acid with three carbons, butyric acid with four carbons, valeric acid with five carbons, and upward to palmitic acid with sixteen carbons, stearic acid with eighteen carbons; and melissic acid with thirty carbons. Fatty acids are considered to be the oxidation product of saturated primary alcohols. These acids are stable, being very difficult (with the exception of formic acid) to convert to simpler compounds; they easily undergo double decomposition because of the carboxyl group; they combine with alcohols to form esters and water; they yield halogen-substitution products; they convert to acid chlorides when reacted with phosphorus pentachloride; and their acidic qualities decrease as their formula weight increases.

Monohydroxy Fatty Acids

Structurally, these acids may be considered as the monohydroxy derivatives of the fatty acids. Included among these acids are hydroxyacetic acid (glycollic acid) and β-hydroxypropionic acid (β-lactic acid). These acids generally are syrupy liquids that tend to give up water readily and form crystalline anhydrides; they decompose when volatilized, and they are soluble in water and usually in alcohol and ether.

Polyhydric Monobasic Acids

Structurally, these acids are considered to be the oxidation products of polyhydric alcohols. However, a number of them can be formed from the oxidation of sugars. The careful oxidation of glycerol will yield a syrupy liquid, glyceric acid, an example of a dihydroxymonobasic carboxylic acid.

Aromatic Carboxylic Acids

In many ways, these acids are similar to the fatty acids. Generally, they are crystalline solids that are only slightly soluble in water, but most often they dissolve easily in alcohol or ether. The simpler aromatic acids may be distilled (or sublimed) without decomposition. The more complex acids, such as the phenolic and polycarboxylic aromatic acids, break down when heated, yielding carbon dioxide and a simpler compound. As an example, salicylic acid degrades to carbon dioxide and phenol. In nature, the aromatic acids are found in balsams, animal organisms, and resins.

The monobasic saturated aromatic acids include benzoic, hippuric, toluic acids (three structures), phenylacetic, phenylchloracetic, and dimethylbenzoic acid. Among the monobasic unsaturated acids are cinnamic, atropic, and phenylpropionic acids. The saturated phenolic acids include gallic and salicylic acids. The alcohol acids include amygdalic, tropic, and mandelic acids. One example of an unsaturated monobasic phenolic acid is coumaric acid.

Formation of Carboxylic Acids

Commercially, these acids are produced in several ways: (1) oxidation of relevant alcohol—e.g., acetic acid from ethyl alcohol; (2) oxidation of relevant aldehyde—e.g., acetic acid from acetaldehyde; (3) bacterial fermentation of dilute alcohols; (4) reacting a methyl ketone with sodium hypochlorite (haloform reaction); (5) carbonation of Grignard reagents; (6) hydrolysis of nitriles; (7) malonic ester synthesis route; (8) oxidation of relevant alkylaromatic—e.g., benzoic acid from toluene; (9) reaction of an alkali metal phenolic with carbon dioxide; and (10) hydrocarboxylation of olefins—e.g., butyric acid from propylene.

CARBURETION. The fuel for an internal combustion engine must be well mixed with the air required for combustion. This is particularly true of the Otto cycle engine, inasmuch as thorough distribution of particles of fuel in the air is essential to rapid and complete explosive combustion of the fuel in that cycle. One of the most effective means of mixing the particles of a liquid fuel with air is by vaporization. The vaporizing and mixing of a liquid fuel with air in the correct proportions is called *carburetion*; the device used is called a *carburetor*.

By using multiple jets, adjustable orifices, and other intricacies, commercial carburetors attain mixture control approximating the desirable performance for a gasoline engine as shown in Fig. 1. Increasing air pollution standards have exacted greater demands on carburetor performance and most of these demands have been met by utilizing solid-state controls over carburetor optimization.

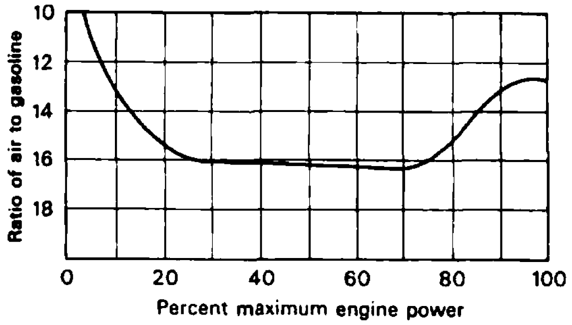

Fig. 1. Optimal carburetor performance for gasoline engine

CARBURIZING. Machine parts requiring high strength, hardness, and toughness can often be made by either of two methods, one based on the use of a medium-carbon steel (0.30–0.50% carbon) heat treated to the required properties, and the other based on the use of a low-carbon steel (0.08–0.25% carbon) carburized to give a high-carbon surface layer and then heat treated. The carburized part will have a harder, more wear-resistant surface and a tougher core than the heat-treated medium-carbon steel. Transmission gears, camshafts, and piston pins are typical parts which can be made advantageously of carburizing grade steels.

The process consists of heating the fully machined part in an atmosphere rich in carbon monoxide or hydrocarbon gases at a temperature in the range 1650–1800°F (899–982°C). Reactions at the surface of the metal liberate atomic carbon which is readily dissolved by the steel and diffuses inward from the surface. In a typical carburized case a depth of penetration of 0.05 inch (0.13 centimeter) was obtained in 4 hours at 1700°F (927°C). The maximum carbon content at the surface was 1.10%. Shallow cases under 0.02 inch (0.05 centimeter) are useful for many purposes and very deep cases over 0.10 inch (0.25 centimeter) thick are required for gears for heavy machinery and for armor plate.

The process is most often carried out in sealed containers in which the parts are packed in carburizing compound consisting of a mixture of charcoal, coke, and other carbonaceous solids, together with barium carbonate and other compounds which act as energizers. At high temperatures these solids burn slowly, maintaining a supply of carbon monoxide. Carburizing is also carried out in batch-type and continuous-type furnaces in an atmosphere of natural gas, propane, butane, or specially mixed gases. Liquid baths consisting mainly of molten cyanide and chloride salts are also used for surface hardening. These baths supply both nitrogen and carbon to the surface of the steel, and where nitrogen is the principal hardener the process is known as cyaniding. Nitrogen hardens steel by forming hard compounds with iron and with certain alloying elements that may be present such as aluminum, chromium, and vanadium. See also **Nitriding**. In general, the salt-bath methods give shallower but harder cases than regular solid-pack carburizing. The pieces are quenched for hardening directly from the bath.

Carburized steels may also be quenched in oil or water directly from the box or furnace, or they may be cooled and reheated for hardening. A low temperature tempering treatment is given for relief of quenching stresses. A surface hardness of 60 Rockwell "C" is readily obtained, and when medium alloy steels of fine grain size are used, the strength and ductility of the core is exceptionally high, for example, 165,000 psi (11,224 atmospheres) tensile strength and 18% elongation.

CARCINOGENS. A carcinogen may be defined as a substance, normally not present in the body that, when absorbed by the body in some manner (breathing, eating, drinking, injecting, skin contact, etc.), will induce the formation of malignant neoplasms (cancers); that is, a carcinogen initiates and nurtures tumor growth.

Progress of the ensuing carcinogenesis is dependent upon many factors, such as the frequency of exposure to the carcinogen (single, multiple, continuous), the concentration of the carcinogen when absorbed (ranging from parts per billion to parts per million and greater), as well as the poorly understood "natural resistance" of individual organisms to expel a given carcinogen. Very important is the total length of time over which exposure has occurred (ranging from seconds to years). Because of these extreme variations, group studies of environmental carcinogenicity are difficult and frequently unreliable. Consequently, the dangers of carcinogens can be over- or underestimated.

In terms of exposure to carcinogens by the average individual, particular attention should be given (1) to the *habitat* (water and air contamination; use of household chemical products), (2) the *workplace* (industrial chemicals), and, of course, (3) the *general environment*, particularly in industrialized urban areas.

There is much the average person can do to minimize exposure to carcinogens as, for example, carefully selecting garden chemicals and using gloves to prevent exposure of the skin when hazardous materials, including paint solvents, are handled—and in assuring good ventilation and air conditioning of living quarters to remove airborne particles. Within practical limitations, it is good practice to consider the local neighborhood environmental quality to avoid locating near known sources of air pollution. A check on possible radon pollution at a given site may be in order. See **Radon**.

Millions of people are avoiding exposure to the carcinogenic substances in tobacco. Millions of others are checking their dietary intake to avoid any substances that are suspected of promoting forms of carcinogenesis within the body, which often are of a long-term nature.

Until the early 1950s, the concept prevailed that the activity of carcinogenic chemicals was somehow related to the fact that they were synthetic "unnatural" substances that, since they are not present in the natural environment, were not factors of selection during developing life processes; hence, contemporary living organisms were not equipped for effective metabolic "detoxification" of these compounds. In the intervening years, however, a number of carcinogenic compounds of plant and fungal origin have been identified, including: safrole in sassafras; capsicine in chili peppers; various tannins; cycasin in the cycad groundnut; parasorbic acid in mountain ash berry; pyrollizidine alkaloids in *Senecio* shrubbery; and patulin, griseofulvin, penicillin G, and actinomycin produced by various molds. It also appears that liver cancer in Africa and the Peoples Republic of China is caused by interaction of aflatoxin and the co-carcinogen, hepatitis B virus. The number and variety of identified naturally occurring carcinogens continues to increase at a rapid rate.

Grouping of Carcinogens

Chemically identified carcinogens may be grouped in many ways, including a division into inorganic ions and organic compounds. The inorganic carcinogens contain the elements beryllium, cadmium, iron, cobalt, nickel, silver, lead, zinc, and possibly arsenic; these can form coordination compounds and/or react with sulfhydryl groups. Also asbestos powder is a powerful carcinogen toward the lung upon inhalation (asbestos cancer of miners). In recent years, the characteristics of asbestos and related substances have caused much controversy in connection with the pollution of certain waters, notably Lake Superior, by taconite processing waste products which contain fibers that have been compared with asbestos fibers. Most likely this situation will require some years for full scientific and legal resolution. Distinction must be made, however, between the supposed carcinogenic properties of asbestos materials and the silicosis engendered by the inhalation of other silicate dusts. There appears no reason to believe that in this latter instance the lesions are related to lung cancer per se.

The organic carcinogens may be subdivided in several ways, including: (a) condensed polycyclic aromatic hydrocarbons and heteroaromatic polycyclic compounds; (b) aromatic amines and *N*-aryl hydroxylamines; (c) amino-azo dyes and di-arylazo compounds; (d) aminostilbenes and stilbene analogues of sex hormones. Further breaking down the aliphatic carcinogens, these include: (1) alkylating agents (such as sulfur and nitrogen mustards, derivates of ethyleneimine, lactones, epoxides, alkane-α-ω-*bis*-methanesulfonates, certain dialkylnitrosamines, and ethionine; (b) lipophilic agents and hydrogen-bond reactors; this class comprises a wide variety of agents, such as chlorinated hydrocarbons (chloroform, carbon tetrachloride, and compounds used as pesticides under the names aldrin and dieldrin), bile acids, certain water-soluble high polymers, certain phenols, urethane and some of its derivatives, thiocarbonyls, and cycloalkynitrosamines; (c) naturally occurring carcinogens.

Until the mid-1970s, most studies in chemical carcinogenesis were experimental, i.e., suspect materials were placed continuously on the skin or in the diets of laboratory animals who were then observed to see if any neoplasms developed. While such work was invaluable in identifying materials which should be removed from the environment, or otherwise avoided, it did not provide any major understanding of the basis of chemical carcinogenesis. Indeed, many of the dermal tests merely indicated allergic reactions and many of the dietary tests showed that some animals thrived on trace additives.

Over the past decade, however, emphasis has been placed upon the molecular biology of carcinogenesis and it has been demonstrated that, in the first steps of carcinogen interaction, most carcinogens must be activated by the host cell's metabolism. Cell culture techniques have demonstrated that normal healthy cells can be transmuted into malignancies by certain chemicals. This in vitro work, however, has yet to transform human cells in the same way.

There is some evidence that the form of the chemical carcinogen that ultimately reacts with cellular macromolecules must contain a reactive electrophilic center, that is, an electron-deficient atom that can attack the numerous electron-rich centers in polynucleotides and proteins. As examples, significant electrophilic centers include free radicals, carbonium ions, epoxides, the nitrogen in esters of hydroxylamines and hydroxamic acids, and some metal cations. It is believed that carcinogens, which in themselves are not electrophiles, are metabolized to electrophilic derivatives that then become the "ultimate" carcinogens.

In this context, oxygen free radicals have been linked to many diseases other than cancer. There is much evidence that such free radicals may be developed in any kind of inflamed tissues and in chronically irritated organs the free radicals produced may convert exogenous chemicals to active carcinogens.

Workplace Carcinogens

During the early 1990s, an extensive study of occupational medicine was undertaken by the Yale-New Haven Occupational Medicine Program, Yale University School of Medicine, and the Occupational Medicine Program, University of Washington School of Medicine. M.R. Cullen, M.G. Cherniack, and L. Rosenstock, members of the Yale-Washington team, reported, "The success of epidemiologists in the 1960s and 1970s in establishing the excess cancer risk for workers exposed to several widespread workplace agents, most notably asbestos, benzene, and benzidine dyes, raised the possibility that cancer overall might largely be attributable to exposure in the workplace. Ecologic (sic) data showed some

congruity between regions with high rates of cancer and high levels of industrial activity, and an unpublished government document purporting to show that 20 to 38 percent of all cancers were attributable to workplace exposure received circulation and attention. The past decade (1980s) has witnessed a considerable sobering and refinement of the prevailing views. Although over 300 compounds have been shown to have carcinogenic potential on the basis of their effects in laboratory animals, no new class of compounds has been added to the list of previously established human carcinogens." See Tables 1 and 2.

Carcinogen Mechanisms

The biochemical pathways in the cell are closely interconnected and are in a state of dynamic equilibrium (homeostasis). This equilibrium is maintained by feedback relationships existing between a great number of pathways. Chemical communication between subcellular organelles, such as the nucleus (within which the chromosomes contain the genetic blueprints for cell reproduction and the synthetic processes of cell life), the mitochondria (the powerhouse of the cell, which assures the synthesis of the universal cellular fuel, ATP, through the metabolism of carbohydrates and fatty acids), and the endoplasmic reticulum (synthesizing the proteins of the cell and assuring the metabolic breakdown—detoxification—of a multitude of endogenous and foreign compounds), depends on the constant interchange of a large variety of metabolic products and inorganic ions between them. There are probably a very great number of loci (receptor sites) upon which these regulatory chemical "stimuli" act. The receptor sites are of an enzymatic and nucleic acid nature. Other control points of protein character regulate the morphology of the intracellular lipoprotein membranes, which serve as "floor space" to the organized arrangements of multi-enzyme systems. The specificity of compounds of chemical control toward given receptor sites is due to a three-dimensional geometric "fit" following the lock and key analogy. Such is the general scheme of functional interrelationships in monocellular organisms which, hence, in a favorable medium multiply unchecked to the limit of the availability of nutrients.

In multicellular organisms, the subordination of the individual cells to the whole is assured by the existence of additional receptor sites which enable the cells to be response to chemical "stimuli" emitted by neighboring cells in the tissue and to hormonal regulation by the endocrine system in higher organisms. Hence, depending on the requirements of the moment, cells may remain stationary or may undergo cell division because of the need for repair of tissue injury, they may secrete different products, or they may perform some other specialized function depending on the nature of the particular tissue.

Carcinogenic substances are nonspecific cell poisons that cause the alterations and hence functional deletion of a large number of metabolic control sites. Present evidence suggests that these alterations are produced by the accumulation of the carcinogen in subcellular organelles, by covalent binding of the carcinogen to cellular macromolecules (proteins and nucleic acids) through metabolism, and by denaturation (i.e., destruction of the three-dimensional geometry) of the control sites through secondary valence interactions (hydrogen bonds, hydrophobic bonding, etc.) with the carcinogen. Early stages of tumor induction generally coincide with extensive cell death (necrosis) in the target tissues because a number of the biochemical lesions cause the irreversible blocking of metabolic pathways essential for cell life. However, because of the random distribution of the biochemical lesions in the cell population, in a small number of cells vital pathways are only slightly damaged and the lesions involve those sites and pathways which are not essential for cell life proper, but are necessary for organismic control. Thus, due to the action of the carcinogen, these cells escape physiological control and revert to a simpler, less specialized cell type (i.e., dedifferentiate). Such cells respond to continuous nutrition with continuous growth, which is an essential characteristic of malignant tumor cells.

The high incidence of skin cancer in coal tar workers was recognized as early as 1880. The carcinogenic activity of coal tar was demonstrated in 1915, when Yamagiwa and Ichikawa obtained epitheliomas (malignant tumor originating from epithelial cells) by its prolonged application to the ears of rabbits. Identification of the active material (in 1933) as

TABLE 1. DEFINITELY ESTABLISHED WORKPLACE CARCINOGENS

(Adapted from Yale-Washington Occupational Medicine Program)

Operations/processes carcinogen	Primary body organ where encountered	Affected
Para-aminodiphenyl	Chemical processing	Urinary bladder
Asbestos	Construction, asbestos mining and milling, production of friction products (brake Linings, etc.), and cement	Pleura and bronchus (lungs) and peritoneum
Arsenic	Copper mining and smelting	Skin, bronchus, liver
Alkylating agents (mechlorethamine hydrochloride) and bis [chloromethyl] ether	Chemical processing	Bronchus
Benzene	Chemical and rubber processing, petroleum refining	Bone marrow
Benzidine, beta naphthylamine and derived dyes	Dye and textile production	Urinary bladder
Chromium and chromates	Tanning, pigment making	Nasal sinus, bronchus
Ionizing radiation	Nuclear industry, health care settings bone marrow	Skin, thyroid, bronchus,
Radon	Uranium and hematite mining	Bronchus
Radium	Watch painting	Bone
Nickel	Nickel plating	Nasal sinus, bronchus
Polynuclear aromatic hydrocarbons (from coke, coal tar, shale, mineral oils and creosote)	Steelmaking, roofing, chimney cleaning	Skin, scrotum, bronchus
Vinyl chloride monomer	Chemical processing	Liver
Wood dust	Cabinetmaking, carpentry	Nasal sinus

TABLE 2. SUSPECTED (WIDELY USED) CARCINOGENS

(Adapted from Yale-Washington Occupational Medicine Program)

Operations/Processes Agent	Primary Body Organ Where Encountered	Affected
Beryllium	Beryllium processing, aircraft manufacturing, electronics, secondary smelting	Bronchus
Cadmium	Smelting, battery making, welding	Bronchus
Ethylene oxide	Hospitals, hospital supply manufacturing	Bone marrow
Formaldehyde	Plastics, textile and chemical processing; health care	Nasal sinus, bronchus
Synthetic mineral fibers (fiberglass)	Fiber manufacturing and installation	Bronchus
Polychlorinated biphenyls (PCBs)	Electrical equipment manufacturing/maintenance	Liver
Organochlorine pesticides (e.g., chlordane, dieldrin)	Pesticide manufacture and agricultural applications	Bone marrow
Silica	Casting, mining, refracting	Bronchus

the polycyclic aromatic hydrocarbon 3,4-benzopyrene (III, Fig. 1) is due to Cook, Kennaway, Hieger and their co-workers. This discovery was followed up by the synthesis and testing of a considerable variety of polycyclic aromatic hydrocarbons. All compounds of this class may be regarded as composed of condensed benzene rings. The arrangement of the hexagonal rings in various patterns results in a variety of compounds having different physical, chemical, and biological properties. However, not all polycyclic aromatic hydrocarbons possess carcinogenic activity; certain requirements of molecular geometry must be met.

For maximum activity, the molecule must have (Fig. 1): (a) an optimum size; (b) a coplanar molecular configuration, meaning that all hexagonal rings must lie flatly in one plane; in fact, hydrogenation of many of the active hydrocarbons results in buckled molecular conformation and this is concomitant with partial or total loss of activity; and (c) at least one meso-phenanthrenic double bond, also called the K-region (indicated by arrows in Fig. 1) of high π-electron density (i.e., of high chemical reactivity). In addition to III, 1,2,5,6-dibenzanthracene (IV), and 20-methylcholanthrene (V) are commonly used to study the experimental induction of tumors. The activity of most hydrocarbon carcinogens was tested on the skin of mice and the subcutaneous connective tissue of mice and rats. There is a vast body of evidence indicating that 3,4-benzopyrene and other carcinogenic hydrocarbons are formed during pyrogenation or incomplete burning of almost any kind of organic material. For example, carcinogenic hydrocarbons have been identified in overheated fats, broiled and smoked meats, coffee, burnt sugar, rubber, commercial paraffin oils and solids, soot, the tar contained in the exhaust fumes of internal combustion engines, cigarette smoke, etc.

It must be pointed out, however, that direct evidence of human involvement is lacking. For example, despite much publicity, N-nitrosamines have *not* been proven to be causative agents on induction of human cancer. They are, however, patent carcinogens in *experimental animals*.

Attention to the carcinogenic aromatic amines was drawn by the high incidence of urinary bladder tumors in dye works exposed to 2-naphthylamine (VII, Fig. 2), and benzidine (IX). The carcinogenic activity of VII, IX, and 4-aminobiphenyl (X) toward the bladder of the dog and the mouse has been demonstrated. In the rat, however, there is a change in target specificity, and tumors are induced by IX and X in the liver, mammary gland, ear duct, and small intestine. Carcinogenic activity is considerably heightened in 2-acetylaminofluorene (XI) without change of target specificity. Increased activity is due to the fact that XI is more coplanar than X, because of the internuclear methylene ($-CH_2-$) bridge in the former. 2-Acetylaminofluorene was proposed as an insecticide before its carcinogenic activity was accidentally discovered; it is a ubiquitous, potent carcinogen in a variety of species. Changing the internuclear bridge of XI

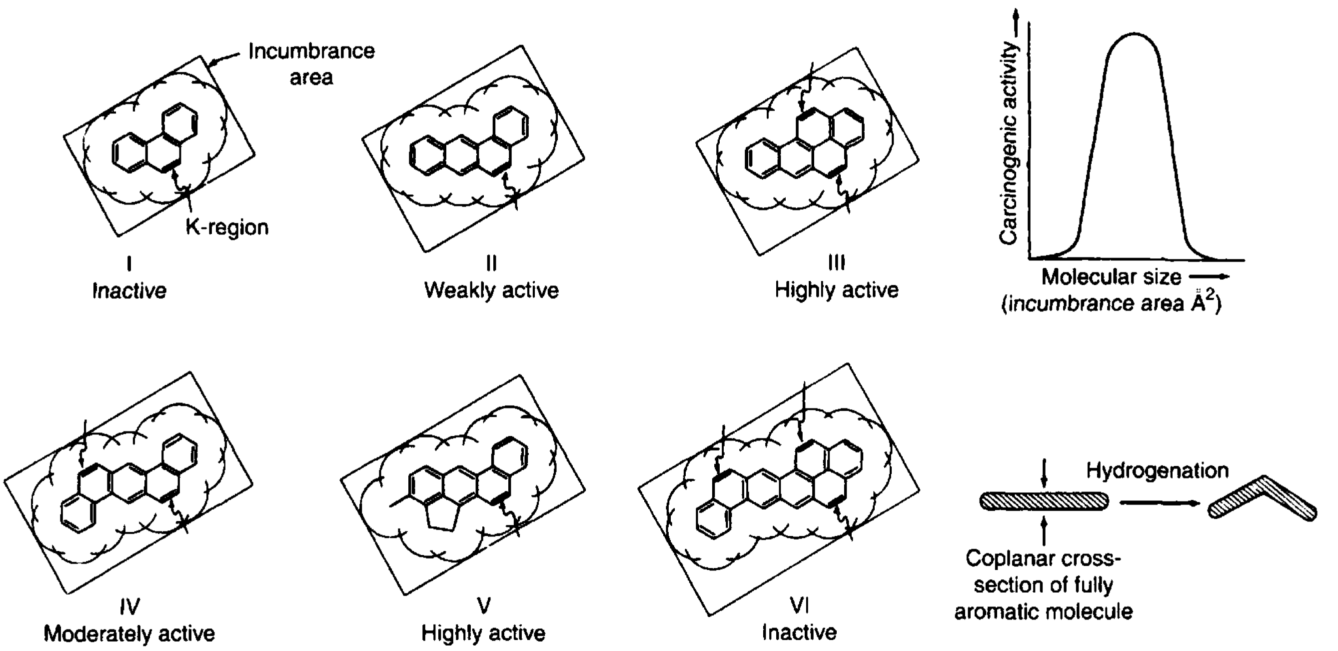

Fig. 1. Polycyclic aromatic hydrocarbons

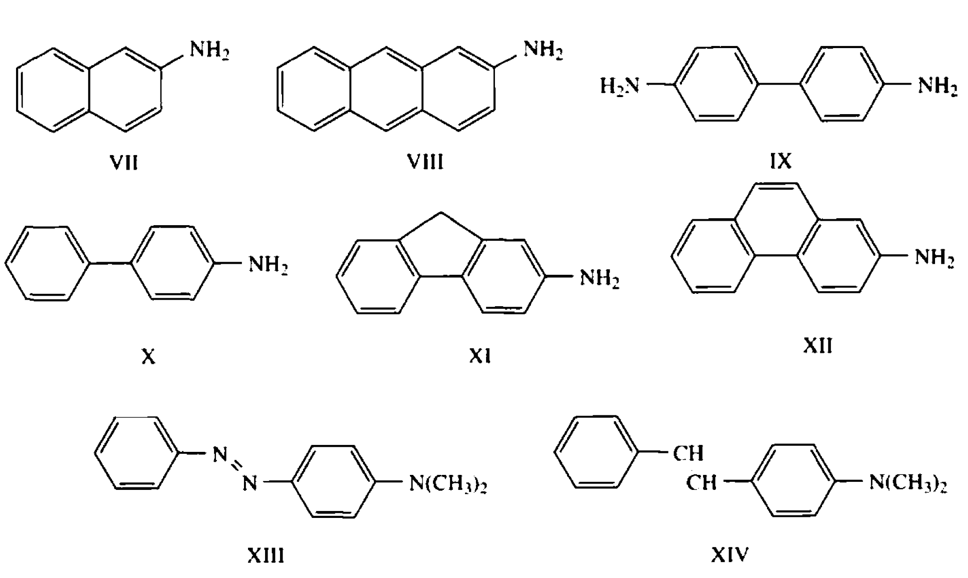

Fig. 2. Carcinogenic aromatic amines

to –CH=CH–, as in 2-aminophenanthrene (XII), causes a shift in target specificity; thus, in the rat, XII is inactive toward the liver, but in addition to inducing tumors in the mammary gland, ear duct, and small intestine, it produces leukemia. Compound XII represents a structural link between the aromatic amine and polycyclic hydrocarbon carcinogens (compare XII with I); it is also interesting in this respect that 2-amino-anthracene (VIII), which is a higher homologue of VII, is inactive toward the bladder, but is able to induce skin tumors in rats.

4-Dimethylamino-azobenzene (XIII) is the parent compound of the amino-azo dye carcinogens; it is also known in the earlier literature as Butter Yellow, because it was used to color butter and vegetable oils before its carcinogenic activity was discovered. Many derivatives of XIII have been prepared and tested for carcinogenic activity. In the rat, the amino-azo dye carcinogens, administered in the diet, specifically induce hepatomas. Tumor induction by most of the amino-azo dyes is delayed or inhibited by high dietary levels of riboflavin (vitamin B_2) or protein. Replacement of the –N=N–azo linkage by –CH=CH–, as in 4-dimethylaminostilbene (XIV), results in widening the target tissue spectrum; XIV induces tumors in the liver, mammary gland, and ear duct. Mice are much more resistant than rats to the carcinogenic activity of both amino-azo dyes and aminostilbenes.

Figure 3 illustrates some aliphatic carcinogens. *N*-Methyl-bis-β-chloro ethylamine (XV), a nitrogen mustard, produces local sarcomas, lung, mammary, and hepatic tumors upon injection in mice; because of its tumor-inhibitory properties, XV has also been used in the therapeutic treatment of certain types of human cancers. Bisepoxybutane (XVI), β-propiolactone (XVII), and *N*-lauroylethyleneimine (XVIII) produce local sarcomas in rats upon injection. Ethylcarbamate (XIX), the parent compounds of several hypnotic drugs used in humans, produces malignant lung adenomas in rats, mice, and chickens. Dimethylnitrosamine (XX) is a potent carcinogen toward the liver, lung, and kidney, and ethionine (XXI) toward the liver of the rat; the former is an intermediate in the manufacture of the rocket-fuel component, dimethylhydrazine $(CH_3)_2N–NH_2$, while the latter is the *S*-ethyl analogue of the natural amino acid methionine.

Testing

Because of their short life span (average 3 years) small rodents (mice, rats, and hamsters) are frequently used for the testing of chemicals for carcinogenic activity; occasionally testing is done with rabbits, dogs, fowls, monkeys, etc. While a great variety of ways of administration has been used, a common method is to introduce substances to be tested in the following ways: (a) skin painting; small volumes of solution of the substance in an inactive solvent (e.g., benzene) are applied to the shaved surface of the skin (generally of mice, in the interscapular region) daily or at longer intervals; (b) subcutaneous injection of the pure substance or its solution (once or at repeated intervals); (c) feeding: the substance is mixed in the diet at given levels, or dissolved in the drinking water. Testing of new substances for possible carcinogenic activity is conducted for a minimum of 1 year to be meaningful. At the end of the testing period, all animals are necropsied, and all tumors and dubious tissues examined histopathologically.

Within the past few years, the costs of carrying out long-term bioassays have increased markedly to the point at which it is too costly for small or medium-size manufacturers to fund a study of the long-term toxicity or carcinogenicity of any chemicals proposed for commercial development. Therefore, many short-term tests are being developed to predict which compounds would more likely be carcinogenic. A prominent one is a test for mutagenicity in various strains of the bacterium *Salmonella typhimurium*. The tests generally involve addition of the compound under test into a culture dish, which is seeded with the bacterium. The medium is deficient or lacking in histidine; therefore, no bacterial growth occurs, unless mutation by the test chemical yields a form of bacteria that does not require histidine. A count of the bacterial colonies can therefore be used as a measure of the mutagenicity of the test compound. The test, although quite rapid, does suffer from certain deficiencies. For one, a fair number of compounds are not mutagenic even though they are strong carcinogens in animals. These are usually compounds that require metabolic activation to demonstrate their carcinogenicity. Several variations on the test conditions have been proposed and, therefore, with these variations and parallel tests in other systems it is possible to establish whether the chemical under test may be a potential hazard.

A carcinogen that is highly active in one species may be totally inactive in another species, and vice versa. The susceptibility of a species to a given carcinogen also depends on the genetic strain, sex, and dietary conditions. Moreover, carcinogenic substances generally show a rather selective specificity toward certain target tissues; e.g., certain compounds produce exclusively hepatomas in the susceptible species. For these reasons, no chemical compound may be stated safely to be devoid of carcinogenic activity toward humans unless it has been found inactive when tested in a variety of mammalian species and by a variety of routes of administration for a length of time corresponding to half the life span of each species.

The foregoing observation emphasizes one of the main problems in cancer research, namely, *extrapolation* of research findings. For a given population to be fully safe, literally tens of thousands of commonly encountered natural materials and synthetic materials, covering the complete spectrum of products with which people are in contact over their lives, would have to be tested and regarded suspect until thoroughly tested on the species of most importance to humans, namely, the testing of reactions among people themselves. But this alone would not suffice because, as stressed throughout biochemical studies of human systems, there is individuality. The problem of developing improved (vastly improved) testing systems and attention to the problem of extrapolation of findings rivals in difficulty the basic problem of identifying the nature of cancer itself.

Many lists have appeared indicating the toxicity and/or carcinogenicity of specific chemicals. It would be invidious to attempt to insert these lists in this article because the number is extensive. Reference can be made to the sources cited at the end of this article.

The interesting observation has been made that, because of the vast amounts of money going into cancer research, the field has become a large business for numerous suppliers. Animal cells now can be procured by the kilogram from suppliers. Because of this availability (mostly two kinds, 3T3 and W138), much information has been accumulated concerning the biology of these cells. But is much of what has been learned in this regard meaningful? Researchers have found that viruses and chemicals can transform 3T3 cells to a neoplastic state and that these cells can produce tumors when inoculated in suitable hosts. It should be noted, however, that the tumors so produced are sarcomas (derived from fibroblasts), which are very rare in human beings. Ninety percent of human tumors are carcinomas. With the exception that epithelial cells and fibroblasts are both animal cells, they have little in common. They stem from two embryonic sources with different functions, and the tumors they produce are different as well.

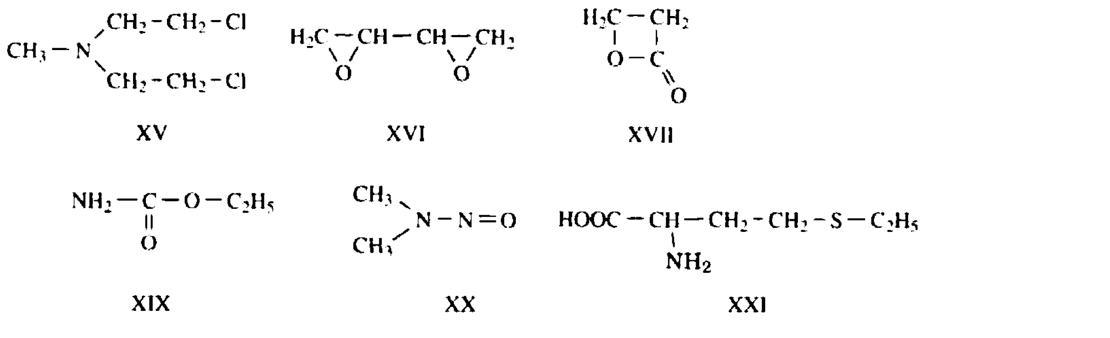

Fig. 3. Aliphatic carcinogens

Greater Knowledge of Carcinogenesis Anticipated

To comprehend the process of carcinogenesis is to understand, at the molecular level, the nature and workings of the cells that constitute life itself. Biochemists and geneticists are making excellent progress toward understanding life at the molecular level and out of this research, possibly by the early 2000s, the identification and role of carcinogens, as described here, will be subject to revision in the light of new knowledge.

CARNALLITE. This mineral is a product of evaporation of saline deposits rich in potash content, as a hydrated chloride of potassium and magnesium, $KMgCl_3 \cdot 6H_2O$. Hardness, 2.5; specific gravity, 1.602. It crystallizes in the orthorhombic system usually as massive, granular aggregates. Luster greasy, with indistinct cleavage and conchoidal fracture. Color grades from colorless to white, into reddish from included hematite scales. Transparent to translucent with bitter taste, deliquesces readily in moist environment.

Found associated with sylvite, halite and polyhalite at Stassfurt, Germany; Abyssinia; the former U.S.S.R.; and in southeastern New Mexico and adjacent areas in Texas. It is an important source of potash for use in fertilizers. See also **Potassium**.

CARNELIAN. The mineral carnelian is a red or reddish-brown chalcedony; the word is derived from the Latin word meaning flesh, in reference to the flesh color sometimes exhibited. See also **Chalcedony**.

CARNOT CYCLE. An ideal cycle of four reversible changes in the physical condition of a substance, useful in thermodynamic theory. Starting with specified values of the variable temperature, specific volume, and pressure, the substance undergoes, in succession, an isothermal (constant temperature) expansion, an adiabatic expansion (see also **Adiabatic Process**), and an isothermal compression to such a point that a further adiabatic compression will return the substance to its original condition. These changes are represented on the volume-pressure diagram respectively by *ab*, *bc*, *cd*, and *da* in Fig. 1. Or the cycle may be reversed: *a d c b a*.

In the forward (clockwise) case, heat is taken in from a hot source and work is done by the hot substance during the high-temperature expansion *ab*; also additional work is done at the expense of the thermal energy of

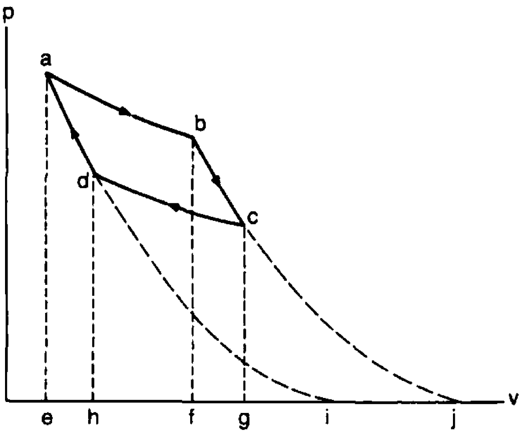

Fig. 1. Carnot cycle on *v p* diagram: *ab* and *cd*, isothermals: *bc* and *da*, adiabatics which, for some theoretical purposes, are produced to infinity

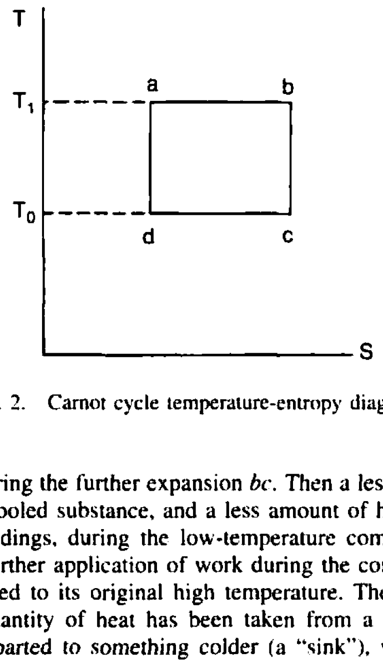

Fig. 2. Carnot cycle temperature-entropy diagram

the substance during the further expansion *bc*. Then a less amount of work is done on the cooled substance, and a less amount of heat discharged to the cool surroundings, during the low-temperature compression *cd*; and finally, by the further application of work during the compression *da*, the substance is raised to its original high temperature. The net result of all this is that a quantity of heat has been taken from a hot source and a portion of it imparted to something colder (a "sink"), while the balance is transformed into mechanical work represented by the area *abcd*. Thus, the forward Carnot cycle can be used for the production of power. If the cycle takes place in the counterclockwise direction, heat is transferred from the colder to the warmer surroundings at the expense of the net amount of energy which must be supplied during the process (also represented by area *abcd*). It can thus serve as a refrigerating cycle.

The temperature-entropy diagram for the Carnot cycle, corresponding to the pressure-volume diagram is shown in Fig. 2.

It should be noted that the efficiency of the forward cycle is highest when T_1 is as high as possible. Since, in practice, T_0 will always be fixed by the temperature of the surrounding atmosphere, a high efficiency corresponds to a large difference $T_1 - T_0$. In contrast, a high coefficient of performance, or a high effectiveness of a heat pump corresponds to a small difference $T_1 - T_0$.

It would appear that decreasing T_0 for a power cycle below that of the surrounding atmosphere is advantageous in that the efficiency η is increased. However, it must be realized that this can only be achieved at the expense of work in operating a refrigerator, and no advantage is gained. See also **Absolute Zero**; and **Solar Energy**.

CARNOTITE. This mineral is a vanadate of potassium and uranium with small amounts of radium. Its formula may be written $K_2(UO_2)_2(VO_4)_2 \cdot 3H_2O$. The amount of water, however, seems to be variable. It occurs as a lemon-yellow earthy powder disseminated through cross-bedded sandstones with rich concentrations around petrified and carbonized trees. Soft; sp gr 4.7. It was mined in Colorado and Utah as a source of radium. Other localities are in Arizona, Pennsylvania, and Zaire.

CARNOT THEOREMS. (1) No heat engine operating between two given temperatures can be more efficient than a perfectly reversible engine operating between the same temperatures. (2) The efficiency of any reversible heat engine working between two temperatures is independent of the nature of the engine and the working substances and depends only on the temperatures.

CAROTHERS, WALLACE H. (1896–1937). Born in Iowa, Carothers obtained his doctorate in chemistry at the University of Illinois. He joined the research staff of Du Pont in 1928, where he undertook the development of polychloroprene (later called neoprene) that had been initiated by Nieuland" research on acetylene polymers. Carother's crowning achievement was the synthesis of nylon, the reaction product of hexamethylenetetramine and adipic acid. Carother's work in the polymerization mechanisms of fiber like synthetics of cyclic organic structures was brilliant and productive, and he is regarded as one of the most original and creative American chemists of the early 20th century.

CARRIER. (1) A neutral material such as diatomaceous earth used to support a catalyst in a large-scale reaction system. (2) A gas used in chromatography to convey the volatilized mixture to be analyzed over the bed of packing that separates the components. (3) An atomic tracer carrier; a stable isotope or a natural element to which radioactive atoms of the same element has been added for purposes of chemical or biological research.

CARRIER (Food Additive). A substance well named because its primary function is that of conveying and distributing other substances throughout a food substance. The role parallels that of a carrier in paint, wherein vehicle (carrier) holds and distributes pigment throughout the entire paint product. Silica gel and magnesium carbonate serve as carriers in food substances. For example, the high porosity of silica gel enables it to adsorb internally up to three times its own weight of many liquids. This property is used to convert various liquid ingredients, such as flavors, vinegar, oils, vitamins, and other nutritional additives, into easy-to-handle powders. These powders, in turn, can be measured easily and blended effectively with other constituents to provide a uniform food substance. Advantage is taken of the properties of carriers in the convenience food field, where flavors remain entrapped inside silica particles until the food product is mixed with water, at which time the flavors are released just prior to consumption, giving the product an aura of richness and freshness.

CAS. Chemical Abstracts Registry or Chicago Academy of Science. See also Chemical Abstract Service Registry Number (CAS).

CASCADE. (1) Any connected arrangement of separative elements whose result is to multiply the effect, such as isotope separation, created by the individual elements. A bubble plate-tower is a cascade whose elements are the individual plates; a plant consisting of many towers in series and parallel is similarly a cascade whose elements may be considered to be either the towers or the individual plates. Similarly, an amplifier in which each stage except the first has as its input the output of the preceding stage is spoken of as a cascade amplifier. A stage of a grounded-cathode vacuum-tube amplifier is defined as the section from a point just before the grid of one tube to that just before the grid of the next. Similarly, for grounded-emitter transistor amplifiers, it is defined as the section from a point just before the base of one transistor to that just before the base of the next. (2) Coined term used to describe a large number of compounds derived from a common source, e.g., the arachidonic acid cascade.

CASCADE COOLING. See **Cryogenics; Natural Gas**.

CASE HARDENING. Hardening of the surface layer or case of a ferrous alloy while leaving the core or center in a softer, tougher condition. There are two basic methods of case hardening. In the first, gaseous elements such as carbon or nitrogen are introduced into the surface layer, thereby forming a hardening or hardenable alloy at the surface. Examples are carburizing, nitriding, and carbonitriding. Alternatively, the surface may be given a hardening heat treatment that does not affect the core. This may be accomplished by flame hardening or induction heating, whereby the surface is rapidly heated into the austenite range and the specimen quenched before the center has obtained a temperature high enough to allow it to be hardened.

CASEIN. [CAS: 9005-46-3]. Casein is the phosphoprotein of fresh milk; the rennin-coagulated product is sometimes called paracasein. British nomenclature terms the casein of fresh milk caseinogen and the coagulated product casein. As it exists in milk it is probably a salt of calcium.

Casein is not coagulated by heat. It is precipitated by acids and by rennin, a proteolytic enzyme obtained from the stomach of calves. Casein is a conjugated protein belonging to the group of phosphoproteins. The enzyme trypsin can hydrolyze off a phosphorus-containing peptone.

The commercial product also known as casein is used in adhesives, binders, protective coatings, and other products.

The purified material is a water-insoluble white powder. While it is also insoluble in neutral salt solutions, it is readily dispersible in dilute alkalis and in salt solutions such as those of sodium oxalate and sodium acetate.

CASSITERITE. The mineral cassiterite, chemically tin dioxide, SnO_2, is almost the sole ore of tin. It is a noticeably heavy mineral crystallizing in the tetragonal system, as low pyramids, prisms, often very slender, and as twinned forms. It is a brittle mineral, hardness, 6.0–7.0; specific gravity, 6.99; luster, adamantine; color; generally brown to black, but may be red, gray to white, or yellow; streak whitish, grayish, or brownish; may be almost transparent to opaque. A fibrous variety somewhat resembling wood is called wood tin. Cassiterite occurs in widely scattered areas, but deposits of a size to be commercially important are few. It is associated with granites and rhyolites.

Cassiterite is heavily concentrated in bands and layers of varying thickness, forming economically valuable deposits, such as those found in the Malay States of southeastern Asia; Bolivia, Nigeria, and the Congo are also major producers of tin ore. Cassiterite is also known as tin stone.

CASTING. A process for producing specific shapes of materials by pouring the material, while in fluid form, into a shaped cavity (mold) where the material solidifies in the desired shape. The resulting shape is also called a *casting*. In terms of metals, the art of casting is one of the oldest methods for making metal parts and is still used extensively even though numerous other methods for producing shaped metal products, such as forging, rolling, and extruding, have been developed. In terms of plastic materials, casting is also widely practiced.

Metal Casting

Production of a metal casting involves the use of a pattern, usually of wood or metal, which is similar in shape to the desired finished piece and slightly larger in all dimensions to allow for shrinkage of the metal upon solidification. The pattern is bedded down in a special damp sand by an operation called molding. When the pattern is removed it leaves an impression of the shape of the desired casting. This impression is completely surrounded by sand and provided with openings called gates through which the molten metal enters. After pouring and cooling the mold is broken open and the casting removed. All adhering sand particles together with any extraneous projections such as those left by the gate system are removed after which the casting is machined to the required finish.

The term is also applied to the casting of pig iron in blast furnace practice and the casting of ingots in steel-mill practice.

Centrifugal casting is applicable to the production of pipe and tubing, wheels, gear blanks, and other castings having rotational symmetry. While the mold is rotated on a horizontal axis for pipe and tubing, and on a vertical axis for wheels and gear blanks, a measured amount of molten metal is added. The mold may be sand or water-cooled metal for more rapid solidification. Centrifugal castings have good structure and density.

Metal molds are also used for making die castings and permanent mold castings. In the latter process a permanent metal mold is filled by gravity in the usual manner, while in die casting considerable pressure is exerted on the molten metal, insuring rapid and complete filling of the mold. Die-casting machines are highly mechanized for rapid and nearly automatic operation. The product is characterized by high dimensional accuracy and clear reproduction of mold details including screw threads, holes, and

intricate sections, all of which greatly reduces the machining required. The process is limited in its application by the high cost of making alloy steel dies or molds. The lower melting zinc alloys and aluminum alloys are most successfully die cast; however, certain brasses and bronzes can also be die cast. Tin- and lead-base alloys are easily die cast but have limited application.

The zinc-base die-casting alloys are the most widely used. A typical composition is 1.0% copper, 3.9% aluminum, 0.06% magnesium, balance zinc. This alloy has a strength of about 45,000 psi (3,061 atmospheres) with 3% elongation in 2 inches (5 centimeters). Typical applications are carburetors, fuel pumps, tools, typewriter frames, instrument cases, and hardware often finished by chromium plating.

The investment or "lost wax" process has lately been revived as a method of making precision castings of metals such as steel and zinc having too high a melting point for die casting. A wax pattern is made in a die-casting machine, sprayed with a highly refractory slurry, dried, and embedded in sand. The mold passes through a furnace where the wax is melted or burned out, and the mold baked. The casting is then poured into the cavity left by the melting out of the wax, resulting in castings that rival die castings for dimensional accuracy.

Vacuum Casting

Although considered theoretically possible for many years, the commercialization of vacuum casting of metals was not demonstrated until the late 1980s. Vacuum casting offers an alternative position between investment and conventional shell-mold or green sand casting. Advantages of vacuum casting include thin-wall, near-net shape; multiple-core, complex shapes; and metallurgical integrity. Costs for vacuum castings appear to be competitive with green sand casting methods.

In the well-established *gravity-pour* process, molten metal is poured into the mold at atmospheric pressure. In the vacuum process, the molten alloy is drawn into the mold through gates in the bottom by a pressure differential between the atmospheric pressure of the melting furnace and a partial vacuum produced in the mold. This increase in molding pressure makes it possible to produce components having wall sections as thin as 1.75 mm (0.07 in.) in near-net shapes with increased metallurgical integrity and consistency. To make the vacuum process cost effective, however, very careful control of all conditions must be maintained, as by controls that have become available through the use of computers and microprocessors.

Heat- and corrosion-resistance materials have not always been compatible when traditional casting methods are used. Vacuum casting, on the other hand, is readily adaptable to a wide range of materials, such as low-nickel heat- and corrosion-resistant alloys. It should be noted that these materials frequently rely on combinations of silicon, chromium, and manganese as alternatives to the higher-cost nickel. These different materials, in the past, have added to casting difficulties. The vacuum process has been well received for making automotive and machinery parts.

Solidification Processing

The microstructure (arrangements of electrons, ions, space lattices, defects, and phases and their morphology) affects an alloy's ultimate properties and performance. As pointed out by Ahmed (Youngstown State University) and a team of research metallurgists, "Phase morphology of a particular microstructure is established during solidification, which essentially is a thermally activated nucleation and growth process requiring simultaneous control of several dependent and independent parameters to achieve a specific end result."

The solidification process is comprised of two principal phases: (1) the *nucleation stage*, the most important parameters of which include: changes in chemical-free energy between the solid and liquid phases, the surface free energy of the solid/liquid interface, the elastic strain energy, the amount of superheating and undercooling, the latent heat of solidification, the thermal conductivities of the phases, and the interdependence among these parameters; and (2) the *growth stage*, which tends to be of even greater complexity. It is during the growth stage that physical defects, such as chemical nonhomogeneities, dislocations, voids, and unwanted phases appear. The aforementioned research team has developed (patent pending) for solidification processing in an applied electric field. It is claimed that this method produces homogeneous nucleation and eliminates porosity.

Improved Melting Practices

Many new alloys were developed to meet the requirements of aircraft-engine manufacture. The principal flurry of activities occurred in the 1940s through the 1970s. As engines' specifications grew tighter to cope with the need for greater performance, the needs for improving the quality of the earlier alloys became evident and, thus, during the 1980s and 1990s, was termed, "cleaner" alloys, was a major goal for metallurgists. Most of these improvements could be achieved during the melting process.

As observed by C.H. White and a team of metallurgists (Inco Alloys Ltd., Hereford, England), "It is well established that the presence of small-scale inclusions limits the maximum stresses at which the material can operate because these inclusions can cause premature failure." To meet these objectives, the principal objectives of melting have been formulated and include: (1) providing adequate deoxidation (via magnesium, calcium, cerium, or zirconium additions) to ensure alloy cleanness and good workability; (2) refining the metal to remove metalloid (sulfur, lead, and bismuth) and gaseous (oxygen, nitrogen, and hydrogen) impurities; (3) minimizing nonmetallic contamination; (4) obtaining a homogeneous mixing of the constituent-alloy ingredients (nickel, iron, cobalt, chromium, tungsten, molybdenum, titanium, aluminum, and niobium) within specified limits; and (5) casting into an ingot suitable for further processing.

A number of melting processes are in use or under consideration. Vacuum induction melting (VIM) substantially reduces gases present in the melt during the melt cycle. Methods under development to improve VIM include gas purging, melt filtering, continuous monitoring of temperatures and pressure, continuous monitoring of furnace atmospheres (residual-gas analysis) by mass spectrometry, and automatic operation and data storage using process-control computers. Remelting also is practiced. Two consumable electrode remelting processes in use are vacuum arc remelting (VAR) and electroslag remelting (ESR). These processes are detailed in the White reference.

Defects that must be appraised continuously include "white spot" and "freckle." White spot is an area of alloy depleted in the lower melting-point alloying additions. Freckle is a mid-radial channel segregation resulting from a deep melt pool and a steeply sloping liquidus profile. This segregation develops in the liquid before solidification.

The C.H. White research group has observed, "Melting without the use of refractories is the only way future cleanness-level requirements are likely to be achieved. Electron-beam cold-hearth refining (EBCHR) possibly is the best candidate for such a melting system. Plasma melting and refining also is being evaluated."

Plastic Casting

Several families of thermoplastic materials are capable of taking form by casting, although the process differs considerably from that used for metals just described. Some plastic casting processes depend upon melting and solidifying, as with metals; others depend upon solubility, as in the case of *solvent casting*.

Acrylic castings usually consist of poly(methyl methacrylate) or copolymers of this ester as the major components, with small amounts of other monomers to modify the material properties. Incorporating acrylates or higher methacrylates, for example, lowers the heat deflection temperature and hardness and improves thermoformability and solvent cementing capability, but with some loss to weathering resistance. Dimethacrylates or other crosslinking monomers increase the resistance to solvents and moisture. Castings are made by pouring the monomers or partially polymerized syrups into suitably designed molds and heating to complete the polymerization. A large reduction in volume, sometimes exceeding 20%, takes place during the cure. The reaction is also accompanied by liberation of substantial heat. At conversion, the polymerization may become auto-accelerated, and the rate of conversion may increase rapidly until about 85% conversion is achieved. Thereafter, the reaction slows down and post-curing may be required to complete the polymerization. On the other hand, with certain materials combinations, a violent runaway polymerization can occur.

The syrups made prior to casting (and final polymerization) can be stored safely at a controlled temperature until required. The preparation of syrups in advance shortens the time in the mold, decreases the tendency for leakage from the molds, and greatly minimizes the chance of dangerous runaways.

The majority of acrylic casting is in the manufacture of sheet. Cast sheet generally is made in a batch process within a mold or cell, but the process can be continuous through the use of stainless steel belts. Molds consist of two pieces of polished (or tempered) plate glass slightly larger in area than the desired finished sheet. The mold (or cell) is held together by spring clips that respond to the contraction of the acrylic material during the cure. The

plates are separated by a flexible gasket of plasticized polyvinyl chloride tubing that controls the thickness of the product. Once filled, the mold is moved to an oven for cure. Thin sheet is cured in a forced-draft oven using a programmed temperature cycle, starting at about 45°C and ending at 90°C. The curing cycle requires several hours, the period increasing with the size of the sheet.

In continuous casting, a viscous syrup is cured between two highly polished moving stainless steel belts. Distance between the belts determines the thickness of the sheets. Although less versatile, the continuous process eliminates a number of problems in handling and breakage of large sheets of plate glass used for the batch process. Continuous processing produces sheets of more uniform thickness and essentially eliminates warping.

Nylon casting is a four-step process: (1) melting the monomer, (2) adding catalyst and activator, (3) mixing the melts, and (4) casting. Molds must be capable of containing a low-viscosity liquid at temperatures of 200°C and must allow for normal shrinkage. Two-piece molds are commonly used for simple shapes. More complex shapes require molds that can be disassembled to remove the cast shape. Stresses that develop during the casting can be controlled by very slowly cooling the casting over a period of 24 hours or longer.

Solvent casting is sometimes used, as in the case of polyvinyl chloride (PVC) film. In this process, resins, plasticizers and other ingredients are added to a solvent (tetrahydrofuran) in an inert, gas-blanketed mixing tank. Thorough mixing and degassing are critical for producing high-quality film. The mixture, below the boiling point, is pumped to a casting tank. The solution is filtered to a particle size not exceeding 5 micrometers. The solution is cast onto a stainless steel belt, which then enters an oven where solvent is evaporated from the film. After cooling, the film is stripped from the belt and wound into rolls. The gage of the film is controlled by the die opening, the pumping pressure, and the speed of the belt, all variables that can be carefully monitored and controlled. Films made by this process have good clarity, low strains, and freedom from pinholes.

CAST IRON. Generic term for a group of metals that basically are alloys of carbon and silicon with iron. Relative to steel, cast irons are high in carbon and silicon, carbon ranging from 0.5 to 4.2% and silicon from 0.2 to 3.5%. All these metals may contain other alloys added to modify their properties.

See also **Iron Metals, Alloys, and Steels**.

CASTOR OIL *(Ricinus communis; Euphorbiaceae).* [CAS: 8001-79-4]. Castor oil is obtained from a short-lived perennial tree that occurs wild in tropical Africa and perhaps in India. Cultivation of the tree is widespread not only in the tropics but also in temperate regions, where it is often grown as an ornamental plant. In the tropics it becomes a tree 36 feet tall, with large coarse leaves often of reddish color, and green flowers. An annual herbaceous variety is grown widely and produces a superior oil. The seeds, borne three in each of the smooth or prickly capsules, have a hard mottled shell. These seeds are ejected violently from the mature fruit.

The principal use of the plant is for the oil contained in the seeds. This oil is pressed out without heating the seeds. The particular properties make this oil valuable for specialized uses, such as low temperature lubrication. It is an important constituent of hydraulic brake fluid and other fluids where the degree of compressibility is important. Castor oil also finds medical uses, as an ingredient of special soaps, and in the preparation of some textile dyes. Ricin, an alkaloid present in castor oil, also has been used in insecticides. Prior to the preparation of refined castor oil for medical purposes, ricin must be removed.

CATALYSIS. Catalysts have been employed since antiquity in such activities as wine, bread and cheese making. In many cases it was found that the addition of a small portion from a previous batch, a "starter," was necessary to begin the next production. In 1835, Berzelius published an account which tied together earlier observations by chemists, such as Thènard, Davy, and Döbereiner, by suggesting that minute amounts of a foreign substance were able to greatly affect the course of chemical reactions, both inorganic and biological. Berzelius attributed a mysterious force to the substance which he called *catalytic*. In 1894, Ostwald proposed that catalysts are substances that accelerate the rate of chemical reactions without themselves being consumed during the reactions. This definition is still applicable today.

The scope of catalysis is enormous. Catalysts are widely used in the commercial production of fuels, chemicals, foods and medicines. They also play an essential role in processes in nature, like nitrogen fixation, metabolism and photosynthesis.

Classification of Catalysts

Catalysts can be protons, ions, atoms, molecules, or larger assemblages. Traditionally, catalysts have been classified as homogeneous, heterogeneous, and enzymatic, reflecting an increasing hierarchy of complexity.

Homogeneous Catalysts: The first of the aforementioned species may be considered examples of *homogeneous* catalysts. In addition, metal complexes and organometallic compounds are important members of this class of catalysts. As the name implies, these catalysts are uniformly dispersed or dissolved in a gas or liquid phase together with the reactant of the reaction.

Heterogeneous Catalysts: In contrast to homogeneous catalysts, *heterogeneous* catalysts are usually solid surfaces, attached to solid surfaces, or part of insoluble matrices, such as polymers, and are thus phase-separated from the fluid medium surrounding them. Regardless of their form, the active catalytic component is located at the interface between the solid and the fluid and may consist of a wide diversity of species. Examples are: One or two atoms of the total surface; a larger ensemble of such surface atoms; an organometallic compound attached to the surface atoms; an organometallic compound attached to the surface by covalent bonds; or a molecular cluster lying on the surface.

Enzymatic Catalysts: These are like homogeneous catalysts in being dissolved in liquid media, but enzymatic catalysts are of biological origin and possess the highest level of complexity among the three types. Ironically, as mentioned in the opening sentence of this article, they were probably the first catalysts to be utilized commercially and industrially. Enzymatic catalysts are proteins composed of repeating units of amino acids, often twisted into helices, and in turn folded into 3-dimensional structures. The protein structures often surround a central organometallic structure. See also **Enzyme**.

Fundamentals of Catalysis

The action of catalysis can be illustrated by an example-the water gas shift reaction catalyzed by iron and chromium oxides.

$$H_2O + CO \longrightarrow H_2 + CO_2$$

This reaction is used in the production of hydrogen in several commercial processes. It is an example of a heterogeneous catalytic reaction, but the principles derived from it are also applicable to homogeneous and enzymatic catalytic reactions. A simplified scheme for the reaction is given as follows:

$$H_2O + {}^* \longrightarrow H_2 + O^*$$

$$CO + O^* \longrightarrow CO_2 + {}^*$$

In the first step, one of the reactants, H_2O, reacts with an empty catalytic site, denoted by * to produce a product, H_2, and a reactive intermediate consisting of an oxygen atom associated with the site, denoted by O^*. In the second step, the other reactant, CO, reacts with the intermediate to produce the product, CO_2, and regenerating the catalytic site, *. The energetics associated with this process are given in Fig. 1. A key aspect of this scheme is that it represents a cycle that occurs many times as the reaction proceeds. Each repetition of the cycle is called a turnover. A good catalyst will have millions of turnovers. In contrast, a stoichiometric reactant will have only one. Several important points are to be made concerning the energetics and scheme just presented.

1. The energy level diagram shows that the catalyzed reaction has a *lower activation barrier* than the uncatalyzed thermal reaction. This is the origin of the enhancement in the rate and it applies both in the forward and reverse directions of the reaction.
2. Regardless of the details of the mechanism and the energetics of the transformation of R into P, their relative energies, as shown by $\Delta H^\circ_{reaction}$, do not change. [*Strictly speaking, it is a free energy of reaction*, ΔG°. The equilibrium constant is given by $K = \exp(-\Delta G/RT)$.] This means that the thermodynamic equilibrium between them does not change. Catalysts increase the *rate of approach to equilibrium*, but do not alter the thermodynamic equilibrium.
3. As shown by the overall reaction stoichiometry, there is no net consumption or production of the catalytic site, *. The reaction proceeds by repetition of the catalytic cycle or chain, with the catalytic species remaining *unchanged* at the end. This explains the observation noted earlier that miniscule amounts of catalyst can give rise to very large amounts of product.
4. The intermediate, O^*, must be neither too stable nor too unstable. If it is too stable, it will not decompose to form the product; if it is too unstable, it will not form in the first place.

Nomenclature of Catalysis

The performance of catalysts is generally described by their activity, conversion, selectivity and yield. *Activity* is a measure of the rate at which the catalyst is able to transform reactants into products and is given in terms of an extensive property of the catalyst, such as mass, volume or number of moles. *Active sites* are the atomic or molecular species responsible for catalytic activity (represented by the symbol* as mentioned previously). Their identity and number are in general very difficult to measure. Various examples of the type of entities they might be are given in the definitions of the three kinds of catalysts. *Turnover frequency*, also known as turnover number or turnover rate, is the most fundamental measure of the activity, and represents the rate at which the catalytic cycle proceeds. It is equivalent to the number of molecules undergoing transformation per active site per unit time. The term *conversion* refers to the percentage of a reactant that is reacted to form all products. The term *selectivity* is applied to a specific product and refers to the percentage of that product among the total products formed. Equivalently, it is equal to the percentage of the product formed of the total reactant consumed. A high selectivity implies little waste of reactant. *Yield* is the product of conversion and selectivity, and is a measure of the efficiency of carrying out a particular transformation. *Specificity* is used mainly with enzymatic catalysts and describes their propensity to carry out only one type of reaction or to act upon only one isomer of a particular compound.

Other terms chiefly pertain to industrial applications of catalysts. *Stability* and *lifetime* refer to the ability and length of time that a catalyst is able to maintain the conversion and selectivity necessary to run a process. *Deactivation* refers to the loss of catalytic function by any of a number of causes, such as decline in surface area, decomposition of active species, or poisoning. *Denaturization* describes the deactivation of an enzyme by the loss of its 3-dimensional folded structure. This is generally caused by extremes in temperature or pH. *Poisoning* is a type of deactivation caused by the strong binding of a foreign substance to the active site of a catalyst in competition with the reactant. *Regenerability* refers to the ability to chemically or physically treat a catalyst that has lost its activity.

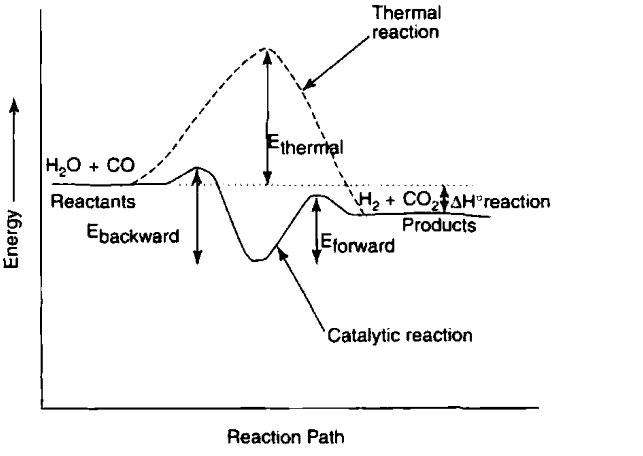

Fig. 1. Energy level diagram for the hypothetical catalytic and thermal water gas shift reaction. The overall heat of reaction is given by $\Delta H^\circ_{reaction}$, the activation barriers in the forward and backward direction by $E_{forward}$ and $E_{backward}$, respectively; and the activation energy for the thermal reaction by $E_{thermal}$

Industrial Usage of Catalysts

The most important catalysts employed commercially are listed in Tables 1 and 2. The remainder of this article is devoted to specific industrial uses of catalysts. The segment dealing with *fuels* covers the major operations used in the refining of petroleum. This is followed by descriptions of a few of the major processes used to produce *industrial* chemicals. The segment covering *foods and medicines* deals exclusively with enzymes.

Fuels. *Catalytic Cracking*: Catalysts are used to refined a moderately heavy crude oil fraction known as gas oil to gasoline. The net result of the process is a lighter product with a high content of branched-chain and aromatic hydrocarbons, the species responsible for raising gasoline octane levels. The transformations are complex, but can be considered to involve the following major acid-catalyzed reactions:

1. C–C *bond breaking*: $\underset{\text{paraffin}}{C_{18}H_{38}} \longrightarrow \underset{\text{paraffin}}{C_{10}H_{22}} + \underset{\text{olefin}}{C_8H_{16}}$

TABLE 1. PRINCIPAL USES FOR CATALYSTS

Petroleum refining	% of Total
Catalytic cracking	7.9
Reforming	≪1
Hydrocracking	≪1
Hydrotreating	≪1
Alkylation	91.2
Chemical production	
Polymerization	44.3
Alkylation	12.1
Hydrogenation	8.0
Dehydrogenation	2.4
Oxidation, ammoxidation, and oxychlorination	21.1
Ammonia, hydrogen, and methanol production	12.1

Note: It is estimated that in 1991, approximately 2400 million kilograms of catalysts were consumed by the petroleum industry; approximately 110 million kilograms were consumed for chemical production. Approximately 650 million kilograms were used strictly for emission and pollution control by various industries.

TABLE 2. PRINCIPAL USES FOR ENZYME (CATALYSTS)

	% of Total
Alkaline protease	53.6
Glucose isomerase	9.7
Rennets	18.3
Glucoamylase	12.2
Other amylases	6.2

Note: It is estimated that in 1991, approximately 2 million kilograms of enzymes were consumed by the chemical and food production industries. Note included in the foregoing figures are enzymes for leather-bating, papain, pectinase, bromelain, and several others.

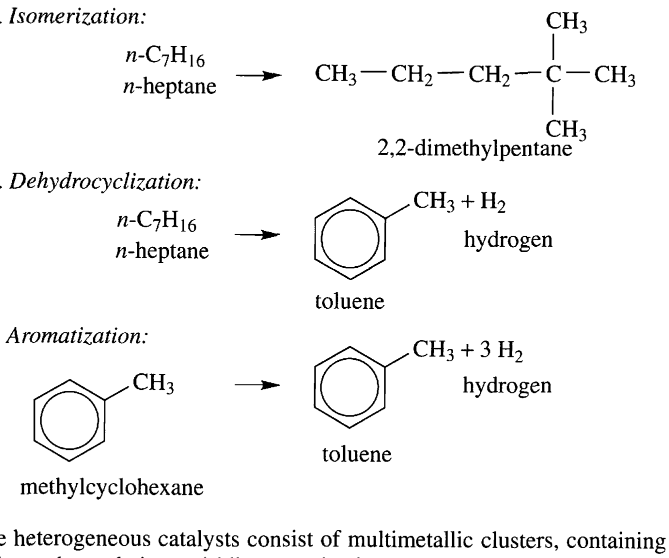
2. *Dealkylation*: $\underset{\text{alkylaromatic}}{ArC_4H_9} \longrightarrow \underset{\text{olefin}}{C_4H_8} + \underset{\text{aromatic}}{ArH}$

3. *Hydrogen transfer*: $\underset{\text{cycloparaffin}}{C_6H_{12}} + 3\underset{\text{olefin}}{C_8H_{16}} \longrightarrow \underset{\text{aromatic}}{C_6H_6} + 3\underset{\text{paraffin}}{C_8H_{18}}$

4. *Isomerization*: $\underset{\text{olefin}}{n\text{-}C_{10}H_{20}} \longrightarrow \underset{\text{isoolefin}}{i\text{-}C_{10}H_{20}}$

The heterogeneous catalysts employed in cracking are acidic materials composed of 3 to 25% (wt) of zeolites embedded in a silica-alumina matrix. Zeolites are crystalline aluminosilicates possessing a network of uniform pores whose walls hold the catalytically active acid sites. The reactant molecules pass through the pores and react within the zeolites.

Reforming: The catalysts are used to treat naphtha, a fraction of crude oil somewhat lighter than gas oil and containing large amounts of straight-chain paraffins. Several examples of typical reactions carried out by these catalysts are given below. The result of these reactions is to reconstruct or "reform" the hydrocarbons in the feed so as to increase the octane level. The catalysts used here differ from cracking catalysts because they tend not to alter the carbon number of the reactants and also because they produce a substantial amount of byproduct hydrogen gas.



These heterogeneous catalysts consist of multimetallic clusters, containing metals, such as platinum, iridium, or rhenium, supported on porous acidic oxide supports, such as alumina. The catalysts are said to be bifunctional because both the metal and the oxide play a part in the reactions. The metal is believed to carry out reversible dehydrogenation of paraffins to olefins, while the oxide is believed to carry out isomerization.

Hydrocracking. In hydrocracking, catalysts are used to reduce the molecular weight of a feedstock. A typical use is the conversion of light gas oil to naphtha for gasoline production through reforming. An example of a characteristic reaction is given as follows.

$$\underset{n\text{-hexadecane}}{n\text{-}C_{16}H_{34}} + H_2 \longrightarrow \underset{n\text{-heptane}}{n\text{-}C_7H_{16}} + \underset{iso\text{-nonane}}{i\text{-}C_9H_{20}}$$

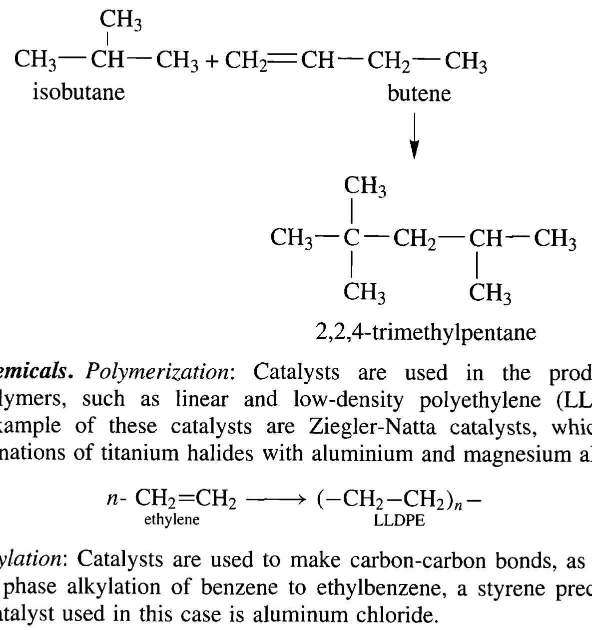
These heterogeneous catalysts contain nickel, cobalt, molybdenum, tungsten, platinum, or palladium on acidic aluminum silicate or zeolite supports. As with reforming catalysts, the catalysts here are also believed to be *bifunctional*—with the metal component carrying out the reversible dehydrogenation of paraffins to olefins. Hydrocracking is carried out in the presence of hydrogen and produces saturated products.

Hydrotreating. This process comprises a mild hydrogenolysis of nitrogen, oxygen and sulfur compounds prior to catalytic cracking. The reactions carried out in this step are as follows.

1. *Desulfurization*: $R{-}SH + H_2 \longrightarrow RH + H_2S$
2. *Denitrogenation*: $R{-}NH_2 + H_2 \longrightarrow RH + NH_3$

Hydrotreating catalysts are composed of cobalt or nickel molybdate or nickel tungstate on an alumina or zeolite support. The materials are sulfided with hydrogen sulfide (H_2S) before use, but the final catalysts may retain some oxide and be of complex composition.

Alkylation: This process converts isobutane and butylenes produced in the catalytic cracking step into a mixture of dimers known as alkylate. This product is a gasoline blending stock of high octane value. Alkylation catalysts are homogeneous liquid catalysts, either sulfuric or hydrofluoric acids.



Chemicals. *Polymerization*: Catalysts are used in the production of polymers, such as linear and low-density polyethylene (LLDPE). An example of these catalysts are Ziegler-Natta catalysts, which are combinations of titanium halides with aluminium and magnesium alkyls.

$$n\text{-}\ \underset{\text{ethylene}}{CH_2{=}CH_2} \longrightarrow \underset{\text{LLDPE}}{({-}CH_2{-}CH_2)_n{-}}$$

Alkylation: Catalysts are used to make carbon-carbon bonds, as in the liquid phase alkylation of benzene to ethylbenzene, a styrene precursor. The catalyst used in this case is aluminum chloride.

$$\underset{\text{benzene}}{C_6H_6} + \underset{\text{ethylene}}{CH_2{=}CH_2} \longrightarrow \underset{\text{ethylbenzene}}{C_6H_5{-}CH_2{-}CH_3}$$

Hydrogenation: These catalysts are used to add hydrogen to unsaturates, as in the hydrogenation of vegetable oils to form hardened oils. Most catalytic systems consist of nickel or a noble metal on a support.

$$\underset{\text{linoleic acid}}{CH_3(CH_2)_4CH{=}CH{-}CH_2{-}CH{=}CH(CH_2)_7COOH} \longrightarrow$$

$$\underset{\text{oleic acid}}{CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH}$$

Dehydrogenation: Catalysts are used to remove hydrogen from hydrocarbons. Many catalysts have been developed, including metals and oxides. An example of the latter is chromia-alumina used in the dehydrogenation of butane.

$$\underset{\text{butane}}{CH_3{-}CH_2{-}CH_2{-}CH_3} \longrightarrow \underset{\text{butadiene}}{CH_2{-}CH{-}CH{=}CH_2}$$

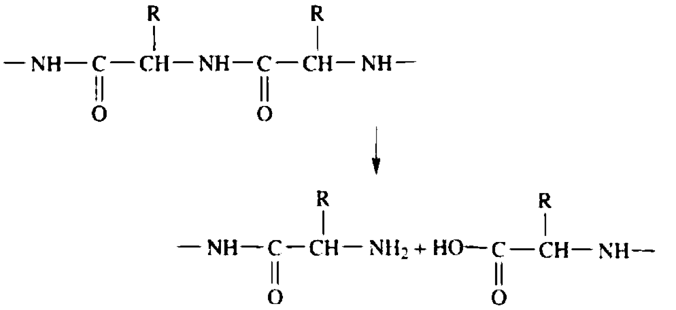
Oxidation, Ammoxidation, and Oxychlorination: Numerous catalysts have been developed for a number of processes in this category. Examples are supported vanadium oxide, complex multimetallic oxides, and supported cupric chloride, used respectively for the following reactions:

1. *Butane oxidation*: $\underset{\text{butane}}{C_4H_{10}} + O_2 \rightarrow \underset{\text{maleic anhydride}}{C_4H_2O_3}$
2. *Ammoxidation*: $\underset{\text{propylene}}{C_3H_6} + O_2 + NH_3 \rightarrow \underset{\text{acrylonitrile}}{CH_2{=}CH{-}CH}$
3. *Oxychlorination*: $\underset{\text{ethylene}}{C_2H_4} + Cl_2 + O_2 \rightarrow \underset{\text{1,2-dichloroethane}}{ClCH_2{-}CH_2Cl}$

Ammonia, Hydrogen, and Methanol Production: The ammonia synthesis catalyst is metallic iron promoted with Al_2O_3, K_2O, MgO, and CaO. The hydrogen-producing (methane reforming) catalyst is supported nickel. The methanol synthesis catalyst is ZnO promoted with Cr_2O_3 or Cu(I)–ZnO promoted with Cr_2O_3 or Al_2O_3. The respective reactions are cited as follows.

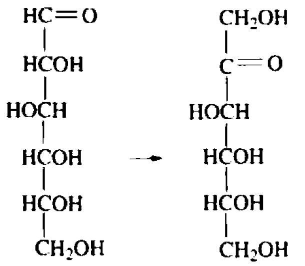
1. *Ammonia synthesis*: $N_2 + 3\ H_2 \longrightarrow 2\ NH_3$
2. *Methane reforming*: $CH_4 + H_2O \longrightarrow CO + 3\ H_2$
3. *Methanol synthesis*: $CO + 2\ H_2 \longrightarrow CH_3OH$

Foods, Medicines, and Other Products. *Proteases*: The function of these enzymes is to hydrolyze the peptide bond in proteins. Considerable variety exists in source, specificity, and reaction conditions for these enzymes. An example follows.



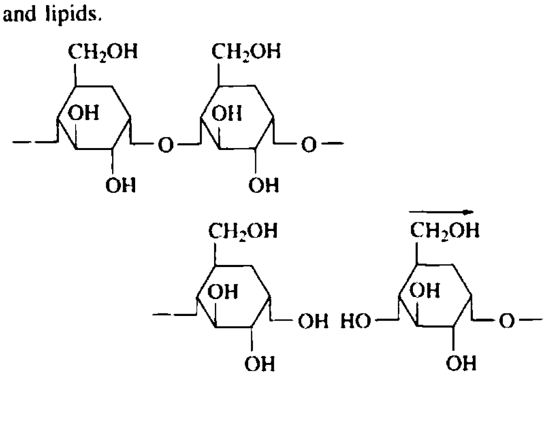
1. *Alkaline Proteases*—derived from bacteria. They find wide application in detergents, leather tanning, protein hydrolysis, brewing, and silver recovery from film.
2. *Papain*—a plant protease derived from the papaya fruit. The enzyme is used in digestive aids, wound debridement, tooth-cleaning and, most importantly, as a meat tenderizer.
3. *Bromelain*—a plant protease with uses similar to those of papain. Bromelain is obtained from stumps left over from pineapple harvest.
4. *Rennet or rennin*—an animal protease derived from the stomachs of calves as well as from microorganisms. Rennet is used in the manufacture of cheese to clot milk.

Glucose Isomerase: This enzyme is found in many organisms and, in practice, is used in the form of entrapped cells or bound to ion-exchange resins. Glucose isomerase converts glucose to fructose, one of the principal components of table sugar.



D-Glucose D-Fructose

Leather Bating Enzymes: Enzymes used in leather manufacture to remove flesh from hides. The enzymes generally are derived from hog and beef pancreas and consist of mixtures of enzymes that attack both proteins and lipids.



Amylases. These enzymes hydrolyze the D-glycosidic linkage in starch.

1. *Glucoamylase*—found in blood, molds, and bacteria. This enzyme produces glucose by removing the end glucose unit in long-chain carbohydrates, such as starch, glycogen, dextrins, and maltoses. The main commercial use of glucoamylase is in the production of glucose syrup, glucose paste, and crystalline glucose.
2. *Other amylases*, constituting a large family of enzymes that act on different substrates, are found in saliva, animal tissues, plants, yeast, and other microorganisms. They find wide use in the manufacture of glue, starchy syrups, and in various steps in the production of brewery and bakery products.

Pectinases: These enzymes carry out the hydrolytic degradation of the D-glycosidic linkage in pectins. The latter substances, also known as pectic substances, are polymeric components of plant cell walls and, like starch, are composed of sugar residues linked by glycosidic bonds. The chemistry is the same as that shown for the amylases previously described. The main application of pectinases is in the production of fruit juices, wines, and certain other food products.

Major portions of this article were prepared by S. Ted Oyama and Prof. Gabor A. Somorjai, Center for Advanced Materials, Lawrence Berkeley Laboratory, The University of California, Berkeley, California.

CATALYTIC CONVERTER (Internal Combustion Engine). A combination of the Clean Air Act Amendments of 1970 and the Energy Policy and Conservation Act of 1975 (United States Congress) has promoted the widespread use of catalytic aftertreatment to control automotive exhaust emissions with a concomitant increase in fuel economy. The catalytic converter, comprised of a ceramic catalyst and the necessary stainless steel hardware to ensure that the exhaust gases pass through the catalyst, permits the conventional spark-ignition automobile engine to run at near optimum efficiency to afford good fuel economy. The catalyst itself has the capability of promoting (or accelerating) the rate at which reactions occur. In the case of an oxidation catalyst, the function is to cause the carbon monoxide (CO) and hydrocarbons (HC) which result from incomplete combustion to be converted to CO_2 and water. In the case of a three-way catalyst, the oxidation reactions (HC and CO) are promoted as well as the reduction reaction of oxides of nitrogen (NO_x).

Converters now in use contain noble metals on a ceramic substrate (e.g., platinum dispersed on alumina). The converter is typically located in the exhaust system in one of two general locations: an underfloor location, or a close-coupled location near the manifold. The operating temperature range for noble metal catalyst is from 600 to 1200°F (316 to 649°C), which is similar to the exhaust pipe skin temperature range normally encountered on standard automobile engines.

Catalytic materials can be physically supported on either pelleted or monolithic substrates. In the case of the pelleted catalyst, the support is an activated alumina. A typical monolithic catalyst is composed of a channeled ceramic (cordierite) support having, for example, 300 to 400 square channels per square inch on which an activated alumina layer is applied. The active agents (platinum, palladium, rhodium, etc.) are then highly dispersed on the alumina.

In the case of pelleted catalyst, the pellets are confined by screens (Fig. 1); the monolithic-type catalyst (Fig. 2); being a single rigid material, needs no such confinement. The arrangement within the container, regardless of which type of catalyst is used, is intended to ensure that the exhaust gases pass through the catalyst bed without bypassing it or "channeling" along outside walls of the catalyst.

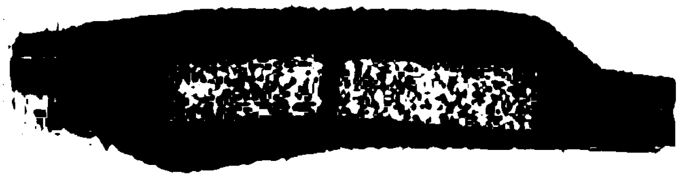

Fig. 1. Converter to use pelleted catalyst

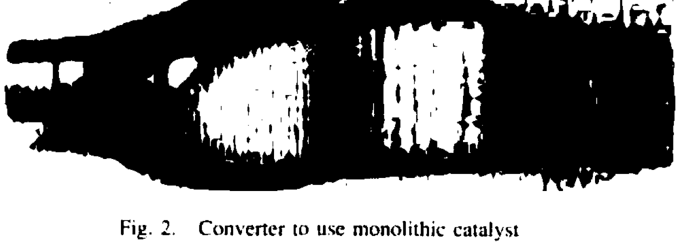

Fig. 2. Converter to use monolithic catalyst

Exhaust emission standards since the 1981 model year vehicles have required the use of three-way catalysts, either alone or in combination with an oxidation catalyst. Three-way catalysts are designed to operate in a very narrow range about the stoichiometric air/fuel ratio. In this range the HC and CO are subject to oxidation and the NO_x compounds undergo reduction. The downstream oxidation catalyst in a dual bed system is generally used as a "clean-up" catalyst to further control HC and CO emissions. The most common catalytic combination in three-way uses is platinum/rhodium. Current production applications use these elements in a relatively rich proportion of 5:1 to 10:1, whereas the respective mine ratio is about 19:1.

Since the introduction of catalytic converters on passenger cars in the 1973 model year in the United States and in the 1974 model year in Japan, the demand for improved air quality has grown worldwide. With that demand has grown converter usage to control mobile source emissions. Several European countries are in the process of drafting and enacting legislation that requires catalytic converters. Australia uses catalytic converters, Korea will soon require them, Brazil is also developing emission control strategies, and several other countries are studying the need for emission controls.

CATENATION COMPOUND. See **Compound (Chemical)**.

CATHODE. 1. In general, the electrode at which positive current leaves a device which employs electrical conduction other than that through solids. 2. In an electron tube, the electrode through which a primary stream of electrons enters the inter-electrode space. 3. The negative terminal of an electroplating cell (i.e., the electrode from which electrons enter the cell, and thus at which positively charged ions (cations) are discharged). 4. The positive terminal of a battery. See also **Batteries**.

CATHODIC PROTECTION. See **Corrosion**.

CATION. A positively charged ion. Cations are those ions that are deposited, or which tend to be deposited, on the cathode. They travel in the nominal direction of the current. In electrochemical reactions they are designated by a dot or a plus sign placed above and behind the atomic or radical symbol as H• or H^+, the number of dots or plus signs indicating the valence of the ion.

In electrolysis, the cathode is negative, and attracts cations. In a battery, the transfer of charges of cations to the cathode makes it the positive terminal.

CAT'S-EYE. This name is applied to varieties of several mineral and gemstone species that enclose fine fibers or cellular structures in parallel arrangement, causing, particularly when cut and polished *en cabochon*, a band of reflected light to play on the surface of it. Because of fancied resemblance to the eyes of cats, such stones are called cat's-eyes, and the effect is referred to as chatoyancy. The stone is said to be chatoyant. True cat's-eye is a variety of chrysoberyl, but tourmaline and quartz are also found which show this same effect. Ordinary quartz cat's-eyes are a pale yellowish or greenish, but a beautiful golden-yellow sort, known from South Africa and called tiger's-eye, probably represents a replacement of crocidolite by quartz.

When the term *tiger's eye* is used, this applies only to chrysoberyl. Other gemstones that exhibit this phenomenon include sillimanite, scapolite, cordierite, orthoclase, albite, and beryl. See also **Chrysoberyl**; and **Crocidolite (Blue Asbestos)**.

CAUSTIC (Chemical). A corrosive substance, almost always of an alkaline nature, such as sodium hydroxide, NaOH; potassium hydroxide, KOH; or calcium oxide, CaO. Such substances attack many metals, plastics, and other materials, including human tissue, and generally fall in the category of *corrosives*.

CAUSTIC POTASH. See **Potassium**.

CAUSTIC SODA. See **Sodium.**

CAVENDISH, HENRY (1731–1810). Cavendish was an English chemist and physicist who performed numerous scientific investigations with experiments on electricity. He measured the strength of a current by shocking himself and then estimating the amount of pain.

Cavendish investigated "fixed air" and isolated "inflammable air", in 1776 he discovered hydrogen. He produced dew (water) by exploding a mixture of hydrogen and air with an electric spark. He also found that a small volume of air did not combine with nitrogen while using electric sparks. Later, Ramsay repeated Cavendish's work and discovered argon.

Cavendish is also known for a sensitive torsion balance, known as the Cavendish balance, to measure the value of the gravitational constant, which defines the strength of the force of gravity.

J.M.I.

CAVITAND. As defined by Cram (1983), a cavitand is a synthetic organic compound that contains an enforced cavity of dimensions at least equal to those of the smaller ions, atoms, or molecules. As Cram points out, if organic compounds that contain such rigid cavities are to be designed and prepared, they must be composed of units that are concave on parts of their surfaces. Very few organic compounds have concave surfaces of any size. Among the most studied of the naturally occurring compounds that contain rigid cavities are the cyclodextrins. In these cyclic oligomers of the 1,4-glucopyranoside unit, from 6 to 8 monosaccharide units are contained in a torus-shaped cavity. Organic hosts are now being designed and synthesized which contain enforced cavities sufficiently large to complex and even surround simple inorganic or organic guest compounds. This new field of investigation is of interest in enzyme and catalytic systems.

CAVITATION. Cavities may form, grow, and collapse in a liquid when variational tensile stresses are superimposed on the prevailing ambient pressure. Pure liquids have theoretical tensile strengths, which are estimated on various grounds to be of the order of 300 to 1500 atmospheres (bars), but the observed tensile strengths of real liquids are much lower. It is presumed, therefore, that the observed tensile strength is a measure of the stress required to enlarge the minute cavities, or cavitation nuclei, which already exist in the liquid rather than the stress required to form new interior surfaces.

The transient cavities formed by tensile stress are unstable and would grow indefinitely if the stress were maintained. After the cavitation nuclei have been expanded to many times their original size, however, they may collapse violently if the stress is reduced or removed. The kinetic energy of the liquid that follows each inwardly collapsing interface becomes highly concentrated as the cavity collapses. If such transient cavities contain very little permanent gas, the peak pressures at collapse may reach thousands of bars, the temperature may reach thousands of degrees, and strong shock waves may be radiated to a distance of several cavity radii. Similar cavities formed in saturated liquids will usually contain more gas and their collapse will be less violent, but the peak pressures attained are sufficient to produce unique mechanical effects, such as the corrosion and pitting of metallic surfaces (as in marine propellers and sonar projectors) and the beneficial removal of embedded dirt (as in ultrasonic cleaners). In the latter case, the soil to be removed provides a prolific source of cavitation nuclei at exactly the sites where cavitation is desired.

In hydrodynamic cavitation, the tensile stress is of relatively long duration and plenty of cavitation nuclei are usually available. As a result, cavitation occurs when the total net pressure, or the stagnation pressure, becomes approximately equal to the vapor pressure of the liquid. In acoustic cavitation, the cyclic pressure required to produce cavitation is a function of the frequency, the partial pressure of any dissolved gas, and the population of cavitation nuclei. For frequencies above about 200,000 Hz, the threshold pressure for cavitation increases with the square of the frequency and is almost independent of the degree of gas saturation. For frequencies below 200,000 Hz, the threshold pressure is a function of the partial pressure of the dissolved gas. In saturated liquids at sound pressures less than a few bars, stable bubbles can grow from cavitation nuclei by the process of rectified diffusion. At higher levels of acoustic excitation, transient cavities can be formed. The threshold sound pressure at which they appear and the violence of their collapse increase as the partial pressure of the dissolved gas is lowered.

Cavitation in Process Control Valves

Serious cavitation problems are sometimes encountered in valves designed to automatically control the flow of fluids in chemical and other processing plants. See Fig. 1. Much research has been directed by valve manufacturers and users to the alleviation of these problems. While the damage rate and the total damage from cavitation in valves are not highly predictable, a number of strategies may be used to reduce hardware damage. These measures involve system design, material selection, and using anticavitation products.

Consideration of potentially damaging cavitation conditions at the time a system is designed is the primary and preferred strategy. For example, the placement of control valves in high back-pressure locations, when possible, reduces the tendency of a valve to cavitate. When placement is not flexible, downstream "breakdown" orifices may be inserted to "artificially" increase the back-pressure. This is not a preferred method because the effective flow velocities through the breakdown orifice may be so low as to eliminate its effectiveness and, at high flow rates, the orifice plate may become the primary restriction and, in turn, limit or completely choke off the flow. If properly sized to a particular valve, the downstream orifice may prevent the valve from cavitating, but the orifice itself may cavitate. In another strategy, the use of a sacrificial member may be considered. In some situations, economics may warrant the installation of a lower-cost valve which is allowed to cavitate. Immediately downstream of such a valve where cavitation damage is likely to occur, a comparatively inexpensive pipe or fitting may be installed and periodically replaced. This method does not afford relief from the other side effects of cavitation, such as noise,

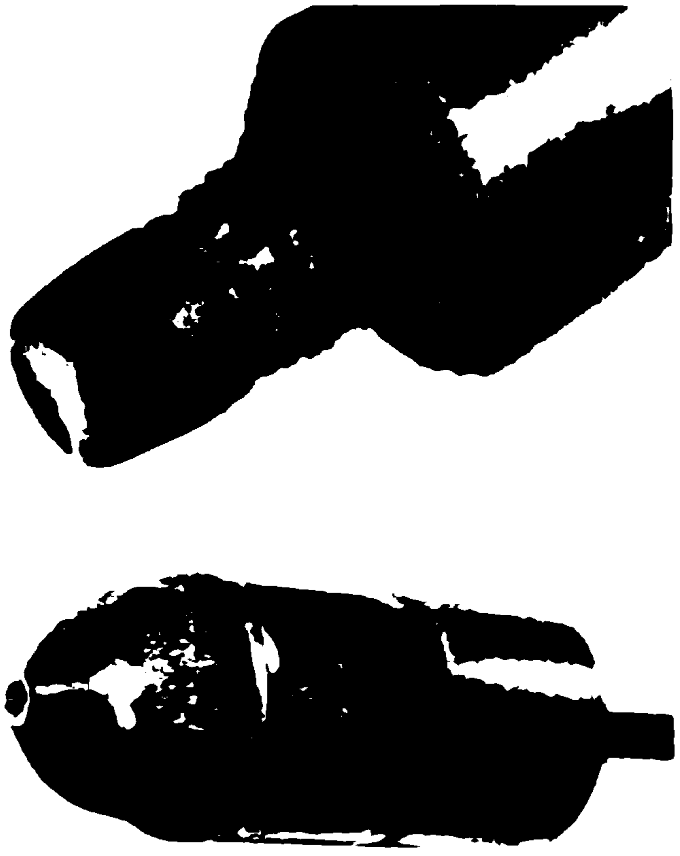

Fig. 1. (*Top*) Typical appearance of Cavitation damage caused by repeated attack by millions of micro-jets and shock waves. (*Bottom*) The term *cavitation* also is used to describe a variety of related phenomena that involve bubble or cavity formation. Examples include effervescence or outgassing, the boiling of a liquid, and flashing, the results of which are shown in bottom view. (*Fisher Controls*)

vibration, and choking, but in certain cases does permit more economical control of damage.

A second category is material selection. However, this does not offer a full solution because no material is completely immune to cavitation damage. Mechanical attack interacts synergistically with corrosion to create a different situation for nearly every application. In general, metals with greater hardness, ultimate resilience, or strain energy to failure offer better resistance to cavitation. Elastomers and compliant surfaces, in general, exhibit an ability to withstand levels of cavitation attack greater than their standard structural indicators may suggest. This apparently results from an interaction between the surface and the bubble, which orients the microjet away from the surface, thus reducing mechanical attack. The temperature and pressure limitations of these materials, however, place restrictions on their use.

The most effective means for controlling cavitation is the use of cavitation control equipment. Valve manufacturers in recent years have employed two basic strategies along these lines: (1) control energy transformations, and (2) isolate cavities. The former is usually attained by *staging*. This approach to damage control routes the flow through several restrictions in series, as opposed to a single restriction. Each restriction dissipates a certain amount of available energy and progressively lowers the inlet pressure to each succeeding stage. This enables the valve to take a large pressure differential, yet maintain the minimum fluid pressure above the vapor pressure of the liquid, and thus may eliminate cavitation. Traditional valve design, on the other hand, was targeted for maximum efficiency and not for cavitation prevention.

In other modern valve designs, the objective may not be that of preventing cavitation fully, but to control the cavitation that does occur. A mechanical component of attack is always present in cavitation damage, taking two forms—microjet impact and shock wave impact—both of which must occur in close proximity to the surface in order to be damaging. Thus, it follows that, if they occur far enough away from the surface, no mechanical attack will occur, thus controlling damage.

CELESTITE. The mineral celestite (also known as celestine) is composed of strontium sulfate, $SrSO_4$, occasionally with calcium and barium. It crystallizes in the orthorhombic system in tabular or prismatic crystals. More rarely it may be pyramidal or simply fibrous or granular. Two essentially perfect cleavages may be observed, one parallel to the base, the other parallel to the prism. Its fracture is uneven; hardness, 3–3.5; specific gravity, 3.97; luster, vitreous; color, white, but may be slightly reddish or bluish; transparent to translucent.

Celestite may occur with gypsum and salt associated with beds of limestone, or by itself in large, commercially important veins. It sometimes occurs with sulfur in volcanic localities and is often a gangue mineral in veins of galena, sphalerite and similar metallic minerals. In Europe there are many localities for fine crystals, especially in England. In the United States celestite is found in New York, Pennsylvania, West Virginia, Tennessee, Kansas, Colorado, and California. The first celestite described was the delicate blue material from Blair County, Pennsylvania. Its "celestial" tints suggested the name. Celestite resembles barite.

CELLULOSE. [CAS: 9004-34-6]. The formula for cellulose is sometimes given as $(C_6H_{10}O_5)_n$. This is an oversimplification inasmuch as the cellulose present in natural substances, such as wood and cotton fibers, usually is combined with other constituents, such as fats and gums. Cellulose is found almost exclusively in plants and accounts for about 30% of all vegetable matter. Cellulose is the principal substance of which the walls of vegetable cells are constructed. The term *cellulose* is derived from the Latin *cellula*, meaning little cell. Relatively pure cellulose can be obtained from cotton fibers (90% cellulose) and flax fibers. Very small amounts of cellulose are found in insects and not in other animal tissues. Digestive juices and enzymes present in animal systems do not appear to attack cellulose and thus ingestion by humans is relatively limited. By means of other biological processes, such as those involving amoeboid protozoa present in the digestive tract, herbivora and insects digest and absorb some cellulose.

Cellulose is a polysaccharide of glucose. See Fig. 1. Cellulose is a white solid, odorless and tasteless, insoluble in cold or hot water, and chemically nonreactive except when treated with strongly corrosive materials. If heated with water at 260°C and under rather high pressure, however, cellulose dissolves, but with decomposition. Concentrated sulfuric acid dissolves cellulose, the solution upon dilution and boiling yielding glucose. When treated with sodium hydroxide (15 to 25% NaOH) cellulose fibers swell up and upon washing and drying possess a lustrous appearance. This is the mechanism of *mercerization*. With iodine in potassium iodide solution plus zinc chloride (Schulze's solution), cellulose produces a dark blue color. When treated with an 80% sulfuric acid solution and rapidly washed and dried, cellulose yields a parchment-like surface.

In biochemical terms, cellulose is the name given both to a specific polysaccharide, consisting of βD-glucose residues joined end-to-end by linkage through –O–of C_1 of one residue to C_4 of the next (see Fig. 2); and to a resistant family of polysaccharides (containing cellulose in the strict sense) isolated from plants by specific chemical treatment. Cellulose appears to be always associated in plants with other polysaccharides and polysaccharide derivatives, such as mannan, xylan, araban, galactan, polygalacturonic acid, and, in woody plants, with lignin.

The mechanism of cellulose synthesis and microfibril orientation is not fully understood. Synthesis probably occurs from a glucose/phosphate precursor, which may be guanosine diphosphate glucose. The enzyme system involved can be extracted from the plant (e.g., from *Acetobacter xylinum*) and synthesis by cell-free extracts has been achieved. The synthetic mechanism in organisms higher than bacteria is thought to be located on the cell surface, and both granular aggregates and microtubules seen in the electron microscope are considered as possible sites.

The "brown rots" (e.g., *Coniphora casebella*, *Poria monticola*) and the "white rots" (e.g., *Polystictus versicolo*) are both basidiomycetes. Both attack cellulose, but only the latter takes lignin to any large extent. "Soft rot fungi," recognized relatively recently as important in this regard are members of the *Ascomycetes* and *Fungi imperfecti* (e.g., *Chaetomium globosum*). They all attack the cellulose of wood, producing characteristic angular cavities. The evidence is that all of these fungi attack the paracrystalline component of cellulose more rapidly than the crystalline component.

Compound celluloses are widely distributed in plants, the two principal types being:

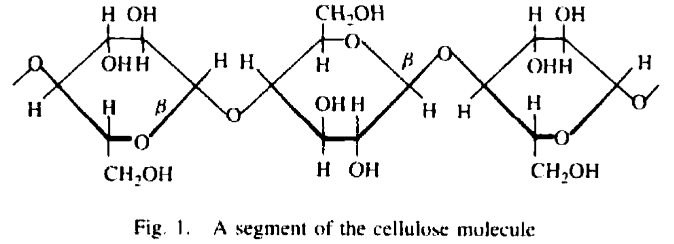

Fig. 1. A segment of the cellulose molecule

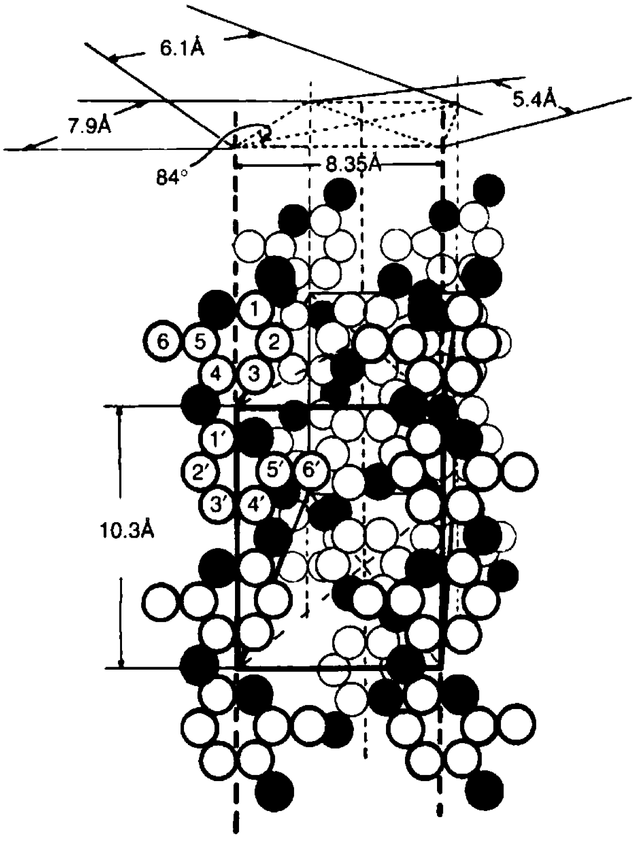

Fig. 2. Diagrammatic representation of the unit cell of cellulose. The monoclinic cell, dimensions 10.3 Å × 8.35 Å = 84°, is delineated by solid lines with one cellulose chain at each vertical edge and one (antiparallel) in the center. Open circles = carbon atoms; solid circles = oxygen atoms. For clearness of the diagram, the hydroxyl groups on carbons 2, 3, and 6 are omitted; and hydrogen atoms are omitted. Two spacing at 6.1 Å and 5.4 Å are included, inasmuch as these are strongly represented in the x-ray diffraction diagram

(a) Lignocelluloses, of woods, cereal straws, jute. These cellulose materials yield lignin by treatment (1) with 43% hydrochloric acid, cold, for 12 hours, (2) with 8 to 12% sodium hydroxide at 140 to 160°C for 6 to 10 hours, (3) with 72% sulfuric acid at ordinary temperature for 18 hours (the common method). Wood yields about 25% of lignin by the last treatment.

(b) Pectocelluloses, of flax, hemp, ramine. These cellulose materials yield pectic substances by treatment with oxalic acid or ammonium oxalate at 85°C for 24 hours, followed by carefully defined treatment with alcohol, acetic acid and calcium chloride. Pectic substances are most abundant in leaves, e.g., ivy, sycamore, and in apples or oranges, especially the white peel of the latter.

Cellulose dissolves in Schweitzer's reagent, an ammoniacal solution of cupric oxide. After treatment with an alkali, the addition of carbon disulfide causes formation of sodium xanthate, a process used in the production of rayon. See also **Fibers**. The action of acetic anhydride in the presence of sulfuric acid produces cellulose acetates, the basis for a line of synthetic materials. See also **Cellulose Ester Plastics (Organic)**. Nitrocelluloses are produced by the action of nitric acid and sulfuric acid on cellulose, yielding compounds that are highly flammable and explosive. See also **Explosives**.

On a heavy tonnage basis, cellulose is important as a raw material in the production of wood pulp and paper. See also **Papermaking and Finishing**.

CELLULOSE ACETATE. See **Acetic Acid; Fibers: Acetate.**

CELLULOSE ESTER PLASTICS (Organic). The cellulosics are unique among the plastics in that the basic materials used in their manufacture are not synthetic polymers. Rather, they are derivatives of a natural polymer, *cellulose*. See also **Cellulose**. The preparation of an organic cellulose ester plastic involves the formation of a suitable cellulose derivative, followed by processing steps that convert the cellulose derivative into a plastic.

Cellulose, with its many hydroxyl groups, can react with organic reagents such as acids, anhydrides, and acid chlorides to form organic esters. The first reported organic ester of cellulose was cellulose acetate, prepared by Schützenberger in 1865 by heating cotton and acetic anhydride to about 180°C in a sealed tube until the cotton dissolved. Franchimont, in 1879, accomplished this reaction at a lower temperature with the aid of sulfuric acid as a catalyst. The product in both cases was very nearly the triester. Miles, in 1903, first described partially hydrolyzed (generally called "secondary") cellulose acetate and distinguished it from the triacetate by its acetone solubility. The solubility of secondary cellulose acetate in such inexpensive and relatively nontoxic solvents as acetone contributed greatly to the development and commercialization of this material.

Cellulose esters of the 2-, 3-, and 4-carbon acids are readily prepared by the cellulose-anhydride reaction; the acetate ester and the mixed acetate butyrate and acetate propionate esters are manufactured and used in large amounts. Esters of higher acids require different synthesis techniques and tend to be prohibitively expensive except as specialty products. Some are in commercial production, however. Cellulose acetate phthalate, for example, is manufactured for use as an enteric coating on pills.

Most commercial preparations of cellulose esters still follow, basically, the methods described by Franchimont and Miles—esterification with sulfuric acid catalyst followed by hydrolysis. The principal steps in this process are shown in Fig. 1.

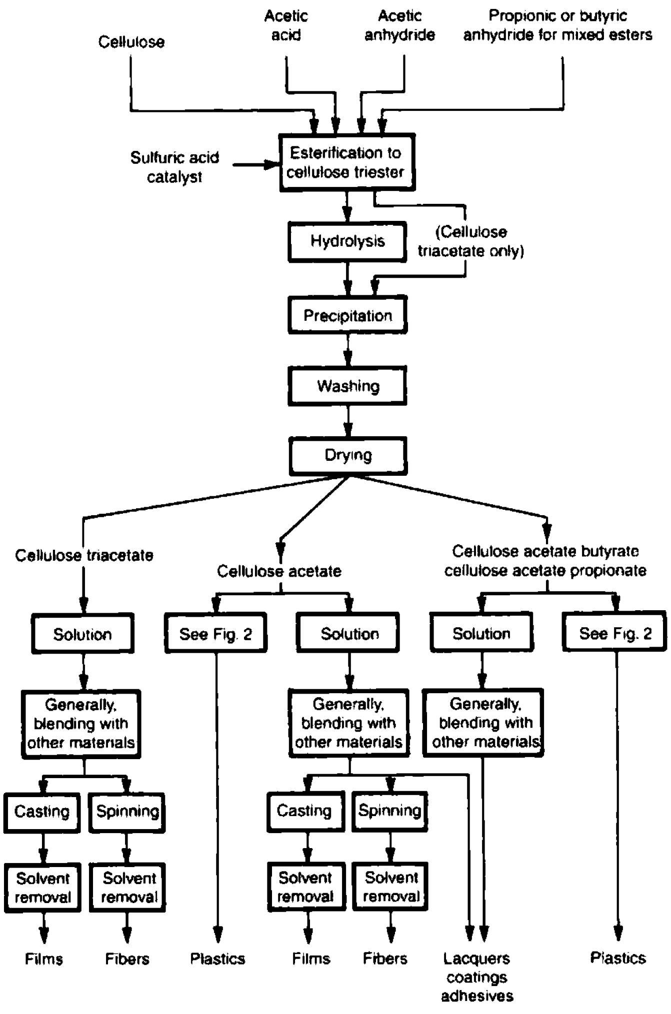

Fig. 1. Production and end-uses of organic cellulose ester

Esterification

The nature of cellulose is such that its esterification does not occur randomly. Even when the DS (degree of substitution—the average number of hydroxyl groups replaced per anhydroglucose unit in the cellulose chain) is approaching 3 (complete reaction), many anhydroglucose units have a DS of zero. If the ester is recovered before the reaction is complete, the product will not be homogeneous and it will be hazy. Regardless of the desired DS of the final product, therefore, the reaction must be allowed to proceed to virtual completion if a homogeneous material is to be produced. In most processes, the ester dissolves in the reaction mixture as the reaction approaches completion.

The cellulose used to manufacture cellulose esters is highly purified cotton linters or wood pulp. It is generally treated to reduce its crystallinity and make it more reactive, then agitated at somewhat elevated temperatures with the appropriate acids, anhydrides, and catalyst until it dissolves. Some of the polymeric chains of the cellulose are broken during the reaction, and consequently the molecular weight decreases; thus, the catalyst concentration, reaction temperature, and reaction time must be controlled very carefully to give a product of the desired molecular weight.

Some acetate ester is recovered at the completion of reaction and marketed as commercial cellulose triacetate; it has a DS very close to 3. Other triesters have found no commercial applications.

Hydrolysis

The compatibility of a cellulose ester with other materials is influenced by the acid or acids used in its preparation, but it is controlled primarily by the hydroxyl content of the ester, which varies reciprocally with the degree of substitution. Cellulose triacetate, for example, does not dissolve in acetone; its solution requires very strong solvents such as methylene chloride. Plasticizers can be added to the triacetate in solution and will remain in the ester if the solvent is removed. Plasticizer added in this manner will affect some of the properties of the triester, but they will not appreciably reduce its softening temperature, which is higher than its decomposition temperature. The hydroxyl groups in secondary cellulose acetate, however, have for other polar materials an affinity that is lacking in the triacetate. The ester will dissolve in acetone, and plasticizers will both affect its mechanical properties and reduce its softening temperature sufficiently for the mixture to be processed as a thermoplastic. It is necessary, then, that cellulose esters to be used for plastics contain a significant number of hydroxyl groups, and these are produced by partial hydrolysis of the triester formed in the reaction step. Since the triester is in solution, hydrolysis is random and produces a homogeneous product.

Hydrolysis is initiated by the addition of water and stopped at the desired point by neutralization of the catalyst.

Precipitation, Washing, and Drying

The cellulose ester in solution in the reaction mixture is precipitated by the addition of water. Some precipitation processes produce a flake precipitate; some produce a powder. The precipitate is removed from the slurry, washed with water until it is free of acids, and dried.

Cellulose Esters

The cellulose esters that result from the process described are chemical raw materials and are used by many branches of the chemical industry. They are generally characterized by acyl content in weight percent and viscosity in seconds, the viscosity being obtained by timing the fall of a steel ball through a solution of the cellulose ester in accordance with ASTM Method D 1343. Low-viscosity esters are generally used in solution processes; high-viscosity esters are used in the production of plastics.

Cellulose Triacetate

It has already been implied that cellulose triacetate will not produce a thermoplastic, as its softening point cannot be reduced appreciably by plasticizers. It is used in solution processes, however, to produce films and fibers. Triacetate films absorb less water than films of secondary cellulose acetate, and they are therefore more dimensionally stable in environments where the humidity is not controlled. Triacetate fibers, with a similar resistance to water, impart to fabrics wrinkle resistance, dimensional stability, and the ability to dry rapidly. Under United States federal regulations, a fiber must be made from a cellulose acetate having at least 92% of its hydroxyl groups acetylated if it is to be called "triacetate."

Cellulose Acetate

Like the triacetate, secondary cellulose acetate (CA) is used in solution processes to produce fibers and films. CA fibers were originally called "rayon," the name that was already in use for regenerated cellulose fibers. In 1951, however, the regulatory authorities formally acknowledged the chemical distinction between CA and cellulose, and the term "rayon" was reserved for fibers of regenerated cellulose. CA fibers are officially called "acetate," and they are used in a wide variety of fabrics. They also are used for cigarette filters. However, the majority of CA produced is used for manufacture of plastics.

Cellulose Acetate Butyrate and Cellulose Acetate Propionate

These two cellulose esters are somewhat similar in properties and applications. Cellulose acetate butyrate is commonly referred to in the chemical industry as CAB, while cellulose acetate propionate is simply termed "cellulose propionate" and referred to as CAP or as CP.

The major usage of CAB and CP is in plastics. Additionally, CAB and CP are mixed with a variety of synthetic polymers to produce lacquers for wood, metal, and plastics. CAB finds relatively small usage in hot-metal coatings and in optical-grade cast film used in the manufacture of sunglass lenses.

Organic Cellulose Ester Plastics

Although the first cellulose plastic (cellulose nitrate plastic-based on an *inorganic* ester of cellulose) was developed in 1865, the first *organic* cellulose ester plastic was not offered commercially until 1927. In that year, cellulose acetate plastic became available as sheets, rods, and tubes. Two years later, in 1929, it was offered in the form of granules for molding. It was the first thermoplastic sufficiently stable to be melted without excessive decomposition, and it was the first thermoplastic to be injection molded. Cellulose acetate butyrate plastic became a commercial product in 1938 and cellulose propionate plastic followed in 1945. The latter material was withdrawn after a short time because of manufacturing difficulties, but it reappeared and became firmly established in 1955.

Since the cellulose esters CA, CAB, and CP are chemical raw materials, the word "plastic" was used in the preceding paragraph to differentiate the product from the raw material. The cellulose ester plastics are commonly called simply "acetate," "butyrate," and "propionate," and these names will be used in the text that follows.

Commercial Production

In the manufacture of cellulose ester plastic, the appropriate ester is blended with plasticizer and other additives, such as stabilizers, ultraviolet inhibitors, dyes, and pigments, commonly in a large sigma-blade mixer. The mixture thus obtained is heated to its softening temperature and kneaded until it is homogeneous. This is done on hot milling rolls, in a compounding extruder, or in a Banbury mixer. The molten mass of plastic that results is formed into small rods or strips that are then cut into cylindrical or cubical pellets, which ordinarily have dimensions of about $\frac{1}{8}$ inch (3 millimeters). See Fig. 2.

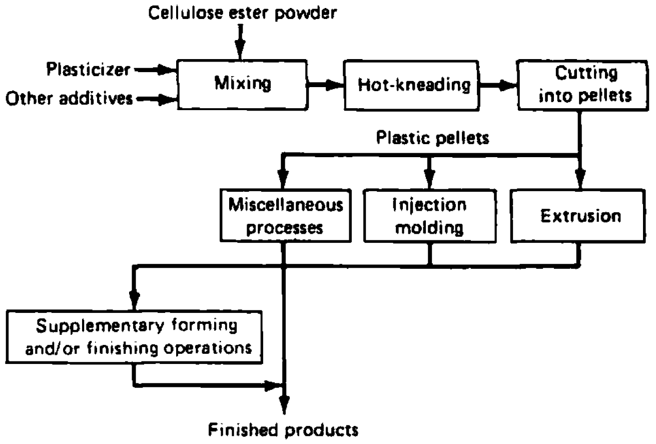

Fig. 2. Manufacture of cellulose ester plastics

Properties

The concentration of plasticizer in a cellulose ester plastic determines its "flow temperature," which in turn determines its "flow designation," as defined by ASTM Method D 569. Flow designations range from various degrees of hardness (H4, H3, H2, H) through medium-hard (MH), medium (M), and medium-soft (MS) to various degrees of softness (S, S2, S3, S4, etc.). At any given flow designation, the characteristics of the plastic will vary somewhat with the identity of the plasticizer used. Some plasticizers, for example, give very hard materials, some give very low water absorption, and some permit unusual ease of processing. The flow temperature is used for quality control and the corresponding flow designation is a part of the purchase specification when material is ordered.

Depending upon plasticizer content, cellulose ester plastics range from soft, extremely tough materials to hard, strong, stiff compositions that still retain a considerable degree of toughness over a wide range of temperatures. They are basically transparent and virtually colorless, which makes it possible for them to be manufactured in almost any desired transparent, translucent, or opaque color. They are resistant to water and aqueous salt solutions, but they are attacked by aqueous solutions that are strongly acidic or basic. They resist several types of organic solvents, such as ethers and aliphatic hydrocarbons, but they are dissolved or swollen by strongly polar liquid organic compounds such as aromatic hydrocarbons, chlorinated hydrocarbons, ketones, and esters. The susceptibility of the plastics to attack decreases as the molecular weight of the attacking compound increases.

All three cellulose ester plastics are available in formulations that meet the regulatory requirements for use in contact with food.

Butyrate and propionate are available in special formulations for continuous use outdoors, where they generally remain useful for several years. Formulations other than the special outdoor-type materials should not be used in this manner. Acetate formulations are not suggested for outdoor use, as CA does not respond well to the addition of protective compounds.

Although acetate, butyrate, and propionate resemble each other in many ways, there are a number of significant differences among them. Butyrate and propionate are generally easier to process than acetate, and this factor, also, subtracts from the price advantage of acetate. Acetate is available in very hard flows, so it can be obtained with higher stiffness, hardness, and tensile strength than can the other two cellulose ester plastics. Butyrate is available in the softest flows, so it can be obtained in the toughest and easiest-processing formulations. Butyrate and propionate are generally considered to be tougher than acetate, even though in some instances the measured impact strengths may be similar. Butyrate retains its toughness better than does propionate at low temperatures. Butyrate and propionate use higher-boiling, less-water-soluble plasticizers than does acetate, which leads to better retention of plasticizer by butyrate and propionate when exposed to elevated temperatures or to the leaching action of water. Better plasticizer retention, in turn, leads to better permanence characteristics in the plastic—i.e., smaller changes in dimensions and properties with time.

Processing

The organic cellulose ester plastics are versatile materials and can be processed by almost any hot-processing technique used for thermoplastics. The principal techniques for all three plastics are injection molding and extrusion. Blow molding is also possible. Butyrate and propionate powder are used in fluidized-bed and electrostatic coating processes, as well as in the rotational molding process.

The toughness of cellulosics nearly always enters into the selection of one of these plastics for a particular application, but if the potential toughness of cellulosics is to be realized, the materials must be processed correctly. Correct processing involves heating the plastic sufficiently for it to flow freely (*not* forcing half-melted plastic through a die or into a mold) and cooling it slowly. Fast cooling causes the outside of the finished product to harden while the inside is still molten. When the inside cools and contracts, powerful stresses form within the plastic, and these frozen-in stresses can detract very significantly from the toughness of the plastic. Sprues, runners, trim, and other scrap from molding and extrusion operations, if kept clean, can be reground, mixed with new feed stock, and reused. Butyrate and propionate are sometimes compatible with each other, but acetate is not compatible with either of the others and must not be allowed to contaminate them. Synthetic polymers must be rigorously excluded from all cellulosics.

CELLULOSICS (Applications). The cellulose ester plastics described in the prior article are suitable for a wide range of uses because of their exceptional balance of properties. Cellulose acetate and cellulose acetate butyrate are widely used for making tool handles because of their toughness, torque strength, and machinability for obtaining a good grip. Tool parts can be solvent vapor-polished to a smooth finish.

Acetate and propionate are widely used in eyeglass frames because their properties are well adapted to the post-finishing operations needed. Cellulosics are frequently used for a variety of home furnishing products, such as table edging and venetian blind wands, and fixtures. The clarity of the finished plastic is desirable for such applications.

Increasing numbers of retail goods, such as small hardware pieces, electronic parts, and some apparel, including T-shirts, underwear, and pantyhose, are packaged in cellulosic tubes. Because of their clarity and toughness, butyrate and propionate are commonly used. Tooth and hair brushes are commonly made of butyrate, again where clarity and toughness are required. Other major uses for cellulosics include extruded tape, audio tape, pressure-sensitive tape, gold-stamped foils, and face shields. Printed signs for interior use frequently are made from butyrate sheet. When coated with a weather-resistant formulation, butyrate is often used for heavy-gage outdoor signs.

In the automotive industry, propionate and butyrate find many over-foil uses, where the plastics are coated over foil strips for vehicle trim.

CELSIUS. Temperature scale proposed by Swedish astronomer Anders Celsius in 1742. A mixture of ice and water is zero on the scale; boiling water is designated as 100 degrees. A degree is defined as one hundredth of the difference between the two reference points, resulting in the original term, "centigrade" (100th part). To convert Celsius to Fahrenheit: multiply the Celsius temperature by 1.8 and add 32 degrees. $F = 9/5\ C + 32$. To convert Fahrenheit to Celsius: subtract 32 degrees from the Fahrenheit temperature and divide the quantity by 1.8. $C = (F-32)/1.8$. See also **Units and Standards**.

CELSIUS, ANDER (1701–1744). Celsius was a Swedish astronomer, mathematician, and physicist. He is best known for his development of a temperature scale based on the decimal system with fixed points separated by one hundred degrees. He proposed all scientific measurements of temperature should be based on the boiling point and the freezing point of water.

Celsius was a professor of astronomy at Uppsala University. He is noted for trying to determine the magnitude of the stars in the constellation Aries. He published 316 of his observations on the aurora borealis.

J.M.I.

CEMENT. Cement is a finely powdered substance that possesses strong adhesive powers when combined with water. Gypsum plaster (see also **Calcium**), common lime, hydraulic limes, Puzzolan, natural and Portland cements are a few of the materials which are used for cementing purposes.

Portland cement, [CAS: 68475-76-3], which is the most important of these materials since it is a basic ingredient of concrete, was first manufactured in England in the early part of the nineteenth century. It derived its name from the fact that this newly discovered cement resembled a building stone that was quarried near Portland, England.

There are three fundamental stages in the process of manufacture of Portland cement, namely, (1) preparation of the raw mixture, (2) production of the clinker, (3) preparation of the cement. Whether the process used is wet or dry, the raw materials are selected, analyzed, and mixed so that, after treatment, the product, or clinker, has a desired, narrowly specified composition. A factory analysis of slurry, where the wet process is in use, is as follows: calcium oxide 44%, aluminum oxide 3.5%, silicon oxide

14.5%, ferric oxide 3%, magnesium oxide 1.6%, loss on ignition about 33% (largely carbon dioxide), showing that the composition of the resulting burned clinker is essentially a calcium aluminosilicate. The system calcium oxide-aluminum oxide-silicon oxide has been determined by Rankin and co-workers. In some places the composition of the rock is practically of the desired composition, and in other places clay and limestone are mixed in the desired proportions.

The raw mixture is heated in a continuously operated, long, almost horizontal, slowly rotated furnace or kiln at a high temperature. The temperature is regulated so that the product consists of sintered but not fused lumps. This is clinker. Too low a temperature causes insufficient sintering, and too high a temperature results in a molten mass or glass, the product in either of these cases being valueless for cement purposes. Clinker is unaffected by water, and may be stored indefinitely without detriment. In 1824, Joseph Aspin, an English bricklayer, took out a patent for the manufacture of an improved cement, which he called Portland cement. The cement thus produced was not what is known now as Portland cement as the temperature of burning was not sufficiently high. The value of burning at a temperature sufficiently high to cause incipient fusion was soon afterwards discovered.

In order to obtain the desired setting qualities in the finished cement, there is added to the clinker about 2% of gypsum (calcium sulfate, $CaSO_4 \cdot 2H_2O$), and the mixture is pulverized very finely. For every ton of Portland cement shipped, over two and one-half tons of raw materials *and* cement clinker must be ground very finely. See Table 1.

The wet process for making cement is shown in the flowsheet in Fig. 1. Selective quarry of raw materials for specific cement requirements is based upon chemical data. A television receiver, mounted on the quarry control panel, oversees these operations. Rocks sent to the crushing plant are reduced to pieces smaller than 2 inches. These are dropped onto a reversible shuttle conveyor that stockpiles the materials according to chemical composition in the raw materials storage located above a reclaiming tunnel. From the stockpiles, vibrating feeders then withdraw specified amounts of raw materials and discharge them over a 1230-foot (375-meter) belt conveyor that passes through the reclaiming tunnel. A television camera at the tunnel entrance observes the materials on their way to the next crushing stage. A second television camera supervises the screening operation, and a third camera observes the unloading of crushed material into the storage silos.

Raw materials, withdrawn from the silos, are conveyed to the raw-grinding mill, and water is added. A sonic system which "listens" to the sound of steel balls impacting the inside of the mill indicates the amount and fineness of the material being ground. Feedback from this system controls the feed rate to the mill. Raw-mill discharge (a slurry of about two-thirds solids content) is screened over a 50-mesh screen cloth and pumped to two slurry basins where it is homogenized. Each basin (44 feet high × 85 feet diameter) (13.2 meters high × 25.5 meters diameter) holds about a 3-day supply for the kiln.

The rotary kiln is 510 feet (153 meters) long and is fired by oil. Maximum daily output of the kiln is 1,760 tons (1,584 metric tons) of clinker, equivalent to 9,700 barrels of cement. Operations are automatically controlled, and two television cameras, one at each end of the kiln, observe all material flow.

TABLE 1. ANALYSIS OF MATERIALS USED FOR MANUFACTURE OF LIME AND CEMENT

Material	SiO_2	Fe_2O_3 / Al_2O_3	CaO	MgO	CO_2	SO_3	Used for

zone is fitted with steel chains to improve fuel efficiency through better heat transfer. Feed rate of the oil is controlled by the gas temperature in the calcining zone. Thermocouples placed at intervals inside the kiln measure the temperature of solid particles and kiln gases. The critical parameters are relayed to the plant central control room.

The initial quarrying, primary, and secondary crushing and screening of raw materials are not shown in the flowsheet. See also **Gypsum**.

When Portland cement is mixed with water, the product sets in a few hours and hardens over a period of weeks. The initial setting is caused by the interaction of water and tricalcium aluminate $3CaO{\bullet}Al_2O_3$, present in the cement, accompanied by the separation of gelatinous hydrated product. The later hardening and the development of cohesive strength are due to the interaction of water and tricalcium silicate $3CaO{\bullet}SiO_2$, also present in the cement, accompanied by the separation of gelatinous hydrated product. In each case the gelatinous material surrounds and cements together the individual grains. The hydration of dicalcium silicate $2CaO{\bullet}SiO_2$, also present in the cement, proceeds still more slowly than that of the above compounds. The ultimate cement agent is probably gelatinous hydrated silica SiO_2. See also **Concrete**. The analyses of some typical Portland cements are given in Table 2.

Deductions regarding the mechanism of setting and hardening, and the identity of the substances concerned are the results of extensive studies, involving the use of the microscope in the examination of thin sections, on the individual compounds, the clinker, and the resulting concrete. Elaborate researches have also been conducted to determine the best way of incorporating the ingredients of concrete, the nature of the aggregate (sand, gravel, crushed rock) to be used, and the proportions of cement, water, and aggregate, in order that the resulting concrete, really an artificial rock, shall possess the greatest possible strength.

Special applications of cements and lutes are frequently demanded, as for example in floor covering, in tank lining, and in the closure of joints. The difference between a cement and a lute is that the former sets to a rigid solid mass whereas the latter retains some plasticity so that some movement of the lute is possible without cracking. A lute must have support in order that it be retained in position.

A somewhat crude though convenient classification can be made on the basis of the principal ingredients, thus, (1) Portland cement, (2) high alumina cement, (3) sodium silicate, (4) magnesium oxychloride plus copper powder, (5) litharge or red lead plus glycerol, (6) rubber latex, and (7) synthetic resins. Supplementary materials to be considered are asbestos, white lead, plaster of Paris, sulfur, graphite, sand, pitch, tar, rosin, and boiled linseed oil.

The choice to be made depends upon the kind of material to which the cement or lute must adhere; what it must withstand in the way of acid, base, sulfate, or organic liquid; also what temperature is involved; and finally the matter of resistance to vibration and shock.

Portland and high alumina cements do not withstand acids but are resistant to bases. High alumina cement attains its maximum strength more quickly than Portland, and has the extra advantage that it withstands solutions of sulfates.

Sodium silicate cement does not withstand bases, but is resistant to acids except hydrofluoric. This cement sets to a very rigid solid, so that when subjected to mechanical shock or to temperature change it is liable to crack.

A cement containing 90% magnesium oxychloride and 10% copper powder is strong, resistant to abrasion, and can be bonded to Portland cement.

Rubber latex cement withstands dilute acids and dilute bases, and adheres well to ceramic materials such as stoneware. This cement remains somewhat pliable, thus resisting mechanical shock and temperature change. Organic liquids in general attack this cement.

Synthetic resin cements withstand hydrochloric acid, dilute nitric acid, dilute sulfuric acid, and dilute bases, and are frequently more resistant to organic liquids than is rubber latex cement. The adherence to ceramic materials is good, and the liability to cracking less than for sodium silicate cement.

As for the miscellaneous ingredients mentioned, some are used as fillers or extenders as in the case of sand, and some are used in their own right as when pitch, tar, rosin, molten sulfur, or packed asbestos can be used. See also **Adhesives**.

CEMENTITE. Iron carbide, Fe_3C, is a compound present at room temperature in nearly all iron-carbon alloys such as steel and cast iron. It is very hard and brittle and weakly magnetic and has an orthorhombic *crystal* structure. In commercial steels, the chemical composition of cementite is usually changed by the presence of manganese and similar carbide forming elements in the steels, which replace iron atoms in the compound. Cementite is a metastable phase and, under the proper conditions, decomposes to form carbon (graphite) and iron. In ordinary steels, this decomposition rarely occurs. Most cast iron, however, contains graphite. This is because the higher silicon content of the cast iron makes cementite less stable. See also **Iron Metals, Alloys, and Steels**.

CENTER FOR THE HISTORY OF CHEMISTRY (CHOC). In 1982 the Center for the History of Chemistry (CHOC) was launched as a pilot project of the University of Pennsylvania and the American Chemical

Society (ACS). In 1984 the American Institute of Chemical Engineers (AIChE) became the third sponsor.

In 1987 the Center was incorporated as a not-for-profit organization, now named the National Foundation for the History of Chemistry, by joint action of the ACS and AIChE. The Foundation rented space in a new building at the University of Pennsylvania and restructured its activities into those of the Beckman Center for the History of Chemistry (established 1987) and the Othmer Library of Chemical History (established 1988).

In 1992 the Chemical Heritage Foundation (CHF) assumed its present name to better reflect the interdisciplinary nature of the sciences and industries it serves and the widening public scope of its activities. In 1995 CHF purchased its permanent home, the First National Bank building at the Independence National Historical Park in Philadelphia, and moved into its new location a year later. Today CHF enjoys the endorsement and support of 29 affiliated organizations.

It is located at 315 Chestnut Street, Philadelphia, PA 19106 www.chemheritage.org.

CENTRIFUGATION. A separation technique based upon the application of centrifugal force to a mixture or suspension of materials of closely similar densities. The smaller the difference in density, the greater is the force required. The equipment used (centrifuge) is a chamber revolving at high speed to impart a force up to 17,000 times that of gravity (much higher in the *ultracentrifuge*). The materials of higher density are thrown toward the outer portion of the chamber, while those of lower density are concentrated at or near the inner portion. A common cream separator is a type of centrifuge in which the flow is continuous. The centrifugal force throws the heavier milk into a different chamber from the lighter cream. Many hundreds of products, particularly in the chemical and food processing industries, require centrifugation at some stage in their manufacture. For example, important applications are found in the beet sugar and sugar cane industries, in the processing of corn (maize) products, in soybean processing, and in milk and dairy products manufacture.

Basic Principle of Centrifuging

The force acting on a particle within a centrifugal field is defined by Newton's fundamental force equation: $FM = ma$. Acceleration acting upon the particle, directed toward the center of rotation is $a = rw^2$. Therefore, the centrifugal force acting on the particle is $F = mrw^2$, or expressed as multiples of gravity,

$$F = 14.2 \times 10^{-6} DN^2 \ (D \text{ in inches})$$

$$= 5.59 \times 10^{-6} DN^2 \ (D \text{ in centimeters})$$

where m = mass of particle, g
a = acceleration, cm/s^2
r = radical distance of a particle in a centrifugal field from axis of rotation, cm
ω = angular velocity, rad/s
D = inner diameter of centrifugal bowl
N = bowl speed, rpm

A particle and a mixture introduced, confined, and rotated within a circular enclosure accelerates as it moves from a neutral center toward the maximum diameter (inner periphery) of the enclosure. Thus, if a mixture is introduced to the center of a 24-inch (61-centimeter) diameter solid-bowl centrifuge rotating at 1500 rpm, the particle will be caused to move at a speed of 32.2 feet (9.8 meters) per second at the center. At the maximum diameter, the particle will have a terminal velocity of 766.8 × 32.2 feet per second, or 24,690 feet (7525 meters) per second. Essentially, the separation occurs at 766.8 × *g*.

Industrial Designs

Industrial centrifuges are available in a variety of designs. Bowl sizes range from less than 0.5 to over 4 feet (15.2 to 122 centimeters) in diameter. Forces applied generally range from about 500 to 14,200 times the force of gravity. Operating temperatures range up to 260°C or higher; pressures up to about 8.5 atmospheres. Liquid flow rates range from 5 to 500 gallons (19 to 1893 liters) per minute; solid rates from 0.2 to 68 metric tons per hour. Depending upon design, the range of size of particles that can be handled is from 1 micrometer to as large as 0.6 centimeter. Centrifuges often are equipped with filters to provide a highly clarified effluent. The majority of industrial centrifuges are designed for continuous operation, although batch designs are obtainable.

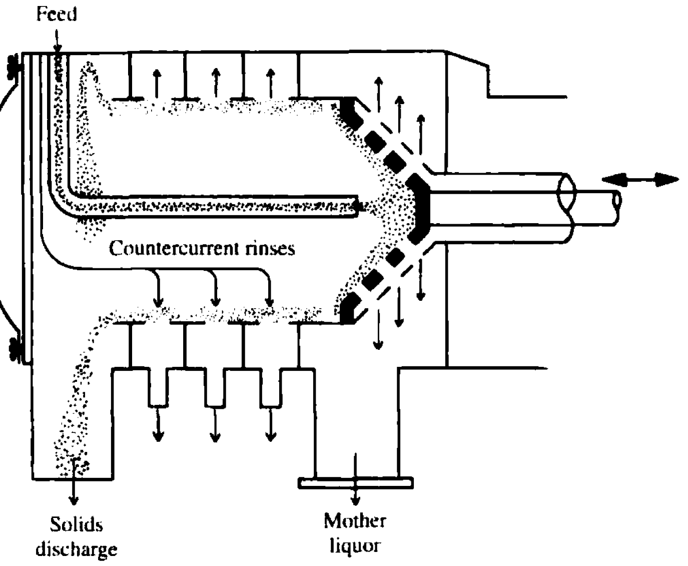

Fig. 1. Continuous horizontal, pusher (reciprocating) filter centrifuge. Double arrow at right indicates motion of ram

One of several types of industrial designs is shown in Fig. 1. This is a continuous horizontal, pusher (reciprocating) filter centrifuge. The feed is continuously introduced through a stationary pipe. The solids settle to the screen surface and form a filter bed through which the liquid passes. The liquid continues through the basket and is discharged from the machine, while the solids, having formed a uniform filter-bed thickness in the cylinder basket, are assisted to discharge by a pusher ram. Washing of cake solids, following the initial dewatering, is a feature of this design.

Among other types are the gas centrifuges, which have been used for the separation of isotopes. In the concurrent type, one or more streams of gas enters at one end of the centrifuge and the partially separated isotopes are removed in two or more streams at the other end. In the countercurrent type, countercurrent circulation is established in a centrifuge either thermally or mechanically. By the circulation of the gas the radial concentration gradient is converted into an axial gradient. The evaporation type operates on volatile liquids, which evaporate within the apparatus. Two streams of vapor are removed from a point near the axis of the centrifuge, having been separated by diffusion through the centrifugal field.

Large industrial centrifuges can cause serious vibration problems. Some centrifuges as found, for example, in separating water from caustic potash slurries may accommodate loads of up to 1 ton. To avoid unduly vibrating an entire building that may house up to twelve of the large centrifuges, some means for damping the vibrations is required. Heavy-duty isolators must be installed. One solution is the use of multistranded steel wire rope. The ropes are coiled into helical assemblies. Under load, the wire rope helices assume an oval shape and deflect in any direction, providing isolation in compression, tension, shear, or roll. In most cases the helices provide up to 90% isolation at high frequencies and amplitudes.

Ultracentrifuge

Centrifuges which operate at very high speeds and which find applications in colloid chemistry and biochemical research are sometimes called *ultracentrifuges*. In research laboratories where proteins, polymers, and other substances with high molecular weights are studied, the ultracentrifuge is effectively used. The sedimentation of large molecules in a strong centrifugal field enables the determination of both average molecular weights and the distribution of molecular weights in various systems. When a solution containing polymer or other large molecules is centrifuged at forces up to 250,000 times gravity, the molecules begin to settle, leaving pure solvent above a boundary, which progressively moves toward the bottom of the cell. This boundary is a rather sharp gradient of concentrations for molecules of uniform size, such as globular proteins. For polydisperse systems, the boundary is diffuse, the lowest molecular weights lagging behind the larger molecules. An optical system can be provided for viewing this boundary, and a study as a function of time of centrifuging yields the rate

of sedimentation for the single component, or for each of many components of a polydisperse system. These sedimentation rates may then be related to the corresponding molecular weights of the species present after the diffusion coefficients for each species are determined by independent experiments. Both the sedimentation and diffusion rates are affected by interactions between molecules, so that each must be studied as a function of concentration and extrapolated to infinite dilution, as is done for the colligative properties. The result of this detailed work is the distribution of molecular weights in the sample, which is available by few other methods. Extrapolation of diffusion coefficients to infinite dilution is difficult for high-molecular-weight linear polymers, and so alternate means are used to relate sedimentation constants to molecular weights in these important applications.

For research applications, ultracentrifuges may be equipped with microprocessors for programming, as well as automated handling of samples.

CERAMICS. Derived from the Greek word *keramos* ("burnt stuff"), ceramics comprise a wide variety of materials that constitute a major industry. The principal facets of the ceramic industry, in order of increasing value of annual production, are: (1) abrasives; (2) porcelain enamel coatings; (3) refractories; (4) whitewares; (5) structural clay products; (6) electronic and technical ceramic products; and (7) glass. Glass accounts for about 45% of all ceramics produced. See also **Glass**.

Porcelain enamels are used to protect and decorate steel and aluminum metals. Actually, they are glasses especially designed to have high thermal expansions to match the base metal and to mature (to become glassy) at temperatures low enough to prevent distortion of the underlying metal sheet. Glazes perform a similar function on ceramic substrates, again, as special glasses matching the thermal expansion of the base and maturing at the desired temperature. Although not relatively large in terms of production value, the preparation of ceramic composites is important and growing. This area covers a variety of combinations, such as sapphire, Al_2O_3, whiskers in metals, metal-bonded carbides used in the machine tool industry, and directionally solidified two-phase ceramic systems. In a system of this type, an oriented fibrous second phase is grown in a primary matrix phase to maximize in a selected direction various important characteristics, such as minimum long term, high-temperature creep. An example of use is in gas turbine rotor blades.

Conventional Ceramics (Structurals)

The essential raw material is clay. Clay is essentially a hydrated compound of aluminum and silicon $H_2Al_2Si_2O_9$, containing more or less foreign matter such as (1) ferric oxide Fe_2O_3, which contributes the reddish color frequently associated with clay, (2) silica SiO_2 as sand, (3) calcium carbonate $CaCO_3$ as limestone. Since clay is formed by the decomposition of igneous rocks, followed by transportation of the fine particles by running water and later deposition of these particles by sedimentation when the flow of water diminishes in speed, the quality of clays shows a wide range. When clay is wet it is plastic and can be shaped according to the desire and skill of the operator. The shape is retained on drying, and subsequent heating produces a coherent, hard mass, which suffers in the process more or less shrinkage and deformation depending upon the composition of the raw materials, and the method and temperature of treatment. Common bricks are made of crude materials without careful regulation of the conditions of treatment.

Bricks and plain clay products possess an earthy surface and fracture, are porous, and the strength depends upon the materials and treatment. Porcelain, on the other hand, possesses a glasslike or vitreous surface and fracture, and is not porous. Porcelain is made by mixing with the clay some powdered feldspar mineral, potassium aluminosilicate ($KAlSi_3O_8$ approximately). At the temperature of firing, feldspar undergoes a gradual change from the crystalline to the glassy state, the rate depending upon the time of heating and the temperature to which it is subjected. The fusion point of feldspar is of the order of 1300°C, whereas that of kaolin (pure clay) is of the order of 1700°C. Subjection of the porcelain raw material to the latter temperature would result in the formation of a glass. But when the temperature used is below the melting point of the clay portion and about the melting point of the feldspar, the latter produces a glass cement which binds together the particles of the former. When ground quartz SiO_2 is added to the original clay mixture the shrinkage of the material in the processes of drying and firing is reduced, the resistance to deformation during firing is increased, and the temperature coefficient of expansion of the product is affected.

The range of clay, feldspar, and quartz, as to the ratios in the mixture and as to individual composition of each (see Tables 1 and 2), as well as the available range of temperature of firing makes possible the production of products of a wide variety of physical structure. There has been proposed an arbitrary line of demarcation, namely that the unglazed product, such as has been described, which absorbs not more than 1% of its weight upon and after immersion in water, shall be termed porcelain, otherwise it shall be called earthenware. Such a nonporous material as porcelain, which includes chinaware, is also distinctly translucent in thicknesses of a few millimeters, whereas earthenware is nontranslucent and somewhat porous.

Materials that are to be glazed are dipped in a slip (the mixture of raw materials and water), dried, and refired. The glaze mixture is made up so that its fusion temperature is lower than that of the body of the ware, and the firing temperature is such that a surface of glass is formed over the body of the ware.

Designs and colors may be placed, as is commonly done, on the glaze and refired, or, as less commonly and more recently done with fine effect, placed directly on the body under the glaze, in which case the glaze when produced covers and protects both the body of the ware and the decoration.

The properties of ceramics depend mainly on how the atoms are arranged and the interatomic bonds they form. The most important bonding force in the crystalline phases in most ceramics is ionic bonding, the metallic atoms losing an outer electron to become positive ions; and the nonmetallic atoms gaining an outer electron to form a negative ion. Ionic crystals are brittle and hard, melt at high temperatures, and have low electrical conductivity at room temperature. Compounds of metals with oxygen ions that are largely ionic are MgO, Al_2O_3, and ZrO_2. Covalent bonding is also found in ceramic crystalline materials. In this case, a pair of electrons is shared by two atoms. Covalent crystals, such as diamond and silicon carbide, have high hardness, high melting points, and low electrical conductivities at low temperatures.

TABLE 1

Raw materials	Chinaware	Earthenware
Total clay, usually blended	46.5%	50.5%
Feldspar	15	13.5
Quartz	36	36
Dolomite	2.5	—
Porosity average	0.5	8

	Silica	Alumina	Lime	Magnesia	Iron oxides	Soda	Potash
	%	%	%	%	%	%	%
Kaolin	58	29	0.2	0.3	1	1	1
Fire clay	61	26	0.3	0.4	1	1	1
Common brick clay	58	14	7	1.5	4	3	3
Feldspar	71	16	0.3	0.0	0.5	4	7
Quartz	100	—	—	—	—	—	—

The basic building block for the silicate crystal structures is the silicon-oxygen tetrahedron with a silicon atom at the center and four oxygen atoms at the corners. The silicates are classed by the types of bonding existing between the tetrahedra in their crystal structures. In orthosilicates, the tetrahedra are independent of each other. These structures make good refractories because of their high melting points. This group includes the olivine minerals, garnets, zircon, kyanite, and mullite. When the tetrahedra are joined at only one corner (oxygen atom), they form pyrosilicates, which are rare. In metasilicates, the tetrahedra share two corners to form a variety of ring or chain structures. Minerals of this type include the pyroxines, such as spodumene, and the amphiboles, such as asbestos. Sharing three corners, the tetrahedra form disilicates, which exist as sheets or planes, forming such minerals as mica. In the various forms of silica, such as quartz and crystobalite, all four tetrahedron corners are shared.

Most ceramic shapes do not consist of one single crystal, but are composed of numerous crystals joined together to form polycrystalline structures. The characteristics of the grain boundaries between crystals can influence the strength, chemical stability, and electrical properties as much as do the crystalline structures within the individual grains.

Glass is a very important part of ceramics. The glass industry is the largest single element of the entire ceramic industry, and the glassy portions of many ceramic bodies are the bonds that hold many ceramics together. Probably the majority of the ceramics produced are a mixture of crystalline grains and a glassy phase. The glass frequently acts as the bond. This is the basis of the vitrified-grinding wheel industry and much of the structural and whiteware branches of the ceramics industry.

The rare-earth elements have found application in the ceramics field. In one example, a mixture of about 90% yttrium oxide powder and 10% thorium oxide powder is pressed into the desired shape and then sintered at about 2200°C. This heat treatment removes the microscopically small pores from between the powder particles. The result is a single-phase, polycrystalline material with a grain size normally between 10 and 50 micrometers in diameter. Yttrium oxide has a cubic crystal structure, thus light is not scattered at grain boundaries. This property, combined with the absence of a second phase and pores, imparts exceptional transparency (with polishing) to visible and infrared light. The transmission cutoff in the ultraviolet range occurs at 0.24 micrometers and in the infrared range at about 9 micrometers. Although the index of refraction of the ceramic is high, about 1.91 at the sodium D line wavelength, the optical dispersion of the material is very low. See also **Rare-Earth Elements and Metals**.

High-Technology Ceramics

Development of these materials stems from the need for improved performance in terms of thermal, wear, and corrosion resistance, superior electrical insulation properties, high magnetic permeability, and, sometimes, unusual optical properties. Through precise control of composition, particle shape, and particle size distribution, some materials can be engineered and processed to provide specific properties that may be required of a an application for which readily available standard materials are inadequate. The demanding conditions of engines and turbines are frequently mentioned to illustrate applications where complete satisfaction with alloyed metals has not been achieved. In some instances, engineered ceramics can replace higher-cost materials, such as the use of cobalt, in jet aircraft engine applications. In addition to high-performance engines and machines, advanced ceramics are finding uses in the electronics industry for their electrical and optical behavior.

The ceramic materials most successfully applied to date are high-researching monoli purity oxides, nitrides, carbides, and borides in combination with silicon, tungsten, titanium, tantalum, zirconium, zinc, aluminum, and magnesium. Currently, the oxides dominate the market, commanding about 85% of the critical uses. The application of high-technology ceramics in aircraft and some automotive engines includes turbocharger rotors, rocker arms and cam followers, valves, valve guides, and valve seats, pistons, piston pins, piston rings, cylinder liners, and exhaust port liners.

In the United States, as early as 1987, a program known as "Ceramic Technology for Advanced Heat Engines" was established at Oak Ridge National Laboratory. Some of the research targets of this program included: (1) to develop more reliable monolithic ceramics, toughened ceramic composites, and ceramic coatings via improved and unique synthesis and fabrication technology; (2) to achieve reliable ceramic attachments by new and improved joining technology; (3) to understand better the physical and chemical mechanisms that control the friction and wear of ceramic materials and coatings under heat-engine operating conditions; and (4) to identify and explain the mechanisms that control the long-term mechanical reliability of structural ceramics in advanced-engine environments.

The program also addressed the need to develop tough ceramic-matrix composites (CMCs) with much greater resistance to brittle fracture. Early in the program, researchers found that the chemical structure that imparts superior thermal and mechanical properties to ceramics also results in negative attributes, particularly of brittleness, which easily can lead to catastrophic failure.

In addition to research monolithic parts, ceramic coatings also are being investigated. Although there are numerous problems to be solved, including very extensive testing of materials under standard operating conditions, most professionals in the field forecast that monolithic ceramics and ceramic coatings will be found in conventional automotive engines by the early 2000s. The full acceptance of ceramic parts in jet aircraft engines may not occur until well into the 2000s. For example, C.T. Sims (Rensselaer Polytechnic Institute) observed in mid-1991, "The chronicling of the imminent demise of superalloys in gas-turbine engines appears to have been premature. The lack of toughness in monolithic ceramics and CMCs remains a serious obstacle to their use in gas-turbine engines."

Manufacturers of ceramic components, often composites, must commence fabrication with exquisitely pure raw materials, most frequently in the form of powders. Some of the new ceramic powders include the lesser-known elements, such as niobium and hafnium. Ceramic powders fall into three fundamental classes—the carbides, the nitrides, and the oxides. The powders are synthesized by a number of means, including (1) carbothermal reduction; (2) solid-solid, solid-gas combustion; (3) vapor-phase synthesis; (4) laser synthesis; and (5) plasma synthesis. At the late-1980s state of the art, plasma synthesis, an efficient simple and continuous process, appears in the lead. However, because of some of its disadvantages, including high power demand, large capital and operating costs, health hazards, and sometimes low powder yields, among other negative factors, all of the other methods are also being intensively researched. As pointed out by Sheppard (April 1987), in plasma synthesis, the powders are formed in a vapor-phase reaction under a high-temperature gas (~10,000 K) generated by the plasma. Ultrafine (< 100 micrometers), ultrapure powders, often in a metastable high-temperature phase, are produced by rapid quenching of the hot gases. No milling or grinding is usually required. By comparison, the RF-inductively-coupled plasma requires no electrodes and has the ability to inject the reactants axially. The dc plasma, formed by a high current flow between two electrodes, has high thermal efficiency, and higher plasma temperatures, among other factors.

Some of the ceramic powders now being researched or made in quantity by plasma synthesis are indicated in Table 3.

Ceramic materials also are being used in a limited fashion by the chemical process industries for such applications as high-temperature (1,100°C) heat exchangers, as absorption and distillation column packing, catalyst supports, and high-temperature refractory linings.

Ceramic-Fiber Reinforced Metal-Matrix Composites (MMCs)

These engineered materials provide good strength at high temperatures, good structural rigidity and dimensional stability, light weight, and good fabricability. The incorporation of ceramic fibers in these materials greatly increases their endurance at high temperatures.

- Graphite fibers have been incorporated with aluminum, magnesium, lead, and copper for use in satellite, missile, and helicopter structures; storage battery plates, and electrical contacts and bearings.
- Boron fibers have been used in connection with aluminum, magnesium, and titanium for such applications as compressor blades and structural supports, antenna structures, and jet-engine fan blades.
- Borsic fibers have been used with aluminum and titanium for jet-engine fan blades and high-temperature structures.
- Alumina fibers have been incorporated with aluminum, lead, and magnesium for superconductor restraints in fusion power reactors, storage battery plates, and helicopter transmission structures.
- Silicon carbide fibers have been used with aluminum, titanium, and cobalt-based superalloys for high-temperature structures and engine components.

TABLE 3. SOME CERAMIC POWDERS PREPARED BY PLASMA SYNTHESIS

Ceramic compound	Starting materials	Type of plasma used
CARBIDES		
SiC	CH_3SiCl_3	RF/Arc
SiC	$SiO_2 + CH_4$	Arc
SiC	$SiH_4 + CH_4$	RF
WC	$W + C/W + CH_4$	Arc

ZrO_2/SiO_2	$Zr(NO_3)_2(aq)$ + Silicone Oil	RF

Information Source: Los Alamos National Laboratory, New Mexico.

Molybdenum and tungsten fibers also have been used with superalloys for a variety of applications.

A process known as *squeeze casting* (solidification of liquid metal under pressure) contributes to producing defect-free castings with improved metallurgical properties. See also **Casting**.

Preforms for squeeze-cast composites are comprised of ceramic fibers, such as Al_2O_3 and SiO_2, which are bound into near-net (finally desired dimensions) shapes.

Some researchers have found that the reinforcement of ceramics with microscopic "whiskers" as opposed to continuous fibers, increases fracture toughness, even though the basic material nominally remains brittle. It has been reported that the mechanisms by which whiskers toughen the composite include both whisker bridging and whisker pullout within the region immediately beyond the tip of a crack (fracture). Toughness appears to be affected by the volume fraction of whiskers, elastic properties of the matrix, relative fraction energy of the fiber/matrix interface, and whisker diameter and strength.

As observed by D. Johnson and J. Stiegler, "Polymer-precursor routes for fabricating ceramics offer one potential means of producing reliable, cost-effective ceramics. Pyrolysis of polymeric metalloorganic compounds can be used to produce a wide variety of ceramic materials." Silicon carbide and silicon oxycarbide fibers have been produced and sol gel methods have been used to prepare fine oxide ceramic powders, such as spherical alumina, as well as porous and fully dense monolithic forms.

D. Johnson and J. Stiegler also observe, "Polysilazines, which contain the (−Si−N) unit, typify the type of product that can be expected to result from this merging of ceramic science with organic- and inorganic-preparation chemistry."

Liquid-Ceramic Process

A process for producing ceramic or ceramic-matrix-composite (CMC) parts via a liquid route, instead of the conventional power method, was announced in mid-1992. Silicon nitride, for example, is produced by reacting a silicon-based liquid with ammonia, removing byproducts through supercritical fluid extraction, and then heat-treating. Carbide ceramics, such as silicon carbide, also can be made by using a hydrocarbon as one of the reactants. Developers of the process claim that the procedure is less damaging to reinforcing fibers for CMC applications. Other advantages include better adaptability of the process to mass production, considerably lower costs than traditional powder processing, and the manufacture of more complex shapes.

As described by A.J. Klein and T.M. Sullivan, "The Sullivan process uses supercritical fluid extraction to remove carbon and halide impurities from liquid ceramic that has been reacted with ammonia or another reactant under supercritical temperatures and pressures. Supercritical temperatures and pressures are those above the critical point, or the point where two phases (gas and liquid) of a material are continually approximating each other, and become identical to form one phase. In the process, inexpensive raw materials are converted under pressure to amorphous ceramics by reaction, distillation, fluid extraction, and densification. First, by-products of the reacted liquid ceramic are extracted in the supercritical fluid. The fluid then is decompressed and cooled in a separator to precipitate solids. Gases are trapped or condensed and then are recycled. Slight changes in temperature and pressure in the critical region cause large changes in solvent density and dissolving power. The supercritical fluid extraction process has wide flexibility for extractive separation by varying temperature, pressure, choice of solvent used, and entrainers (additives). Otherwise insoluble polymers may dissolve in supercritical fluids to an extent that there may be two to seven orders of magnitude in excess of that predicted by the ideal gas law.

In one application (production of aluminum beverage can lids), a monolithic silicon nitride punch has demonstrated a useful life greater than ten times that of a cemented carbide tool.

CERIUM. [CAS: 7440-45-1]. Chemical element, symbol Ce, at. no. 58, at. wt. 140.12, first in the Lanthanide Series in the periodic table, mp 798°C, bp 3433°C, density 6.770 g/cm^3 (20°C). Elemental cerium has a face-centered cubic crystal structure at 25°C. Cerium is the most abundant element of the rare-earth group and is 28th in ranking of the naturally occurring elements in the earth's crust. The element is a silver-gray metal which oxidizes readily at room temperature, particularly in moist air, to form the oxide CeO_2, which is of a pale yellowish-green color. Above 300°C, the element may ignite and burn with a bright red glow. Of the nineteen isotopes of cerium, only four occur in nature, ^{136}Ce, ^{138}Ce, ^{140}Ce, and ^{142}Ce. The thermal neutron-absorption cross section of the element is low. The element has a low toxicity rating. Electronic configuration is $1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}4f^15s^25p^65d^16s^2$. Ionic radius Ce^{3+} 1.034 Å, Ce^{4+} 0.92 Å Metallic radius 1.825 Å. First ionization potential 5.47 eV; second 10.85 eV. Other important physical properties of cerium are given under **Rare-Earth Elements and Metals**. See also **Chemical Elements**.

Cerium was first identified by M.H. Klaproth in 1803 and, independently, in the same year by J.J. Berzelius and W. Hisinger. The element occurs in four source minerals, allanite, bastnasite, cerite, and monazite. Bastnasite, which is a rare-earth fluorocarbonate, is found in southern California. Monazite, a phosphate that contains thorium and the light lanthanides, is distributed widely throughout the world. See also **Bastnasite**; and **Monazite**. Cerium is recovered from the minerals through an extractive process using H_2SO_4, followed by precipitation with oxalic acid, which separates the light lanthanides from thorium, yttrium, and the heavy lanthanides. Cerium metal is produced from its salts, such as CeF_3 or $CeCl_3$, by thermal reduction in a tantalum or molybdenum crucible. Alternative processes include the electrolysis of $CeCl_3$ or CeO_2. The latter compounds are soluble in a complex molten halide flux. The Ce^{3+} is reduced to metal at a molybdenum electrode. The process is carried out at from 800 to 1,000°C.

A major use for CeO_2 is in decolorizing soda-lime container glass. The compound also is used for polishing gemstones and glass, notably precision optical glasses. Cerium is particularly useful in glass that is subject to α-, γ-, and x-radiation, and the impingement of light and electrons because the cerium prevents discoloration that may arise from the presence of Fe(II) by oxidizing the Fe(II) as it is formed to Fe(III). This is an important factor in color television tubes. Cerium dioxide also is used in cathodes, capacitors, phosphors, ceramic coatings, refractory oxides, semiconductors, and photochromic glasses. The compound also is used as a catalyst and as an opacifying agent in porcelain enamels. Because of its low nuclear cross section, CeO_2 may be applied as a diluent in oxide nuclear fuels.

Cerium metal finds wide application in mischmetal, which is a rare-earth metal comprised of 50% Ce, 25% La, 18% Nd, 5% Pr, and 2% other rare earths. This alloy is used in shell linings for military projectiles, as an alloying agent for improving the malleability of ductile iron, and in lighter "flints" where the alloy is compounded with a 30% iron alloy. The pyrophoric and incendiary nature of cerium are evident when cerium-base alloys are machined. Mischmetal also improves the creep resistance of magnesium alloys, the resistance to oxidation of nickel alloys, the hardness of copper alloys, and the strength of aluminum alloys. Both cerium metal and mischmetal are used as getters to remove traces of oxygen in vacuum tubes and equipment. When alloyed with cobalt, cerium is gaining importance as a magnet material. $CeCo_5$, as a permanent magnet material, has properties that exceed those of the alnicos and ferrites. Mixed rare-earth oxides and fluorides containing up to 50% cerium are used as cores for carbon arcs which, for illuminating purposes, have much greater intensity and color balance. The mixed oxides with cerium also are used as catalysts (petroleum cracking and chemical oxidation reactions) and in a variety of waterproofing agents, fungicides, and polishing materials.

CERMET. See **Chromium**; **Nuclear Reactor**.

CERUSSITE. The mineral cerussite, lead carbonate, $PbCO_3$, is orthorhombic with tabular, prismatic and pyramidal crystals, with twinned forms very common. If not in crystal aggregates it may occur in granular or compact masses. Cerussite is very brittle with a conchoidal fracture; hardness, 3–3.5; specific gravity, 6.55 (a heavy mineral); luster, adamantine but may be vitreous to resinous, pearly or even submetallic. Its color is variable, white to gray, grayish-black or blue or green, transparent to translucent.

Cerussite is of secondary origin, being found associated with other lead minerals, and is widely distributed. There are many European and American localities. Fine crystals have been obtained from Phoenixville, Pennsylvania; Joplin, Missouri; Leadville, Colorado; Pima County, Arizona, and Dona Ana County, New Mexico. It is an ore of lead, and frequently carries values of silver. Derived from the Latin cerussa, white lead.

CESIUM. [CAS: 7440-46-2]. Chemical element, symbol Cs, at. no. 55, at. wt. 132.905, periodic table group 1, mp 28.40°C, bp 669°C, density 1.88 g/cm^3 (20°C). Elemental cesium has a body-centered cubic crystal structure. Cesium is a silver-white, very soft metal, one of the softest of all metals. The element tarnishes instantly on exposure to air, soon igniting spontaneously with flame to form the oxide. Generally, the element is preserved under kerosene. Cesium reacts vigorously with H_2O, forming cesium hydroxide and hydrogen gas. The element first was identified by Bunsen and Kirchhoff in 1860 through spectroscopic observations. Cesium occurs in nature as the ^{133}Cs isotope. There are 15 radioactive isotopes ^{125}Cs through ^{132}Cs and ^{134}Cs through ^{139}Cs. The half-life of ^{137}Cs is 33 years. This isotope is used as a source of gamma radiation, particularly in radiography and therapy. See also **Radioactivity**. First ionization potential, 3.89 eV; second, 23.4 eV. Oxidation potential $Cs \longrightarrow Cs^+ + e^-$, 3.02 V. Other important physical characteristics of cesium are given under **Chemical Elements**.

The main source of cesium is carnallite $KCl \cdot MgCl_2 \cdot 6H_2O$ which contains a small percentage of cesium compounds. See also **Carnallite**. Cesium also occurs in pollucite (cesium aluminosilicate, 35% Cs_2O) and lepidolite (lithium aluminosilicate). See also **Lepidolite**; and **Pollucite**. In early processes, cesium metal was obtained by the reduction of cesium salts, such as the hydroxide or chloride. In current practice, the metal is produced by electrolyzing the cyanide. The latter compound usually is fused cesium barium cyanide mixture.

The uses for cesium and its compounds are limited. Cesium is used in photoelectric devices because of its high sensitivity to light, finding applications in television, motion picture, radar, and instrumentation equipment. Cesium also has been used in luminescent tubes and screens. Certain processes for the manufacture of synthetic resins, such as chloroprene, use cesium as a catalyst. Some interest has been indicated in cesium as a fuel for ion-propulsion engines of low thrust for spacecraft. Like sodium, cesium also has been considered as a heat-transfer medium for special applications. The function of cesium in time measurement is important. As officially defined in 1967 by the International Bureau of Weights and Measures, the atomic second is equivalent to 9,192, 631,770 oscillations of the atom of ^{133}Cs. This value expresses the ephemeris time (ET) second as closely as practical in terms of an atomic standard. To derive this value, scientists at Great Britain's National Physical Laboratory and the United States Naval Observatory used a dual-rate moon-position camera and a cesium-beam clock.

Cesium forms several solid solutions with rubidium. These alloys are used as *getters* for eliminating residual gases from vacuum tubes and

systems. Because of their extreme reactivity in air, the alloys are difficult to apply. For easier handling, cesium can be alloyed with calcium, barium, or strontium. The ternary alloys of cesium, aluminum, and barium or strontium are employed in photoelectric cells. Cesium alloyed with antimony, silver, bismuth, and gold also displays photoelectric properties.

Chemistry and Compounds

Cesium is more electropositive than rubidium (or the lower alkali metals) as is consistent with its position in group 1.

Because of the ease of removal of its single 6s electron (3.89 eV) and the difficulty of removing a second electron (23.4 eV) cesium is monovalent in its compounds, which are ionic.

In its solutions in liquid NH_3, cesium is like the other alkali metals, a powerful reducing agent, so that in such solutions, titrations of cesium polysulfide with cesium are made by electrometric methods. The solubility of cesium salts in liquid NH_3 increases markedly with the radius of an anion (the chloride, CsCl, 0.0227 moles per kg, the bromide, CsBr, 0.215 moles per kg, and the iodide, CsI, 5.84 moles per kg), though the values are less than for the corresponding rubidium compounds.

As reported by Knittle and Jeanloz (1984), cesium iodide, a simple ionic salt at low pressures, undergoes a second-order transformation at 40 gigapascals (400 kilobars) from the cubic B2 (cesium chloride-type) structure to the body-centered tetragonal structure. Also, the energy gap between valence and conduction bands decreases from 6.4 eV at zero pressure to about 1.7 eV at 60 gigapascals, transforming cesium iodide from a highly ionic compound to a semiconductor. The structural transition increases the rate at which the band gap closes, and an extrapolation suggests that cesium iodide becomes metallic near (or somewhat above) 100 gigapascals. It is noted that similar changes in bonding character are apt to occur in other alkali halides at pressures exceeding 100 gigapascals.

As in the case of the other alkali metals, cesium forms compounds generally with the inorganic and organic anions. For a general discussion of these compounds (see also **Sodium**) because the sodium compounds differ principally in their greater extent of hydration and greater number of hydrates. However, cesium coordinates with large organic molecules, such as salicylaldehyde, even though it does not with H_2O.

One respect in which cesium (and rubidium) are outstanding among the alkali metals is the readiness with which it forms alums. Cesium alums are known for all of the trivalent cations that form alums, Al^{3+}, Cr^{3+}, Fe^{3+}, Mn^{3+}, V^{3+}, Ti^{3+}, Co^{3+}, Ga^{3+}, Rh^{3+}, Ir^{3+}, and In^{3+}.

As in the case of potassium and rubidium, cesium forms a superoxide on reaction of the metal with oxygen. The compound is orange in color and paramagnetic because it contains the O_2^- ion with an odd electron in an antibonding orbital, and has the formula CsO_2. On heating, this compound loses oxygen to form black Cs_2O_3, which contains both CsO_2 and Cs_2O_2 (peroxide), which is the product of further heating. A series of suboxides of cesium is known, Cs_7O, Cs_4O (uncertain), Cs_7O_2, Cs_3O and Cs_2O. Moreover the normal oxide, Cs_2O, can be prepared by heating cesium nitrite with metallic cesium. It reacts explosively with oxygen to form CsO_2.

Cesium hydroxide, [CAS: 21351-79-1], CsOH, is the strongest of the five alkali metal hydroxides, as would be expected from its position in the periodic table (francium hydroxide, when prepared, would be expected to be stronger). For the same reason, it has the lowest lattice energy of the five (135.6 kcal per mole).

The most numerous organic compounds of cesium are the oxygen-connected ones, such as the salts of organic acids, and alkoxy and aryloxy compounds (alcoholates, phenates, etc.). Among the carbon-connected compounds, an ethyl cesium, CsC_2H_5, and a phenyl cesium, CsC_6H_5, have been reported.

Later studies by investigators (Alberts et al., 1979) have shown that ^{137}Cs introduced into a watershed is attached to soil particles, which are removed by erosion and runoff. Some of the eroded soil particles comprise the sediments of the catchment basins in the watersheds and act as "sinks" for ^{137}Cs. Other investigators have reported an almost irreversible fixation of this element in clay interlattice sites in freshwater environments, and, that it is unlikely that this nuclide will be removed from these sediments under normal environmental conditions other than by exposure to solutions of high ionic strength, such as may occur in estuarine environments. Studies of ^{137}Cs have been important because the element can be introduced into a water system from a leak in a nuclear fuel element. These findings are reported in some detail by Alberts et al. in *Science*, **203**, 649–651 (1979).

It has been estimated that the most serious long-term threat to health and the environment as the result of the Chernobyl (former U.S.S.R) nuclear power plant disaster (1986) may come from radioactive cesium, which has a half-life of 33 years. Exposure to cesium-137 could increase the death rate from cancer in western Russia by a maximum of 0.4% over the next 70 years. That would equate with almost 40,000 excess deaths.

CHABAZITE. The mineral chabazite is a member of that group of hydrous silicates, the zeolites, and corresponds to the formula $CaAl_2Si_4O_{12} \cdot 6H_2O$ with sodium sometimes replacing a part of the calcium. Potassium, barium and strontium may be present in very small amounts. Chabazite is hexagonal, usually in rhombohedrons that tend to resemble cubes. It has a rhombohedral cleavage; is brittle; hardness 4–5; specific gravity 2.05–2.10; luster vitreous; color white to flesh-red; streak white; translucent to transparent. Chabazite is found in the amygdaloidal cavities of basalts often associated with other zeolites. It is occasionally found in such crystalline rocks as syenites, gneisses and schists. Chabazite is a rather common zeolite, being found in many localities in Europe. In the United States it occurs in the Triassic traps of New Jersey and Maryland. The Triassic lavas of Nova Scotia have yielded fine specimens. The name chabazite is derived from the Greek word meaning a precious stone.

CHADWICK, JAMES (1891–1974). Chadwick was a distinguished English physicist. After receiving a Master's, he went to Germany to work with Hans Geiger. New research here showed that beta particles possess a range of energies up to some maximum value. During World War I he was interned in the Zivilgefangenenlager, Ruhleben. After the war, he was released and returned to England. He worked with Rutherford at the Cavendish Laboratory, Cambridge, on the bombardment of elements with alpha particles. He discovered the neutron, a particle in the nucleus of an atom that carries no electric charge. He received the Nobel Prize in 1935 for Physics. His work was a tool for investigating the atom and also led to the production of a variety of new radioisotopes.

See also **Neutron**.

J.M.I.

CHAIN REACTION (Free Radical). See **Free Radical**.

CHALCANTHITE. This mineral of triclinic crystallization is found only as a rare secondary mineral in the oxidized zones of sulfide copper ores within arid regions. It is a hydrous copper sulfate, $CuSO_4 \cdot 5H_2O$, and is a most unstable mineral in moist atmosphere environments, altering readily to a powder-blue dust. The mineral possesses a vitreous luster of deep azure-blue color, ranging from transparent to translucent. Chalcanthite is found in abundance only in Chuquicamata and other arid regions of Chile where it is an important copper ore.

CHALCEDONY. One of the cryptocrystalline varieties of the mineral quartz, having a waxy luster. It may be semitransparent or translucent and is usually white to gray or grayish-blue or some shade of brown, sometimes nearly black. Light colored clear red chalcedony is known as carnelian; deep reddish brown as sardonyx; a green variety colored by nickel oxide is called chrysoprase. Prase is a dull green. Plasma is a bright to emerald-green chalcedony sometimes found with small spots of jasper resembling blood drops; it is then referred to as blood stone or heliotrope.

Chalcedony and agate are essentially porous, which permits their being dyed various colors by artificial means. Red color is produced by iron nitrate solution; nickel nitrate produces vivid green color; ammonium bichromate produces blue-green; and ferrocyanide salts a vivid blue. The black onyx used extensively in rings is a product of soaking chalcedony in sugar solutions and later in sulfuric acid.

The term chalcedony is derived from the Greek name Chalkedon, a town in the Middle East.

CHALCOCITE. This mineral is cuprous sulfide, Cu_2S, crystallizing in the orthorhombic system, often in pseudohexagonal forms. Above a temperature of 91°C, chalcocite changes into an isometric form. It has conchoidal fracture; hardness, 2.5–3; specific gravity, 5.5–5.8; metallic luster; color, dark gray to blackish-gray, frequently with bluish-green tarnish. Chalcocite is of widespread occurrence and a valuable copper ore. It seems in some cases to be definitely secondary in origin, in other cases primary. It may have been formed from bornite by the action of alkaline solutions. It sometimes carries valuable amounts of silver.

Among the many European localities might be mentioned Cornwall, England, the Ural Mountains, and Rumania. It occurs also in the Congo, South West Africa, Peru, Mexico, and Alaska. In the United States it is found at Bristol, Connecticut, in fine crystals, Montana, Tennessee, Arizona, Nevada, and California.

The word *chalcocite* is derived from the Greek word meaning "copper." Chalcocite also is known as *copper glance.*

CHALCOPYRITE. The mineral chalcopyrite (also known as copper pyrites) is a sulfide of copper and iron corresponding to the formula $CuFeS_2$. Its tetragonal crystals are often complex with repeated twinning; massive chalcopyrite is common. It has an uneven fracture; is brittle; hardness, 3.5–4; specific gravity, 4.1–4.3; luster, metallic; color, brass-yellow, may be iridescent from tarnish; streak, greenish-black; opaque. Chalcopyrite is the most common copper-bearing mineral known and it is the most important ore of copper. It is a primary mineral in many igneous rocks and from it a host of secondary copper minerals have been derived.

Among the many localities where fine specimens of this mineral have been obtained might be mentioned: Freiburg, Saxony; Alsace; Rio Tinto, Spain; Cornwall, England; Australia; Chile, Peru, and Bolivia, South America; and in the United States, Ellenville, New York; Chester County, Pennsylvania; Joplin, Missouri; Gilpin County, Colorado; Arizona, Montana, Utah, Nevada, California, New Mexico and Tennessee. In Canada there are notable deposits of chalcopyrite in the Provinces of British Columbia, Ontario, and Quebec. The name *chalcopyrite* is derived from the Greek word meaning "copper," and the word *pyrites.*

CHALK. Chalk is a soft, porous limestone of white, grayish-white or buff color made up of the minute shells of foraminifera and fragments of cocospheres. It occurs extensively in England and France and less so in the United States.

Chalk consists almost entirely of calcite, formed principally by shallow-water accumulation of (1) calcareous tests of floating microorganisms and (2) comminuted remains of calcareous algae. The most widely distributed chalks are of Cretaceous age, as exemplified by the cliffs on both sides of the English Channel. Although an unaltered deposit, chalk masses may contain nodules of chert and pyrite.

CHARACTERISTIC EQUATION. 1. A class of equations connecting those variables, such as temperature, pressure, and volume, which define the physical condition of a given substance and are called variables of state.

The ideal gas law and the Boyle-Charles law represent approximately the behavior of all gases, but if one wishes to be accurate, some modification of these must be sought which will take into account the differences between individual gases. The best known characteristic equation for gases is that of van der Waals. Using the same notation as for the ideal gas law, this may be written

$$\left(p + \frac{n^2a}{v_2}\right)(v - nb) = nRT$$

where n is the number of moles of gas, and a and b are constants characteristic of the gas in question. They are very small; if they were zero we should have the ideal gas law. Following are their approximate values for certain gases, where a is expressed in atmosphere (liter/gram-mole)^2 and b in liter/gram-mole:

Gas	a	B
Ammonia	4.170	0.03707
Helium	0.034	0.03412
Hydrogen	0.244	0.02661
Nitrogen	1.390	0.03913
Oxygen	1.360	0.03183

Characteristic equations of this sort are also known as equations of state. See also **Berthelot Equation**.

2. Equations that have solutions, subject to particular boundary conditions, only for certain specific parameters occurring in them. In differential equations, the complete solution includes the characteristic solution and the particular solution. The characteristic solution is obtained from the roots of the characteristic equation, and defines the transient or time response of the system. The particular solution is obtained from the forcing function or input signal and defines the steady-state response.

3. An equation in the linearized theory of hydromagnetics whose solutions show the frequencies and modes of the initial perturbations that will decay or grow exponentially in time for any given system. The solutions to this equation indicate the regions of stability for various hydromagnetic systems. See also **Hydromagnetic Equations**.

CHARDONNET, H. (1839–1924). A native of France, he has been called the father of rayon because of his successful research in producing what was then called artificial silk from nitrocellulose. He was able to extrude fine threads of this semi-synthetic material through a spinnerette-like nozzle, and the textile product was made on a commercial scale in several European countries. He was awarded the Perkin medal for his work

CHARGE-MASS RATIO. This term refers to the relationship between the electric charge of a particle and its mass, so important in the physics of electrons, ions, and other electrified bodies of molecular orders.

The earliest information on the subject followed from the researches of Faraday on electrochemical equivalents. From his results it appears that, in the electrolysis of chlorine, for example, 1 coulomb of negative electricity is carried by 0.00037 gram of this element, and hence that the carriers or ions have a charge-mass ratio of about 2,700 coulombs, or 8.1×10^{12} electrostatic units of electricity to the gram. Similarly, 1 coulomb of positive electricity is carried by 0.0000104 gram of hydrogen, which gives about 95,700 coulombs or 2.87×10^{14} electrostatic units to the gram for hydrogen ions. This is 35 times the ratio for chlorine ions. But the atomic masses of hydrogen and chlorine are in the ratio 1:35, which means that if the carriers are atoms, the charge per carrier is the same for both elements. Bivalent elements, on the other hand, carry twice this charge per ion.

When J.J. Thomson applied a magnetic field to a stream of hydrogen canal rays, and then neutralized the resulting deflection by means of an electric field, he was able to calculate the charge-mass ratio of these particles from the curvature of the magnetically deflected stream and the values of the two field intensities. This he found to be either 95,700 coulombs per gram as in the electrolysis of hydrogen, or $\frac{1}{2}$ that value, which indicated that some of the ions were atoms and some were molecules carrying the some charge as the atoms. But when a similar test was applied to the cathode rays in a Crookes tube, the ratio was found to be about 5.303×10^{17} electrostatic units per gram, or about 1,850 times that for hydrogen atoms, whatever the nature of the cathode. We know now that this enormous difference is one of mass, not of charge, and, that these experiments were the first direct revelation of the identity of the electron, the mass of which is now known to be approximately 1/1,836 of the mass of the proton (nucleus of hydrogen atom).

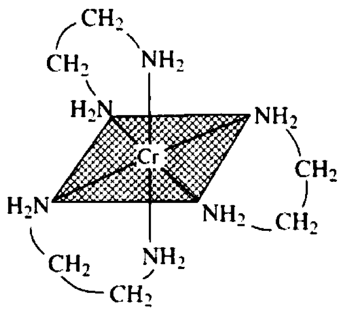
CHARLES LAW. Although the coefficients of expansion of different solids or of different liquids are notably different, the coefficients of expansion of all gases are nearly the same, namely, about $\frac{1}{273}$ of the volume at 0°C per centigrade degree. The law, stated by Charles in 1787 and independently by Gay-Lussac in 1802 (hence sometimes called Gay-Lussac's law) is not strictly true. Regnault obtained the following values of the volume coefficient for various gases:

Air	0.0036706
Hydrogen	0.0036613
Carbon dioxide	0.0037099
Sulfur dioxide	0.0039028
Carbon monoxide	0.0036688
Nitrous oxide	0.0037195
Cyanogen	0.0038767

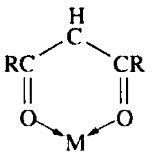
None of these is far from $\frac{1}{273}$ = 0.003663, which is therefore commonly taken as the expansion coefficient for gases; especially as the value for hydrogen, commonly used in the standard gas thermometer, is very near it. If the pressure as well as the volume is allowed to vary, the behavior of the ideal gas must be expressed by the Boyle-Charles law or the ideal gas law; and the behavior of a real gas by one of the other equations of state. See also **Ideal Gas Law**.

CHARNOCKITE. Charnockite is a granular variety of hypersthene granite, first described from the gravestone of Job Charnock, who founded the city of Calcutta, India, whence the derivation of the name charnockite.

CHELATES AND CHELATION. Chelation compounds are coordination compounds in which a single ligand occupies more than one coordination position. Such ligands are called chelating agents (the word being derived from the Greek meaning *crab's claw*). Thus ethylenediamine, $H_2N-CH_2-CH_2-NH_2$, abbreviated as *en*, forms a $Cr(en)_3^{3+}$ ion having three molecules of ethylenediamine, each occupying two coordination positions.

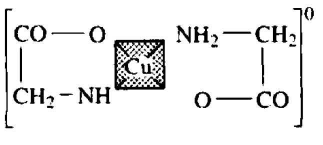


Ethylenediamine is therefore called a bidentate group, as are many other ligands, such as the β-diketones, which form chelation compounds of the type where M is a metal ion.

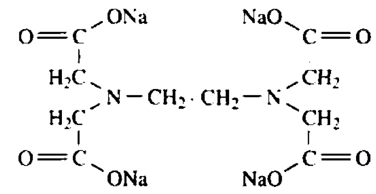


Although bidentate ligands are more common, there are polydentate ligands, which occupy more than two coordination positions; ethylenediaminetetraacetic acid is such a polydentate ligand.

While ethylenediamine, and many other chelating agents, form only covalent bonds, there are others which attach by both covalent and ionic bonds. Thus glycine forms with cupric ions (Cu^{2+}) the compound copper bisaminoacetate.



A number of synthetic chelating agents have been developed. They are substances like ethylenediaminetetraacetic acid (EDTA) (Structure 1) and N-hydroxyethylethylenediaminetriacetic acid (HEDTA) and their salts, usually sodium salts. Many of these compounds and mixtures of these compounds are sold under trademarks.



(1)

Chelating agents are being used in increasing amounts for a number of important purposes. These uses may be put into two important categories: first, artificial trace metal carriers and, second, sequestering agents.

As artificial carriers for trace metals, chelating agents can be used as aids in agriculture by supplying the metals for soils which are deficient in their trace metal content. Both EDTA and HEDTA are adequate iron carriers and EDTA can be used as the carrier for bivalent copper, zinc, manganese, and cobalt. By use of such carriers certain plant deficiency diseases can be controlled. Another example of artificial carrier use is the employment of chelating agents such as the EDTA derivatives or mixtures of such derivatives with pyrophosphates or a mixture of EDTA and the sodium salt of N,N-di(2-hydroxyethyl) glycine in controlling polymerization reactions in synthetic rubber manufacture by the controlled release of trace metal catalysts.

As sequestering agents, chelating compounds have a wide variety of uses, for instance: for water softening in both soaps and synthetic detergents; in textile processing, as in kier boiling operations, where iron, copper, zinc, etc., ions are inactivated, so that discoloration of cloth is prevented; in the stabilization of hydrogen peroxide; and in boiler and heat exchanger cleaning.

Chelation in Biological Systems

Chemical reactions in biological systems are usually mediated by selective catalysts called enzymes. The high efficiencies and stereospecificities achieved require that enzymes have definite and characteristic geometries, whereby specific functional groups coordinated to the metal ion are held in definite spatial positions relative to each other and relative to the substances on which they exert their catalytic effects. The incorporation of metal ions into enzyme structures can assist in the maintaining of a definite geometrical relationship between ionic and polar groups, through the geometric requirements of the coordinate bonds of the metal ion. Certain metal ions may also participate in the catalytic properties of enzymes through ionic and coordinate bonding between the metal ion and electron donating groups of the enzyme and substrate, and through the ability of the metal ion to initiate oxidation-reduction reactions. Because of these chemical and steric effects, coordinated metal ions in the complex compounds that catalyze biological reactions frequently are found. See also **Metalloproteins**.

Most of the metal ions that have biological functions have a coordination number of six, with the donor groups arranged in an octahedral fashion. There are a few metals, such as Mg^{2+} and Zn^{2+}, that frequently coordinate only four donor groups tetrahedrally, and Cu^{2+}, which has four coordinations directed to the corners of a square plane with the metal ion at the center of the plane.

Many simple acid-base reactions are catalyzed by both metal ions and hydrogen ions. Because of small size, the electronic interaction of the hydrogen ion with a substrate is much greater than that of a metal ion. The latter, however, has properties not possessed by hydrogen ions, which are useful in catalysis, i.e., the ability to coordinate a large number of electron donor groups simultaneously, the specific geometric orientation of the coordinate bonds of certain metal ions, and the ability of metal ions to undergo oxidation-reduction reactions. Many of these reactions are models of the more complex catalytic effects that occur in biological systems. Since these reactions of simple coordination compounds aid in the understanding of biological reactions, a few of the more common examples are given in Table 1.

The function of the metal ions in the reactions listed is to attract electrons from the substrate. When this effect takes the form of simple polarization of the functional groups of the substrate, charge variations and electron shifts in these groups facilitate the chemical reactions listed under solvolysis and acid catalysts. When the metal ion removes completely one or more electrons from the substrate, the first step in an oxidation reaction occurs.

TABLE 1. METAL ION AND METAL CHELATE CATALYSIS OF CHEMICAL REACTIONS

Solvolysis and other reactions involving acid catalysis by the metal ion reaction type		
Reaction type	Substrate	Catalyst
Solvolysis	Amino acid esters, peptides, and amides	Cu^{2+}, Co^{2+}, Mn^{2+}
	Phosphate esters	La^{3+}, Cu^{2+}, VO^{2+}
	Fluorophosphates	Cu^{2+}, $UO_2{}^{2+}$ diamine-Cu(II) complexes
	Polyphosphates	Ca^{2+}, Mg^{2+}
	Schiff bases	Cu^{2+}, Ni^{2+}
Transamination	Schiff bases of pyridoxal and α-amino acids	Fe^{3+}, Cu^{2+}, Al^{3+}, Zn^{2+}, Ni^{2+}, Co^{2+}
Decarboxylation	α-Keto polycarboxylic acids (e.g., oxalacetic and oxalsuccinic acids)	Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, Fe^{2+}
Acylation	Acetylacetone	Co(III), Rh(III) or Cr(III) chelates of acetylacetone

Catalysis of Oxidation Reactions by Electron Exchange with Metal Ions or Metal Complexes		
Reaction	Substrate	Metal Ion or Complex
Oxidation by molecular O_2	Ascorbic acid, catechols, quinoline, salicylic acid	Fe(III), Fe(III)-EDTA, Cu(II), Cu(II)-EDTA, V(IV)
Oxidation by H_2O_2	Phenol, anisole	Fe(II) (Fenton's reagent), Fe(II)-hydroquinone Fe(II)-EDTA-ascorbic acid
Formation of oxygen	Hydrogen peroxide	Fe3+, Fe(III)-phthalocyanine chelate
Formation of disulfides From mercaptides	Thioglycolic acid	Fe3+, Cu2+

This type of catalysis can be accomplished only by metals capable of existing in more than one valence state.

There is a saturation effect in the coordination of a metal ion by donor groups of both the enzyme and the substrate. Therefore, one would expect that the interaction of a free metal ion with the substrate would be greater than that of the metalloenzyme (in which the metal is already partially coordinated). If this were true, the metal ion would have a greater catalytic effect than the metalloenzyme. The reverse is always the case; thus far, no metal ions, or metal complex enzyme models, have been found to approach the catalytic activities of the corresponding enzyme. This high activity of the enzyme is ascribed to the special environment of the substrate around the active site of the enzyme, through which additional binding of the substrate by adjacent organic groups of the enzyme takes place.

The enzyme aconitase, which contains the Fe^{2+} ion at the reactive center, catalyzes the interconversion of citric, isocitric, and aconitic acids. The reaction has been shown to occur through the formation of a single intermediate carbonium ion structure in which the Fe^{2+} ion is always bound to the same donor atoms, while the interconversion of the substrate occurs through the migration of only protons and electrons.

Some of the more important biological reactions that are catalyzed by metal ions are summarized in Table 2.

TABLE 2. BIOLOGICALLY ACTIVE METAL CHELATES

Metal	Metalloenzyme	Other Biological Functions
Mg	Polynucleotide phosphorylase, ATPase, choline acylase, deoxyribonuclease, acetate kinase, adenosine phosphokinase, fructokinase, glyceric kinase, hexokinase	Chlorophyll
Ca	α-Amylase, aldehyde dehydrogenase, lipase	
V		Green algae, blood of marine worm (ascidian)
Cr		Glucose tolerance factor
Mn	Arginase, carnosinase, prolinase, enolase, isocitricdehydrogenase, 3-phospho-glycerate kinase, glucose-1-P kinase	
Fe	Aconitase, formic hydrogenylase, phenylalanine hydroxylase, peroxidase, catalase, cytochromes	Hemoglobin, ferritin, hemosiderin, siderophilin
Co	Aspartase, acetylornithinase	Vitamin B12
Cu	Lactase, phenolase, tyrosinase, uricase	Ceruloplasmin, cytochrome
Zn	Carbonic anhydrase, carboxypeptidase, alcohol dehydrogenase, glutamic dehydrogenase, acylase	
Mo	Nitrate reductase, xanthine oxidase	

Chelates in Food Processing

The most commonly used sequestrants in the food field include:

Calcium acetate	Potassium phosphate (di- and monobasic)
Calcium chloride	Sodium acid pyrophosphate
Calcium citrate	Sodium citrate
Calcium gluconate	Sodium diacetate
Calcium phosphate, monobasic	Sodium gluconate
Citric acid	Sodium metaphosphate
Disodium EDTA	Sodium tartrate
Glucono delta-lactone	Sodium thiosulfate
Oxystearin	Sorbitol
Phosphoric acid	Tartaric acid
Potassium citrate	Triethyl citrate

Phosphates have the ability to combine with metal ions, such as calcium, magnesium, iron, and copper, and so render the metals nonactive. Calcium and magnesium are primarily responsible for the hardness of water. The addition of tripolyphosphate or hexametaphosphate will bind these elements and produce soft water. In a similar manner, sequestration is used to soften the skins of fruits and vegetables for faster cooking, and to increase the extraction and recovery of pectin in fruit. Calcium pectinates, which are insoluble, are converted into sodium pectinates, which are soluble and readily extracted.

Pyrophosphates are especially effective sequestrants for iron, which catalyzes oxidative darkening of fruits and vegetables. Potatoes, in particular, turn dark after cooking unless the iron in the potato is sequestered. Iron or copper is also responsible for catalyzing oxidative rancidity in meat, poultry, and fish. The effectiveness of combinations of an antioxidant, chelating agents, and polyphosphates in retarding the chemical and organoleptic deterioration of mechanically deboned flounder meat during frozen storage has been investigated. Treatment with polyphosphates, usually applied for moisture binding, will also inhibit rancidity and prolong storage life of various meats. Canned fish frequently develops crystals of a compound known as *struvite*, which appears to the user to be pieces of glass. Although not harmful, these substances are the cause for rejection. Struvite formation is effectively prevented by the addition of a small amount of pyrophosphate to the canned fish.

CHEMICAL ABSTRACT SERVICE REGISTRY NUMBER (CAS). This universally used number permits use and comparison of data on a given material no matter the synonym with which it might be published. It will, in fact, permit absolute identification of a compound with all of its synonyms. CAS numbers also facilitate extraction of information from computerized data bases. See also **Chemicals (Number of)**.

CHEMICAL AFFINITY. The entropy production due to a chemical reaction has the form

$$\frac{d_iS}{dt} = \frac{1}{T}\mathbf{A}v \geq 0 \qquad (1)$$

where **A** is the chemical affinity and v, the reaction rate. **A** is related to the characteristic functions U, H, A, G, and to the chemical potentials μ by the relations:

$$\begin{aligned}\mathbf{A} &= -\left(\frac{\partial U}{\partial \xi}\right)_{S,V} = -\left(\frac{\partial H}{\partial \xi}\right)_{S,p} \\ &= -\left(\frac{\partial A}{\partial \xi}\right)_{T,V} = -\left(\frac{\partial G}{\partial \xi}\right)_{T,p} \\ &= -\sum_i v_i\mu_i\end{aligned} \qquad (2)$$

when ξ is the extent of reaction and v_i the stoichiometric coefficient.

The basic properties of the affinity **A** are that it is always of the same sign as the reaction rate, and that if the affinity is zero the reaction rate is also zero, i.e., the system is in equilibrium.

This definition of affinity is essentially due to De Donder and is called De Donder's fundamental inequality. In the notation used by G.N. Lewis and his school, it is supposed that ξ increases by unity; therefore the relations of (2) are written in the form:

$$\mathbf{A} = -(\Delta U)_{S,V}, = -(\Delta H)_{S,p} = -(\Delta A)_{T,V} = -(\Delta G)_{T,p}, \qquad (3)$$

Note that in this entry, **A** is the affinity and A, the Helmholtz function (work function).

See also **Chemical Reaction Rate**.

CHEMICAL COMPOSITION. Matter is composed of the chemical elements, which may be in the free or elementary state, or in combination. In the former case, as exemplified by iron, tin, lead, sulfur, iodine, and the rare gases, matter commonly exhibits the properties of the atoms of the particular element, including the chemical properties whereby they combine to form molecules. Molecules may (1) be monoatomic; (2) they may consist of atoms of one element only, such as nitrogen or hydrogen molecules (N_2 or H_2), (3) they may be composed of atoms of more than one element, called compounds, which usually have distinctive properties.

The molecular formulas of gaseous compounds are obtained from a study of the composition by elements and the density, by a method introduced by the Italian chemist, Cannizzaro, in 1858. Later, in 1872, in the course of his Faraday Lecture before the Chemical Society (London) on the subject, "Some Points in the Teaching of Chemistry", Cannizzaro stated that "Symbols and formulas, in my opinion, constitute the introduction, preparation, and base of the study of the transformations of matter, which is the true object of our science." The simplest way to understand the *Cannizzaro method* is to arrange in tabular form: (1) the individual gases; (2) the weight in grams of 1 liter (at 0°C, 760 millimeters of mercury pressure) of each gas; and (3) the weight in grams of *each element* present in the above volume (1 standard liter) found by exact analysis (percentage composition by chemical elements using the methods of analytical chemistry). See Table 1.

TABLE 1. CANNIZZARO METHOD OF COMPOUND COMPUTATION

Gas	Grams per Standard liter	Percentage composition by Chemical elements		Grams per standard liter by chemical elements: Hydrogen	Oxygen	Carbon	Nitrogen	Sulfur	Chlorine
1. Hydrogen chloride	1.639	{Hydrogen {Chlorine	2.76%} 97.24}	0.045					1.594
2. Ammonia	0.771	{Hydrogen {Nitrogen	17.75} 82.25}	0.137			0.634		
3. Carbon dioxide	1.977	{Oxygen {Carbon	72.73} 27.27}		1.438	0.539			
4. Carbon monoxide	1.250	{Oxygen {Carbon	57.14} 42.86}		0.714	9.536			
5. Methane	0.717	{Hydrogen {Carbon	25.14} 74.86}	0.180		0.537			
6. Ethylene	1.260	{Hydrogen {Carbon	14.38} 85.62}	0.181		1.079			
7. Acetylene	1.173	{Hydrogen {Carbon	7.75} 92.25}	0.091		1.082			
8. Oxygen	1.429	Oxygen	100.00		1.429				
9. Hydrogen	0.090	Hydrogen	100.00	0.090					
10. Nitrogen	1.251	Nitrogen	100.00				1.251		
11. Chlorine	3.214	Chlorine	100.00						3.214
12. Sulfur dioxide	2.927	{Oxygen {Sulfur	49.95} 50.05}		1.462			1.465	
13. Hydrogen sulfide	1.539	{Hydrogen {Sulfur	5.91} 94.09}	0.091				1.448	
14. Nitrous oxide	1.978	{Oxygen {Nitrogen	36.35} 63.65}		0.719		1.259		
15. Nitric oxide	1.340	{Oxygen {Nitrogen	53.32} 46.68}		0.715		0.625		
Minimum weight (approximate)				0.045	0.715	0.538	0.626	1.45	1.60

Note: Data are displayed in this table to illustrate the Cannizzaro method of arriving at the symbol and symbol weight of chemical elements; and the formula and formula weight of chemical compounds.

Careful examination of the figures in the last six columns reveals the experimental fact that (1) in each separate vertical column the figures represent a minimum weight or a small multiple (approximately) of this weight, and (2) the smallest of the six minimum weights is that for hydrogen, namely, 0.045 gram in 1 standard liter of hydrogen chloride gas.

The next step involves changing 0.045 gram of hydrogen to exactly 1.000 gram and finding arithmetically the volume of hydrogen chloride containing this weight (1.000 gram hydrogen). The volume is found to be 22.2 standard liters.

Therefore, 1.000 gram minimum weight of hydrogen is contained in 22.2 standard liters of hydrogen chloride.

Using this standard volume of 22.2 liters, the next step is to ascertain the minimum weight of the other elements in this volume.

Chemical element	Approximate minimum weight in grams of each of the six chemical elements in the standard volume, 22.2 liters
Hydrogen	1
Oxygen	16
Carbon	12
Nitrogen	14
Sulfur	32
Chlorine	35.5

Then, the abbreviation is introduced by the representation:

COMMONLY USED SYMBOL WEIGHTS OF EACH ELEMENT BY THE SYMBOLS

1 gram of hydrogen by the symbol H
16 grams of oxygen by the symbol O
12 grams of carbon by the symbol C
14 grams of nitrogen by the symbol N
32 grams of sulfur by the symbol S
35.5 grams of chlorine by the symbol Cl

By setting up again the second half of the table for the 15 gases, this time for 22.2 standard liters instead of 1 standard liter, the results obtained may be observed in Table 2.

Thus, it is seen, the chemical formulas and formula weights (last column) of 15 gaseous chemical compounds have been arrived at, using the Cannizzaro method, by purely experimental and rational means, involving no theoretical considerations. Extension of the method serves to ascertain the chemical formula of all gases and vaporizable substances. For compounds which are neither gases nor vaporizable, other methods are available. Of these the most used are those of Raoult depending upon the depression of the freezing point or the elevation of the boiling point of a compound dissolved in a given solvent.

TABLE 2. DERIVATION OF FORMULAS AND FORMULA WEIGHTS OF GASES

Gas (symbol weight) (symbol)	1 × 22.2 liters 1 g. H	16 g. O	12 g. C	14 g. N	32 g. S	35.5 g. Cl	Formula of gas	Grams of same gas in 22.2 liters
1. Hydrogen chloride	1					1	HCl	36.5
2. Ammonia	3			1			NH_3	17
3. Carbon dioxide		2	1				CO_2	44
4. Carbon monoxide		1	1				CO	28
5. Methane	4		1				CH_4	16
6. Ethylene	4		2				C_2H_4	28
7. Acetylene	2		2				C_2H_2	26
8. Oxygen		2					O_2	32
9. Hydrogen	2						H_2	2
10. Nitrogen				2			N_2	28
11. Chlorine						2	Cl_2	71
12. Sulfur dioxide		2			1		SO_2	64
13. Hydrogen sulfide	2				1		H_2S	34
14. Nitrous oxide		1		2			N_2O	44
15. Nitric oxide		1		1			NO	30

Note: Derivation assumes data available on the percentage composition by chemical elements of each gas and the symbols and symbol weights of the elements contained.

It remains to be noted that, when there is no method available for ascertaining the formula weight of a compound, the *simplest* formula, based on chemical analysis and the use of symbol weights of the contained elements, is used, e.g., ferric oxide, Fe_2O_3, ferroferric oxide, Fe_3O_4, ferrous oxide, FeO, cupric oxide (black copper oxide), CuO, cuprous oxide (red copper oxide), Cu_2O. The customary formula of water is H_2O, which is correct at temperatures above 100°C—actually, liquid water is mainly dihydrol $(H_2O)_2$.

It should be understood from the above discussion that a chemical formula is no chance throwing together of chemical symbols, but represents the results of careful analysis, and the scrutiny and deduction of the most skillful workers in the field. On this score alone, chemical formulas demand the greatest respect in understanding and use.

Symbol weights and atomic weights are used synonymously, as are formula weights and molecular weights. Unless otherwise stated, symbol weights and formula weights are expressed in grams, and the numbers used are those taken from the accepted list of atomic weights. See **Chemical Elements**.

One formula volume of a gas is 22.242 liters. It is necessary to state that actual gases under ordinary conditions show some variation from this value, so that for accurate work the records should be consulted in each case.

Summarizing, the formula "HCl" states that "36.5 grams of hydrogen chloride gas occupies a standard volume of 22.2 liters and is composed of 1 gram of hydrogen element chemically united with 35.5 grams of chlorine element." The reason for the formulas of the simple gases, oxygen, O_2, hydrogen, H_2, nitrogen, N_2, chlorine, Cl_2, is apparent from the general method of deduction. The formula O_2 represents 22.2 liters or 32 grams of oxygen *gas*, whereas O represents 16 grams of oxygen *element* in any substance, or more precisely, 15.9994 grams.

Non-Stoichiometric Compounds

It has become customary in chemical literature to use the formula of a substance as an accepted abbreviation for the name of the substance, especially in cases of frequent repetition.

Up to this point, the discussion in this entry has related to substances that are either elements, or single compounds of elements combined in proportions that can be represented by the ratio of small whole numbers. Such compounds are called *stoichiometric compounds* or *Daltonide compounds* (after the British chemist Dalton). There exist, however, some compounds in which the ratios of the amounts of elements present are not integral. Such compounds are called *non-stoichiometric compounds* or *Berthollide compounds* (after the French chemist Berthollet), and are exemplified by some oxides of the transition elements, by many intermetallic compounds, by the copper sulfide $Cu_{1.7}S$, the copper selenide $Cu_{1.6}$ Se and the cerium hydride $CeH_{2.7}$. Some such compounds vary over a range of composition, depending upon their method of preparation.

In spite of these departures of some compounds from whole number formulas, the fact remains that the great majority of compounds with which the chemist is concerned do contain their constituent elements in integral multiples of their atomic weights. In fact, there is even a further uniformity in the behavior of many of the elements. Thus the great majority of the compounds of the alkali elements (Group 1 in the periodic table) contain equal atomic weight proportions of hydrogen or its equivalent in other elements. Thus the hydrides of this group have compositions corresponding to the formulas LiH, NaH, KH, etc.; the halogen compounds of the group have the compositions, LiF, NaF, KF, LiCl, NaCl, KCl, etc.; while their simple sulfur compounds (since in many of its compounds sulfur combines with two hydrogen equivalents as represented by the formula H_2S) have the compositions Li_2S, Na_2S, K_2S, etc. However, there also exist more complex binary sulfur compounds of these elements, which contain higher proportions of sulfur, so that they combine with sulfur in more than one atomic proportion. Thus this relative combining power, which is called valence, has more than one value for many elements, but is still useful in organizing the data of chemistry. It is discussed at length in the entry on valence, and is explained in structural terms in the entry on molecule.

Radicals

In many chemical compounds there are groups of two or more elements that frequently have the properties of or enter into chemical reaction as a unit. Of those which are of outstanding importance the following are cited:

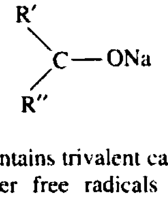
1. Ammonium NH_4—behaves as a unit in ammonium compounds and in some of these compounds is very similar to potassium K—in potassium compounds.
2. Hydroxyl—OH which behaves as a unit in bases (e.g., sodium hydroxide, NaOH), alcohols (e.g., methyl alcohol, CH_3OH), and phenols (e.g., phenol, C_6H_5OH).
3. Anion-groups of acids, their salts and their esters: Sulfate $>SO_4$, sulfite $>SO_3$, nitrate $-NO_3$, nitrite $-NO_2$, phosphate $\rightarrow PO_4$, perchlorate $-ClO_4$, chlorate $-ClO_3$, chlorite $-ClO_2$, hypochlorite $-OCl$, carbonate $> CO_3$, formate $-CHO_2$, acetate $-C_2H_3O_2$, palmitate $-C_{16}H_{31}O_2$, stearate $-C_{18}H_{35}O_2$, oleate $-C_{18}H_{33}O_2$, oxalate $> C_2O_4$, lactate $-C_3H_5O_3$, malate $> C_4H_4O_5$, tartrate $> C_4H_4O_6$, citrate $\rightarrow C_6H_5O_7$, benzoate $-C_7H_5O_2$, cinnamate $-C_9H_7O_2$, phthalate $> C_8H_4O_4$, salicylate $-C_7H_5O_3$.
4. Alkyl- and aryl-groups of alcohols, phenols, their esters and their alcoholates and phenolates: (a) Alkyl (non-benzenoid)-methyl CH_3-, ethyl C_2H_5-, propyl C_3H_7-, butyl $C_4H_8-$and similar radicals of alcohols; (b) Aryl (benzenoid)-phenyl C_6H_5-, tolyl C_7H_7-, xylyl C_8H_9-, naphthyl $C_{10}H_7-$and similar radicals of phenols.
5. Acyl-groups of organic acids: acetyl CH_3CO-, benzoyl C_6H_5CO-.
6. Miscellaneous radicals, for example, cacodyl $(CH_3)_2As-$, celebrated on account of the investigations by Bunsen (1838).

All of the above radicals are associated with a corresponding radical or element in a compound. While a radical frequently and rather generally enters into chemical reaction as a unit, it is not implied that this is always so, the stability in each case is characteristic of each radical and each reaction in which it is involved. Thus, ammonium hydroxide NH_4OH yields ammonia gas NH_3 and water H_2O at room temperature; ammonium nitrate NH_4NO_3 is decomposed, upon heating, with the accompanying disruption of both the ammonium and nitrate radicals to yield nitrous oxide N_2O gas and water H_2O.

Radicals enter widely into reactions involving electrolytic dissociation of salts, acids, bases in water solution.

Radicals exist most commonly in combination with atoms or other radicals. However, they can be produced "free," and can so exist for a finite period. Even when it is very short, the radical itself is often of great interest in elucidating reaction mechanisms. The first free radical discovered was triphenylmethyl.

Gomberg, by treating triphenylmethyl chloride in carbon dioxide, with zinc, silver, or mercury, obtained the free radical, triphenylmethyl. On dissolving the colorless solid in organic solvents a yellow solution is obtained, and the reactivity (due to unsaturation) of the yellow solution is marked towards oxygen, dissolved iodine, ether. Triphenylmethyl is present in solution in two forms, (1) monomolecular $(C_6H_5)_3C$ yellow, in equilibrium with (2) dimolecular $((C_6H_5)_3C)_2$ colorless. But tribiphenylmethyl $(C_6H_5-C_6H_4)_3C$ occurs only in the monomolecular form, purple. The action of alkali metals on ketones in some cases produces metallic ketyl (Schlenk, 1913) thus:



which is a free radical, or contains trivalent carbon as does monomolecular triphenylmethyl. Many other free radicals are known. See also **Free Radical**.

This entry has dealt with two types of chemical composition—elements and compounds. Many materials, including the great majority of those found in nature, are mixtures of compounds and often elements. Practically all biochemical materials and rocks are complex mixtures. Obviously the first step in the determination of the composition of such substances is their separation into the individual compounds, and elements if any, which they contain.

CHEMICAL ELEMENTS. A chemical element may be defined as a collection of atoms of one type which cannot be decomposed into any simpler units by any chemical transformation, but which may spontaneously change into other units by radioactive processes. A chemical element is a substance that is made up of but one kind of atom. Of the over 100 chemical elements known, only 90 are found in nature. The remaining elements have been produced in nuclear reactors and particle accelerators. Theoretical physicists do not all agree, but some believe that fission-stable nuclei should exist at atomic numbers 109, 114, and 126. Claims thus far have been made for the discovery, isolation, or creation of elements up to 110. The element with the highest atomic number officially named and entered into the formal table of atomic weight is darmstadtium (Ds) with an atomic number of 110.

The chemical element group numbering system was officially changed in the mid-1980s. The new notations are used throughout this encyclopedia. For clarification of differences between former IUPAC numbers and prior CAS versions, consult table in the entry on the periodic table.

Some of the principal characteristics of the elements are given in Table 1. All of the 110 elements described on this table also are explained in further detail under individual alphabetical entries throughout this volume. The lanthanide series elements also are described further under **Rare-Earth Elements and Metals**. The platinum group metals are further detailed under **Platinum and Platinum Group**; the refractory metals are detailed under **Niobium**. The great versatility of carbon is described under **Organic Chemistry**. In 1817, Johann Dobereiner noticed that strontium had similar chemical properties to calcium and barium, and that its molecular weight fell midway between the two. Additional work led him to discovering a similar trend for another triad of elements: chlorine, bromine and iodine along with lithium, sodium and potassium. In 1829 he proposed the "Law of Triads" which states that, " nature contains triads of elements where the middle element has properties that are an average of the other two members of the triad when ordered by the atomic weight. It was later noticed that these patterns extended beyond that of a triad and eventually led to the "Law of Octaves" discovered by John Newlands in 1863. This discovery originated from Newlands to classifying the current 56 elements into 11 groups based on similar physical properties. He noticed that many pairs of similar elements existed with atomic weights that differed by a multiple of eight. The Law of Octaves states that any given element will exhibit analogous behaviour to the eighth element following it in the 11 groups. Not much later in 1869 did Dimitri Mendeleev publishing a table from elements with symbols and atomic weights on them, arranged in a periodicity of eight. The resulting matrix arrangement is called the Periodic Table. See also **Periodic Table of the Elements**.

The first listing of the elements is generally attributed to Lavoisier in 1789. Of the twenty elements listed, the discovery of five was the result of research conducted by Scheele of Gothenberg. With the development of nuclear physics and the application of these principles to astronomy and cosmology, in recent years the chemical elements have been viewed from new vantage points with much concentration on physical and nuclear characteristics as well as chemical properties.

Origin of the Elements

An excellent summary of progress made in the study of the origin of the elements was given by Penzias in a lecture delivered in Stockholm when he received the Nobel Prize in Physics in 1978. See reference listed.

Another outstanding account was given in the lecture by William A. Fowler (Kellogg Radiation Laboratory, California Institute of Technology) in his acceptance of the 1983 Nobel Prize in Physics (shared with Chandrasekhar). Although life on Earth depends upon the energy of sunlight (originating from nuclear fusion of hydrogen and helium in the solar interior), the sun did not produce the chemical elements found in the earth. Rather, it is theorized by some scientists that these first two elements and their stable isotopes emerged from the first few minutes of the early

TABLE 1. PRINCIPAL CHARACTERISTICS OF CHEMICAL ELEMENTS

Name	Symbol	Atomic number	Atomic weight	Periodic group[b]	Valency (oxidation state)	Specific gravity (20°C)	Melting point, °C	Boiling point, °C	Discovery (year)
Actinium	Ac	89	227[a]	3	3	10.1	1050	2800–3500	1899
Aluminum	Al	13	26.98	13	3	2.699	660	2467	1827

[a] Mass number of isotope of longest known half-life (or a better known one for Bk, Cf, Po, Pm and Tc).
[b] New Periodic Group notation.
[c] Specific gravity, arsenic: Yellow orpiment form, 1.97; gray metallic form, 5.73.
[d] Specific gravity, boron: Crystalline, 2.34; amorphous, 2.37.
[e] Density, bromine: Gas, 7.59 g/l; liquid, 3.12 g/ml.
[f] Specific gravity, carbon: Amorphous, 1.8 to 2.1; graphite, 1.9 to 2.3; diamond, 3.15 to 3.53 (gem). Melting point, carbon: Natural, 3550°C: graphite sublimes, 3342–3392°C (at 12–13 GPa). Triple point, graphite-liquid-gas, 3577–3677°C (at 10.1 MPa); graphite-diamond-liquid, 3830–3930°C (at 12–13 GPa)
[g] Density, chlorine: 3.2 g/l. Specific gravity (−33.6°C), 1.56.
[h] Density, fluorine: 1.696 g/l (0°C, 1 atm). Specific gravity, 1.108 (at boiling point).
[i] Density helium: 0.1785 g/l (0°C, 1 atm).
[j] Density, hydrogen: Gas, 0.08988 g/l; liquid (−253°C), 70.8 g/l; solid (−262°C), 70.6 g/l.
[k] Density, krypton: 3.7 g/l (0°C).
[l] Specific gravity, manganese: 7.2–7.4, depending on allotropic form.
[m] Density, neon: Gas (0°C. 1 atm), 0.8999 g/l; liquid (at boiling point), 1.207 g/cm^3.
[n] Niobium is sometimes called columbium in the U.S. and a few other countries.
[o] Density, nitrogen: 1.25 g/l. Specific gravity, liquid (−195.8°C), 0.808; solid (−252°C), 1.026.
[p] Density, oxygen (0°C), 1.429 g/l. Specific gravity, liquid (−182.96°C), 1.4.

high-temperature, high-density stage of the expanding Universe (so-called big bang concept). Although it has been theorized that a small quantity of lithium (element 3 in the periodic table) was also produced during the big bang, it has been proposed that the remainder of the Li and all of the beryllium and boron (elements 4 and 5, respectively) were produced by the spallation of still heavier elements in the interstellar medium by the process of cosmic radiation. The fact that these latter elements are relatively rare is consistent with this concept.

Early 1990s studies of very old stars, such as HD140283, brought some surprises. This star, considered so old that it only has about 1% of the oxygen and other heavy elements of the sun, was found by one of the first observations of the Hubbel Space Telescope to contain about 1000 times more beryllium than could be attributed to cosmic radiation. See **Beryllium**.

As pointed out by Fowler, the question remains pertaining to the origin of the heavier elements, namely, those ranging upward from carbon (6) to radioactive uranium (92). The origin of these elements has been attributed to nuclear processes in the interior of stars, particularly in the stars of our own Galaxy and prior to the formation of the solar system (some $4\frac{1}{2}$ billion years ago). The general process is believed to have occurred during a period of some 5 to 15 billion years prior to formation of the solar system and is related to star formation and degradation in our Galaxy during that long period. It is believed that old stars, during their giant stage of stellar evolution, were sources of the heavier elements. Possibly, greater activity occurred during outbursts (*novae*) or stellar explosions (*supernovae*). The current commonly held concept is that the planets of the solar system, including Earth, condensed under the forces of gravitation and rotation from a gaseous solar nebula in the interstellar medium, this medium containing hydrogen and helium (from the big bang) and admixed with the heavier elements synthesized in the earlier generations of galactic stars. It is interesting to note that the abundance of heavy elements in the older galactic stars is less than 1 percent of that found in the solar system. Element building in the manner described is sometimes referred to as the *nucleosynthesis* in stars. It is assumed, of course, that a similar process has occurred and continues to occur in galaxies other than our own, such as the Andromeda Nebula, and that the process is thus universal.

The principal targets of nuclear astrophysics are: (1) an understanding of the energy generation in the sun and other stars at all stages of stellar evolution, and (2) a comprehension of the nuclear processes which caused the relative abundances of the elements and their isotopes in nature. Suess and Urey, in 1956, first systematized the terrestrial, meteoritic, solar, and stellar data that are related to the origins and abundances of the elements. During the interim, these data have been periodically updated by Cameron; major work in the experimental measurement of atomic transition rates required to determine solar and stellar abundances has been contributed by Whaling. Check references at the end of this article. See also Fig. 1(**a**) and (**b**).

The remainder of the Fowler article is of great interest, but in detail that is beyond the scope of this encyclopedia. Topics covered by Fowler include early research on element synthesis; stellar reaction rates from laboratory cross sections; hydrogen burning in main-sequence stars and the solar neutrino problem; synthesis of ^{13}C and ^{16}O and

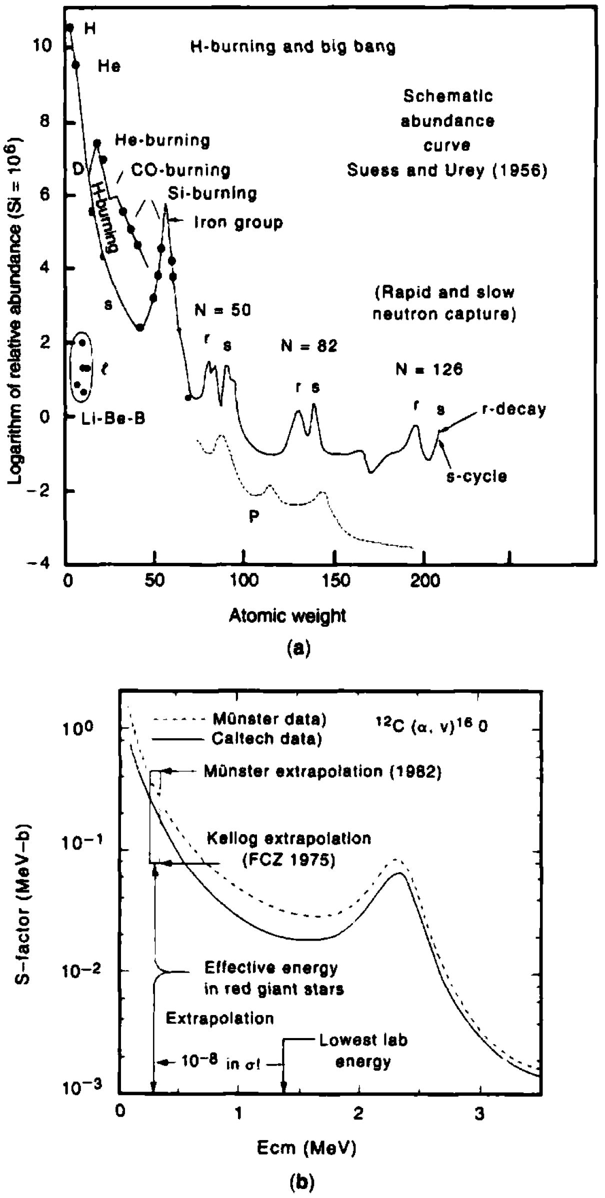

Fig. 1. (**a**) Atomic abundances relative to Si = 10^6 versus atomic weight for the sun and similar main-sequence stars. (**b**) Cross-section factor S (in MeV-varns) versus center-of-momentum energy (in MeV) for $^{12}C(\alpha, \gamma)O$ Dashed and solid curves are theoretical extrapolations of Münster and Kellog Caltech data by Langanke and Koonin (see references). TABLE 1. (*continued*)

[q] Specific gravity, phosphorus: White, 1.82; red, 2.20; black, 2.25 to 2.9. 1.14.
[r] Density, radon: Gas, 9.73 g/l; liquid (−62°C), 4.4.
[s] Specific gravity, rubidium: Solid (20°C), 1.532; liquid (39°C), 1.475.
[t] Specific gravity, selenium: Gray, 4.79; vitreous, 4.28.
[u] Atomic weight of sulfur varies slightly because of naturally occurring isotopes 32, 33, 34, and 36, the total possible variation amounting to ±0.003.
[v] Specific gravity, sulfur: Rhombic, 2.07; monoclinic, 1.957.
[w] Melting point, sulfur: Rhombic, 112.8°C; monoclinic, 119.0°C.
[x] Specific gravity, tin: Gray, 5.75; white, 7.31.
[y] Density, xenon: Gas, 5.89 g/l. Specific gravity (liquid at −109°C), 3.52.

Abbreviations used in table:

est	Estimated
sub	Sublimation temperature
atm	Unit of pressure
fp	Freezing point

Note: Terms such as *alpha*, *gray*, and *white* refer to specific forms of element.

Values for all rare-earth elements furnished by Rare-Earth Information Center, Energy and Mineral Resources Research Institute, Iowa State University, Ames, Iowa.

neutron production in helium burning; carbon, neon, oxygen, and silicon burning; astrophysical weak interaction rates; calculated abundances for $A \lesssim 60$ and comments on explosive nucleosynthesis; isotopic anomalies in meteorites and evidence for ongoing nucleosynthesis; observational evidence for nucleosynthesis in supernovae; neutron-capture processes in nucleosynthesis; and nucleocosmochronology.

In his concluding remarks, Fowler observes; "In spite of the past and current research in experimental and theoretical nuclear astrophysics, the ultimate goal of the field has not been attained. Hoyle's grand concept of element synthesis in the stars will not be truly established until we attain a deeper and more precise understanding of many nuclear processes operating in astrophysical environments. Hard work must continue on all aspects of the cycle: experiment, theory, and observation. It is not just a matter of filling in the details. There are puzzles and problems in each part of the cycle which challenge the basic ideas underlying nucleosynthesis in stars."

Fowler further concludes: "My major theme has been that all of the heavy elements from carbon to uranium have been synthesized in stars. Our bodies consist for the most part of these heavy elements. Apart from hydrogen, we are 65 percent oxygen and 18 percent carbon, with smaller percentages of nitrogen, sodium, magnesium, phosphorus, sulfur, chlorine, potassium, and traces of still heavier elements. Thus, it is possible to say that each one of us and all of us are truly and literally a little bit of stardust."

Abundance of the Chemical Elements

Considering the large number of chemical elements, it is interesting to note that insofar as the earth's crust and the oceans are concerned, and given our knowledge of the cosmos to date, there is far from a uniform distribution of the elements. In fact, the distribution is exceedingly unbalanced with, for example, only nine elements making up 99.25% of the earth's crust. In terms of abundance, many of the materials considered quite common are, in fact, scarce in terms of their percentage of the total materials in the earth's crust. In order of descending occurrence in the earth's crust, all but the very scarce elements are listed in Table 2. The occurrence of these elements in seawater also is given where data are available.

The situation alters considerably in terms of cosmic abundance of the elements, although again the abundance is heavily slanted toward a comparatively few of the total number of elements. In 1952, Harold C. Urey made an estimate of the abundance of the chemical elements in the cosmos, wherein earlier values of V.M. Goldschmidt and Harrison S. Brown were used in the calculations. A base figure of 10,000 for silicon was used, the other elements being expressed in relationship to that base figure. The study indicated that hydrogen (3.5×10^8) is the most likely superabundant element in the cosmos, closely followed by helium (3.5×10^7). Other elements high on the list include oxygen (220,000), nitrogen (160,000), carbon (80,000), and neon (with a range estimated between 9,000 and 240,000). Magnesium, silicon, and iron also are relatively high.

Researchers at California Institute of Technology (Pasadena, California) have been studying the occurrence of various isotopes in the earth's crust as a lead to understanding the mechanics of continental crust formation. A means for determining the time of formation of new crustal segments is paramount to an understanding of how the continental crust was evolved. In this work, they have studied samarium-neodymium and rubidium-strontium isotopic systematics. In a study by Anderson (Seismological Laboratory, California Institute of Technology), more recent estimates of solar composition pose new questions. Compared with earlier findings, the study shows an enrichment of Fe and Ca relative to Mg, Al, and Si. The Fe/Si and Ca/Al atomic ratios are some 30–40% higher than chondritic values as found in chondrules (meteoric stones assumed to be of cosmic origin). Anderson suggests that the new data may require a revision in the estimates of cosmic abundance and the composition of nebula from which the planets accreted-inasmuch as the latter data previously have been based upon chondritic values. If so applied, the earth's mantle would contain about 15% (weight) more of FeO and more $CaMgSi_2O$ than once calculated.

Critical Importance of Certain Elements

The uneven distribution of the chemical elements in the earth's crust causes severe imbalances in their availability for industrial manufacturing uses. Frequently, the largest consuming nations are long distances from elemental sources, as in the case of the United States This clearly indicates the need for the various political entities of the world to stockpile and to project their needs many years in advance. Hence, for obvious reasons, these needs are commonly reflected in foreign policies.

TABLE 2. ABUNDANCE OF THE CHEMICAL ELEMENTS (In Grams/Metric Ton)[a]

Element	Terrestrial Abundance	Occurrence in Seawater	Element	Terrestrial Abundance	Occurrence in Seawater

[a] Presented in order of diminishing terrestrial abundance.

Nuclides, Isotopes, and Isobars

A nuclide may be defined as a species of atoms, with specified atomic number and mass number. The term *nuclide* should be used, *not* isotope. Different nuclides having the same atomic number *are* isotopes. Different nuclides having the same mass number are *isobars*.

A comprehensive listing of the nonradioactive nuclides of the chemical elements is given in Table 3. The isotopic abundance and mass number are given. In all but a few instances, the isotopes listed are stable. The elements also have a number of radioisotopes each, the number varying considerably from one element to the next. Extensive tables also listing the radioactive isotopes, giving lifetime, modes of decay, decay energy, particle energies, particle intensities, and thermal neutron capture cross section, among other factors, can be found in the literature.

An important fact pertaining to naturally occurring elements is that many of them consist of several isotopes and that these isotopes are present in nearly all cases in the same proportion by weight. These constant isotopic compositions have enabled scientists over the years to analyze materials by weight, making reference to a table of atomic weights. In fact, for many years the atomic weight of an element was regarded as its most distinguishing characteristic, even though some discrepancies were noticed in the periodic table. It was not until the work of Mosley on characteristic

[a] Following elements in increasing mass number are all radioactive: Po, At, Rn, Fr, Ra, Ac, Th, Pa, U, Np, Pu, Am, Cm, Bk, Cf, Es, Fm, Md, No, and Element 104 and heavier.

x-ray spectra and the development of positive-ray analysis that the nuclear charge was recognized as the fundamental chemical characteristic of an element. The use of mass spectrography, with other methods of determining the masses of the atoms in a given element and the proportions in which they are present, has permitted the determination of the isotopic composition of the elements.

Sulfur is one of the few exceptions to the constancy of isotopic proportions, in that there is sufficient variation, dependent upon the source of the sulfur, to cause a variation in its atomic mass by approximately $\pm 0.01\%$. For normal stoichiometric calculations, however, this small variation is unimportant.

Naturally occurring elements which do not display any isotopic behavior include aluminum, arsenic, beryllium, bismuth, cobalt, fluorine, gold, helium, holmium, iodine, manganese, niobium (columbium), phosphorus, praseodymium, rhodium, scandium, sodium, terbium, thulium, and yttrium. Elements that have one predominating isotope (in excess of 98%) include argon, carbon, lanthanum, lutetium, nitrogen, oxygen, tantalum, and vanadium. Elements that have several isotopes and in which no one isotope is in excess of 80% of the total include antimony, barium, bromine, chlorine, copper, dysprosium, erbium, gadolinium, gallium, germanium, hafnium, iridium, krypton, lead, magnesium, mercury, molybdenum, nickel, osmium, palladium, platinum, rhenium, rubidium, ruthenium, selenium, silver, tellurium, tin, titanium, tungsten, xenon, ytterbium, zinc, and zirconium. Tin leads with a total of ten isotopes; xenon has nine isotopes; cadmium and tellurium each have eight isotopes.

Radioactive Elements

There are (1) naturally occurring radioactive and (2) artificially produced radioactive elements. There are three series of naturally occurring radioactive elements:

The Actinium Series. This series commences with ^{235}U and ends with the stable isotope ^{207}Pb. The decay scheme is represented by:

$$^{235}\mathrm{U} \xrightarrow{\alpha}$$

$$^{231}\mathrm{Th} \xrightarrow{\beta} {}^{231}\mathrm{Pa} \xrightarrow{\alpha} {}^{227}\mathrm{Ac} \xrightarrow{\beta\ and\ \alpha} {}^{227}\mathrm{Th} \xrightarrow{\alpha} {}^{223}\mathrm{Fr} \xrightarrow{\beta} {}^{223}\mathrm{Ra}$$

$$\xrightarrow{\alpha} {}^{219}\mathrm{Rn} \xrightarrow{\alpha} {}^{215}\mathrm{Po} \xrightarrow{\alpha\ and\ \beta} {}^{211}\mathrm{Pb} \xrightarrow{\beta} {}^{215}\mathrm{At} \xrightarrow{\alpha} {}^{211}\mathrm{Bi} \xrightarrow{\beta\ and\ \alpha}$$

$$^{211}\mathrm{Po} \xrightarrow{\alpha} {}^{207}\mathrm{Tl} \xrightarrow{\beta} {}^{207}\mathrm{Pb}\ \text{(stable).}$$

The Thorium Series. This series commences with ^{232}Th and ends with the stable isotope ^{208}Pb. The decay scheme is represented by:

$$^{232}\mathrm{Th} \xrightarrow{\alpha}$$

$$^{228}\mathrm{Ra} \xrightarrow{\beta} {}^{228}\mathrm{Ac} \xrightarrow{\beta} {}^{228}\mathrm{Th} \xrightarrow{\alpha} {}^{224}\mathrm{Ra} \xrightarrow{\alpha} {}^{220}\mathrm{Rn} \xrightarrow{\alpha} {}^{216}\mathrm{Po}$$

$$\xrightarrow{\alpha} {}^{212}\mathrm{Pb} \xrightarrow{\beta\ and\ \alpha} {}^{216}\mathrm{At} \xrightarrow{\alpha} {}^{212}\mathrm{Bi} \xrightarrow{\beta\ and\ \alpha} {}^{212}\mathrm{Po} \xrightarrow{\alpha} {}^{208}\mathrm{Tl} \xrightarrow{\beta}$$

$$^{208}\mathrm{Pb}\ \text{(stable).}$$

The Uranium-Radium Series. This series commences with ^{238}U and ends with the stable isotope ^{206}Pb. The decay scheme is represented by:

$$^{238}\mathrm{U} \xrightarrow{\alpha} {}^{234}\mathrm{Th} \xrightarrow{\beta} {}^{234}\mathrm{Pa} \xrightarrow{\beta} {}^{234}\mathrm{U} \xrightarrow{\alpha} {}^{230}\mathrm{Th} \xrightarrow{\alpha} {}^{226}\mathrm{Ra}$$

$$\xrightarrow{\alpha} {}^{222}\mathrm{Ra} \xrightarrow{\alpha} {}^{218}\mathrm{Po} \xrightarrow{\alpha\ and\ \beta} {}^{214}\mathrm{Pb} \xrightarrow{\beta} {}^{218}\mathrm{At} \xrightarrow{\alpha} {}^{214}\mathrm{Bi} \xrightarrow{\beta\ and\ \alpha}$$

$$^{214}\mathrm{Po} \xrightarrow{\alpha} {}^{210}\mathrm{Tl} \xrightarrow{\beta} {}^{210}\mathrm{Pb} \xrightarrow{\beta} {}^{210}\mathrm{Bi} \xrightarrow{\beta\ and\ \alpha} {}^{210}\mathrm{Po} \xrightarrow{\alpha} {}^{206}\mathrm{Tl}$$

$$\xrightarrow{\beta} {}^{206}\mathrm{Pb}\ \text{(stable).}$$

In the foregoing series, the type of radiation given off during the decay process is indicated above the arrows.

The production of artificially produced radioactive elements dates back to the early work of Rutherford in 1919 when it was found that alpha particles reacted with nitrogen atoms to yield protons and oxygen atoms. Curie and Joliot found (1933) that when boron, magnesium, or aluminum were bombarded with alpha particles from polonium, the elements would emit neutrons, protons, and positrons. They also found that upon cessation of bombardment the emission of protons and neutrons stopped, but that the emission of positrons continued. The targets remained radioactive. They also found that the radiation emitted dropped off exponentially as would be expected from a naturally occurring radioactive element. Further investigation indicated that nuclear reactions lead to the formation of radioactive isotopes. This and subsequent work by several investigators led to the formulation of another series of radioactive elements, namely, the Neptunium Series, which commences with ^{245}Cm (curium) and ends with the stable isotope 209Bi. The decay scheme is represented by: ^{245}Cm

$$\xrightarrow{\alpha} {}^{241}\mathrm{Pu} \xrightarrow{\beta} {}^{241}\mathrm{Am} \xrightarrow{\alpha} {}^{237}\mathrm{Np} \xrightarrow{\alpha} {}^{233}\mathrm{Pa} \xrightarrow{\beta} {}^{233}\mathrm{U}$$

$$\xrightarrow{\alpha} {}^{229}\mathrm{Th} \xrightarrow{\alpha} {}^{225}\mathrm{Ra} \xrightarrow{\beta} {}^{225}\mathrm{Ac} \xrightarrow{\alpha} {}^{221}\mathrm{Fr} \xrightarrow{\alpha} {}^{217}\mathrm{At} \xrightarrow{\alpha}$$

$$^{213}\mathrm{Bi} \xrightarrow{\beta\ and\ \alpha} {}^{213}\mathrm{Po} \xrightarrow{\alpha} {}^{209}\mathrm{Tl} \xrightarrow{\beta} {}^{209}\mathrm{Pb} \xrightarrow{\beta} {}^{209}\mathrm{Bi}\ \text{(stable).}$$

A *radioactive element* is an element that disintegrates spontaneously with the emission of various rays and particles. Most commonly, the term denotes radioactive elements such as radium, radon (emanation), thorium, promethium, uranium, which occupy a definite place in the periodic table because of their atomic number. The term *radioactive element* is also applied to the various other nuclear species, (which are produced by the disintegration of radium, uranium, etc.) including the members of the uranium, actinium, thorium, and neptunium families of radioactive elements, which differ markedly in their stability, and are isotopes of elements from thallium (atomic number 81) to uranium (atomic number 92), as well as the partly artificial actinide group, which extends from actinium (atomic number 89) to lawrencium (atomic number 103), and includes the following transuranic elements: neptunium (atomic number 93), plutonium (atomic number 94), americium (atomic number 95), curium (atomic number 96), berkelium (atomic number 97), californium (atomic number 98), einsteinium (atomic number 99), fermium (atomic number 100), mendelevium (atomic number 101), nobelium (atomic number 102). The radioactive nuclides produced from nonradioactive ones are discussed under **Radioactivity**.

A radioactive element may be designated as being in a *collateral series*. In addition to the three main natural and one artificial disintegration series of radioactive elements, each has been found to have at least one parallel or collateral series. The main series and the collateral series have different parents, but become identical in the course of disintegration, when they have a member in common.

Superheavy and Transactinide Elements

Those elements with an atomic number above 103 are sometimes referred to as the *transactinide elements*; and those with atomic (proton) numbers $Z \geq 110$ are sometimes called *superheavy elements* (SHEs). Considerable research has been concentrated on synthesizing elements heavier than 103. The last of the elements to be synthesized with positive proof of identity, timing of research, and place and persons associated with discovery—and thus relatively little controversy pertaining to the naming of the element—was lawrencium (103), discovered by Ghiorso, Sikkeland, Laesh, and Latimer in March 1961 at Berkeley. Research in this direction had been underway in the early 1960s at the Joint Nuclear Research Institute at Dubna (Russia). The half-lives of the Lr isotopes range from 8 to 35 seconds, enabling researchers to use solvent extraction techniques for determining the chemical characteristics and atomic number of the element. However, with the possible exception of a predicted *island of stability*, as one goes up the scale of heavier elements, the half-lives appear to become progressively shorter, making chemical separation, needed for identifying the atomic number of any laboratory-produced superheavy nucleus, increasingly difficult. Much research has been directed toward improving these techniques and, as of the late 1980s, methodology is available to cope with nuclei having a half-life of 1 second or greater. Separation techniques include the ion exchange behavior of the bromide complexes of the elements; and the ease with which the elements coprecipitate with cupric sulfide (Seaborg-Loveland-Morrissey, 1979).

Applying modern theories of nuclear structure, scientists working in the late 1960s and early 1970s made calculations that showed for superheavy elements in the vicinity of $Z = 114$ (proton number) and $N = 184$ (neutron number), ground states of nuclei were stabilized against fission. As pointed out in the aforementioned reference, "This stabilization was due to the complete filling of major proton and neutron shells in this region and

is analogous to the stabilization of chemical elements, such as the noble gases by the filling of their electronic shells." Some of the calculations indicated that the half-lives of some of these superheavy nuclei might be on the order of the age of the universe. This observation, of course, was stimulating to further research. Calculations indicated that there should be an island of relative stability, which would extend above the *Z* and *N* figures previously given. The calculations also showed that between the presently known elements and these stable superheavy elements, there would be an intervening region of instability.

Although beyond the scope of this volume, in the early 1930s a new mechanism for the interaction of heavy ions was discovered. The method, known as *deep inelastic scattering*, involves a massive transfer of energy and nucleons between the projectile and the target.

A team of researchers from the Oak Ridge National Laboratory, the University of California (Davis, California), and Florida State University reported an x-ray spectrum in June 1976 that appeared to confirm the existence of superheavy elements with atomic numbers near 126. For a short period, this finding created much interest in the scientific community—mainly because the atomic numbers reported were much greater than might be expected at that stage of research, and, possibly of even greater interest, because the findings were based upon the elements being part of monazite crystals believed to be about 1 billion years old, thus giving rise to the previous mention of their life on the order of the age of the universe. Further confirmatory proof was lacking, capped by the finding of a researcher at Florida State University who showed that a gamma ray with the same energy as the x-ray peak for "element 126" is emitted when an excited praseodymium nucleus relaxes after being created from cerium during bombardment by protons. It is noteworthy that cerium is a major constituent of monazite.

Element 104

[CAS: 53850-36-5]. Rutherfordium. Researchers at Dubna (Russia), in 1964, bombarded plutonium with accelerated 113–115 MeV neon ions. During this process, an isotope that decayed by spontaneous fission was observed. It was reported that the isotope had a half-title of 0.3 ± 0.1 second and it was reasoned that the isotope was ^{260}104, resulting from $_{94}^{242}Pu + _{10}^{22}Ne \longrightarrow {}^{260}104 + 4n$. Although subsequent work toward chemically separating the new element from all others has not been conclusive, considerable evidence for evaluation has been obtained. Estimates of the half-life of the element have been reduced from the prior 0.3 second to 0.15 second. Ghiorso, Nurmia, Harris, K. Eskola, and P. Eskola (University of California, Berkeley) reported in 1969 the positive identification of two and possibly three isotopes of the element. The Berkeley discovery resulted from bombarding a target of ^{249}Cf with ^{12}C nuclei of 71 MeV, and ^{13}C nuclei of 69 MeV. The first combination resulted in the instant emission of four neutrons to produce ^{257}104. The isotope was reported to have a half-life of 4–5 seconds. Decay was by emission of an alpha particle into ^{253}No with a half-life of 105 seconds. In further research, several thousand atoms of ^{257}104 and ^{259}104 were produced. Thus far, the Dubna workers have proposed the name *kurchatovium* (Ku): and the Berkeley group has suggested *rutherfordium* (Rf). The name *rutherfordium* (Rf) has been adopted for element 104 in honor of Ernest R. Rutherford.

Element 105

[CAS: 53850-35-4]. Dubnium. In 1967, workers at Dubna (Russia) reported producing a few atoms of element ^{260}105 and ^{261}105, as the result of bombarding ^{243}Am with ^{22}Ne. Appropriate confirmations of identification, however, were lacking, the evidence being based upon time-coincidence measurements of alpha energies. In 1970, it was reported that the Dubna researchers had investigated all the types of decay of the new element and had determined its chemical properties. As of that time, the Dubna group had not proposed a name for element 105. Ghiorso, Nurmia, Harris, K. Eskola, and P. Eskola (University of California, Berkeley) reported a positive identification of element 105. This resulted from bombarding a target of ^{249}Cf with 84-MeV nitrogen nuclei. Upon absorption of ^{15}N nuclei by a ^{249}Cf nucleus, four neutrons are emitted, forming element ^{260}105, with a half-life of 1.6 seconds.

In October 1971, Ghiorso and co-workers at Berkeley, using the heavy ion linear accelerator, announced production of element ^{261}105 by bombarding ^{250}Cf with ^{15}N and by bombarding ^{249}Bk with ^{16}O. The isotope emits 8.93-MeV alpha particles, decaying to ^{257}Lr with a half-life of about 1.8 second. Element ^{262}105 was produced by bombarding ^{249}Bk with ^{18}O. This isotope emits 8.45-MeV alpha particles and decays to ^{258}Lr, with a half-life of about 40 seconds. Element 105 has been name Dubnium (Db) after the location of the Joint Institute for Nuclear Research where the element was created.

Element 106

[CAS: 54038-81-2]. Seaborgium. In late 1974, two groups announced the synthesis of the 14th transurium element, namely, element number 106 (ekatungsten). The Russian group at Dubna bombarded a target of lead atoms with ions of various weights. Argon ions were used to form a short-lived isotope of fermium which decayed by spontaneous fission. After this trial, the Soviet group used ions of titanium to produce a similarly short-lived isotope of element 104. Then, the Soviet scientists finally used ions of chromium to produce what they believe to be element 106. This presumed element is described as having 151 or 152 neutrons, and decays by spontaneous fission with a half-life of about 4 to 10 milliseconds. The Russian scientists claim that the chromium and lead will combine to form element 106.

An American group at the University of California's Lawrence Berkeley Laboratory, using the modified super-HILAC accelerator (heavy ion linear accelerator) to bombard a target of californium-249 with ions of oxygen-18, caused the oxygen ions to combine with molecules in the target, releasing four neutrons per collision and producing eka-tungsten-263. It is reported that this isotope of element 106 has a half-life of 0.9 second. Contrary to earlier predictions, it does not decay by spontaneous fission, but emits an alpha particle with an energy of 9.06 MeV to become an isotope of element 104. The previously observed daughter isotope emits an alpha particle with an energy of 8.8 MeV, becoming nobelium-255. The latter, in turn, emits an alpha particle with an energy of 8.11 MeV. The American scientists believe that observation of this complete sequence of transmutations is conclusive proof of the formation of eka-tungsten. The American team first observed element 106 in 1970, but lead impurities in the target presented difficulties in providing conclusive evidence of the existence of the new element. The HILAC accelerator was shut down shortly after the experiment and two years were required for the improvements that resulted in the super-HILAC. Then other experiments were given a higher priority. Thus there was an approximately four-year delay in the American experiments. The isotope of element 106 synthesized at Berkeley contains 157 neutrons.

Element 106 has been named Seaborgium (Sb) in honor of the Glenn T. Seaborg, the father of nuclear chemistry and discoverer of plutonium.

Element 107

[CAS: 54037-14-8]. Bohrium is a chemical element in the periodic table that has the symbol Bh and atomic number 107. It is a synthetic element whose most stable isotope, Bh-262, has a half-life of 102 ms. It was synthesized in 1976 by a Soviet team led by Y. Oganessian at the Joint Institute for Nuclear Research at Dubna, who produced isotope 261 Bh with a half-life of 1–2 ms (later data give a half life of around 10 ms). They did this by bombarding bismuth-204 with heavy nuclei of chromium-54. In 1981 a German research team led by P. Armbruster and G. Münzenberg at the Gesellschaft für Schwerionenforschung (Institute for Heavy Ion Research) at Darmstadt were also able to confirm the Soviet team's results and produce bohrium, this time the longer-lived Bh-262. The Germans suggested the name nielsbohrium to honor the Danish physicist Niels Bohr. The Soviets had suggested this name be given to element 105 (dubnium). There was an element naming controversy as to what the elements from 101 to 109 were to be called; thus IUPAC adopted unnilseptium (symbol Uns) as a temporary name for this element. In 1994 a committee of IUPAC recommended that element 107 be named bohrium. While this conforms to the names of other elements honoring individuals, where only the surname is taken, it was opposed by many who were concerned that it could be confused with boron. Despite this, the name bohrium for element 107 was recognized internationally in 1997.

Element 108

[CAS: 54037-57-9]. Hassium is a chemical element in the periodic table that has the symbol Hs and atomic number 108. It is a synthetic element whose most stable isotope is Hs-265, with a half-life of 2 ms. It was first synthesized in 1984 by a German research team led by Peter Armbruster and Gottfried Münzenberg at the Institute for Heavy Ion Research at Darmstadt. The name hassium was proposed by them, derived from the

Latin name for the German state of Hessen where the institute is located. There was an element naming controversy as to what the elements from 101 to 109 were to be called; thus IUPAC adopted unniloctium (symbol Uno) as a temporary name for this element. In 1994 a committee of IUPAC recommended that element 108 be named hahnium. The name hassium was adopted internationally, however, in 1997.

Element 109

[CAS: 54038-01-6]. Meitnerium is a chemical element in the periodic table that has the symbol Mt and atomic number 109. It is a synthetic element whose most stable isotope is Mt-266 with a half-life of 3.4 ms. Meitnerium was first synthesized on August 29,1982 by a German research team led by Peter Armbruster and Gottfried Münzenberg at the Institute for Heavy Ion Research at Darmstadt. The team did this by bombing a target of bismuth-209 with accelerated nuclei of iron-58. The creation of this element demonstrated that nuclear fusion techniques could be used to make new, heavy nuclei. The name meitnerium was suggested in honor of the Austrian-Swedish physicist and mathematician Lise Meitner, but there was an element naming controversy as to what the elements from 101 to 109 were to be called; thus IUPAC adopted unnilennium (symbol Une) as a temporary, systematic element name. However in 1997 they resolved the dispute and adopted the current name.

Element 110

[CAS: 54083-77-1]. Darmstadtium (formerly Ununnilium) is a chemical element in the periodic table that has the symbol Ds and atomic number 110. It has an atomic weight of 271 making it one of the super-heavy atoms. It is a synthetic element and decays in thousandths of a second. Due to its presence in Group 10 it is believed to be likely to be metallic and solid. It was first created on November 9,1994 at the Gesellschaft für Schwerionenforschung (GSI) in Darmstadt, Germany. It has never been seen and only a few atoms of it have been created by the nuclear fusion of isotopes of lead and nickel in a heavy ion accelerator (nickel atoms are the ones accelerated and bombarded into the lead). Scientists are not always serious, so some suggested the name *policium* for the new element, because 110 is the telephone number of the German police. The element was named after the places of its discovery, Darmstadt (actually, the GSI is located in Wixhausen, a small suburb north of Darmstadt). The new name was given to it by the IUPAC in August 2003.

Allotropes. Some of the elements exist in two or more modifications distinct in physical properties, and usually in some chemical properties. Allotropy in solid elements is attributed to differences in the bonding of the atoms in the solid. Various types of allotropy are known. In *enantiomorphic allotropy*, the transition from one form to another is reversible and takes place at a definite temperature, above or below which only one form is stable, e.g., the alpha and beta forms of sulfur. In *dynamic allotropy*, the transition from one form to another is reversible, but with no definite transition temperature. The proportions of the allotropes depend upon the temperature. In *monotropic allotropy*, the transition is irreversible. One allotrope is metastable at all temperatures, e.g., explosive antimony.

Examples of allotropes include:

Arsenic with four forms, metallic, yellow, gray, and brown.
Boron with two forms, crystalline and amorphous.
Carbon with fiveforms, amorphous, diamond, graphite, buckmeister-fullerenes, and nanotubes.
Phosphorus with four forms, two white forms, a violet, and a black form. Red phosphorus is a mixture of the white and violet forms.
Selenium with four forms, amorphous, two crystalline monoclinic forms (red), and the stable, crystalline gray metallic form.
Sulfur with two forms, alpha-rhombic sulfur with a density of 2.07 and a mp of 112.8°C, and beta-monoclinic sulfur with a density of 1.96 and a mp of 119°C. The beta form changes to the alpha form below 96°C.

In the case of some of the less common elements, impure forms have been mistaken in the past as allotropic forms. A number of elements that once were considered to exist in both crystalline and amorphous forms have been found to exist in only one form when perfectly pure.

Gaseous Elements. Several gaseous elements (at standard conditions of temperature and pressure) form molecules of two atoms each. These are known as *diatomic gases*. Included in this category are hydrogen, H_2, nitrogen, N_2, oxygen, O_2, and chlorine, Cl_2. The inert gases, helium, neon, argon, krypton, and xenon, are *monatomic gases* and their symbols do not carry a subscript.

Atomic Structure of the Elements

The internal structure of an atom consists of electrons moving within a region having a diameter slightly greater than 10^{-8} cm and of protons and neutrons that are confined to a nucleus at the center of the electron distribution in a region having a diameter of about 10^{-12} cm. The electrons of a neutral atom are sufficient in number so that their total negative charge is equal to the positive charge on the nucleus. For example, atoms of the element hydrogen have in their neutral state a single electron moving about a nucleus, which has a positive charge equal to the negative charge of an electron. Helium, which has two electrons moving about its nucleus, has a positive charge on its nucleus equal to twice one electronic charge and lithium, which has three electrons moving about its nucleus, has a positive charge on its nucleus of three electronic charges. One basis for the classification of atoms is by those numbers which correspond to the number by which the charge on the hydrogen nucleus must be multiplied to equal the nuclear charge of the atom in question. These numbers, ranging from one, for hydrogen, to 110, for darmstadtium, are called atomic numbers.

The atomic number may be defined as the number of protons in an atomic nucleus, or the positive charge of the nucleus, expressed in terms of the electronic charge. Atomic number usually is denoted by the symbol Z. In the symbolic designation of individual nuclides, the atomic number sometimes is written as a subscript to the left of the chemical symbol of the atomic species, such as ${}_8^{16}O$ for the oxygen isotope of mass number 16. This usage is redundant, in that the chemical symbol per se specifies the atomic number of the nuclide.

Besides nuclear charge, atoms also differ in their masses. The mass is determined by the number of protons Z and the number of neutrons N in the atomic nucleus. The total number of nuclear particles, $Z + N$, in an atomic species is known as its mass number A.

The nuclear model for an atom is of relatively recent origin for, at the beginning of the twentieth century, J.J. Thomson's "plum-pudding" model of an atom was the more generally accepted version. In this model Thomson supposed that the positive charge forms a plasma that is distributed throughout the atomic volume and that the electrons are mixed into this plasma with a relatively uniform distribution. E. Rutherford proposed the nuclear model on the basis of experimental work by H. Geiger and E. Marsden in which they observed that a small number of alpha particles from a naturally occurring radioactive source are scattered through angles greater than 90° by thin foils of gold and silver. Although some small-angle scattering is predicted by the Thomson model, such large-angle scattering is not at all expected. Large-angle scattering is, however, completely consistent with the idea that the alpha particles interact with point positively charged objects of large mass at the center of each gold and silver atom.

Subsequently (1913), N. Bohr found that he could use the Rutherford nuclear model to explain in almost complete detail the observed spectrum of hydrogen (see **Atomic Spectra**). Bohr proposed that, in a neutral hydrogen atom, a single electron revolves in a stationary orbit around a point nucleus that has a charge $+e$. This electron is held in its orbit by the electrostatic force between the positive charge on the nucleus and its own negative charge. The stationary-orbit assumption was classically unsatisfactory but necessary to account for the behavior of the electron. If the laws of classical electrodynamics, according to which accelerated charges must be sources of electromagnetic radiation, were strictly obeyed, the electron would gradually lose energy; hence it would revolve in orbits of smaller and smaller radii and eventually fall into the nucleus. Furthermore, Bohr postulated that the magnitude of the orbital angular momentum of each stationary orbit is $L = nh/2\pi = n\hbar$, where n is an integer, h is Planck's constant, and $n\hbar$ is simply an abbreviated form for/2π.

The angular momentum of an electron moving in an orbit of the type described by Bohr is an axial vector $\mathbf{L} = \mathbf{r} \times \mathbf{p}$, formed from the radial distance $\mathbf{r}$ between electron and nucleus and the linear momentum $\mathbf{p}$ of the electron relative to a fixed nucleus. Figure 2 shows the customary method used to illustrate the axial vector $\mathbf{L}$ in terms of the orbital motion of any object, of which the electron of the Bohr atom is only one example. Although Bohr's planetary model needed only circular orbits to explain the spectral lines observed in the spectrum of a hydrogen atom, subsequent

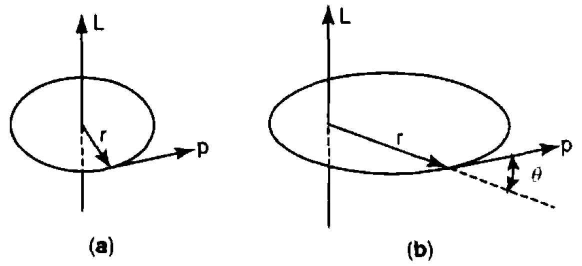

Fig. 2. Direction of angular momentum vector is perpendicular to plane formed by radial vector **r** and momentum vector **p**

development of similar models for other atoms containing more than a single electron needed elliptically shaped orbits to explain the observed spectra. For such orbits **r** and **p** are usually not perpendicular to each other, so that the magnitude $\mathbf{L} = \mathbf{r} \times \mathbf{p}$ is $rp \sin \theta$.

A significant change in the theoretical treatment of atomic structure occurred in 1924 when Louis de Broglie proposed that an electron and other atomic particles simultaneously possess both wave and particle characteristics and that an atomic particle, such as an electron, has a wavelength $\lambda = h/p = h/mv$. Shortly thereafter, C.J. Davisson and L.H. Germer showed experimentally the validity of this postulate. De Broglie's assumption that wave characteristics are inherent in every atomic particle was quickly followed by the development of quantum mechanics. In its most simple form, quantum mechanics introduces the physical laws associated with the wave properties of electromagnetic radiation into the physical description of a system of atomic particles. By means of quantum mechanics a much more satisfactory explanation of atomic structure can be developed.

The quantity n introduced by Bohr in his description of the hydrogen atom is what is called a quantum number. These numbers enter quite naturally from quantum-mechanical descriptions of atomic energy states, including nuclear states. In quantum-mechanical descriptions of atoms, the number n characterizes a limited number of electron states that have very nearly the same energy. A group of electrons in an atom with a common value of n are usually said to be in a single shell of the atom. In the simple two-body problem of the hydrogen atom, all states having the same value of n have the same energy, but in multielectron atoms there are interactions between individual pairs of electrons as well as between electrons and the atomic nucleus. The result is a limited spread in energy between the most-tightly bound and the least-tightly bound electron with the same value of n. Except for $n = 1$, more than one orbital angular momentum state is possible for each shell. Each such state is described by a quantum number l, which can have only whole-number values between zero and $n - 1$. The number n is usually called the principal quantum number and l the orbital angular momentum, or sometimes azimuthal, quantum number. In addition to its characteristic angular momentum, each electron spins on an axis, such that it also has a spin angular momentum, described by a quantum number s. Because all electrons are identical, s has only one value, $\frac{1}{2}$.

In the development of the concepts of atomic structure much of the experimental evidence came from optical and x-ray spectroscopy. From this work certain notations have arisen that are now an accepted part of the language. For example, the $n = 1$ shell is sometimes known as the K-shell, the $n = 2$ shell as the L-shell, the $n = 3$ shell as the M-shell, etc., with consecutively following letters of the alphabet being used to designate those shells with successively higher principal quantum numbers. A Roman numeral subscript further subdivides the shells in accordance with the n, l, and j quantum numbers of the electrons, as shown in Table 4.

A letter notation has been given to the different orbital angular momentum states by optical spectroscopists. In this notation an $l = 0$ state is called an s state (not to be confused with the s used as a quantum number for spin, and which can usually be distinguished from the way it is used), an $l = 1$ state is a p state an $l = 2$ a d state, an $l = 3$ state an f state, with consecutively higher letters above f in the alphabet designating each succeeding value of l. A number often accompanies the state designation to indicate the appropriate value of n. For example, a $3p$ level is an $n = 3$, $l = 1$ state.

Electrically neutral atoms with nuclear charge $Z > 1$ are not hydrogen-like, but have more than a single orbital electron. With more than one electron in an atom, it is necessary to determine the relationship of one electron to its neighbors. A clue to this relationship is found from the observation that the energy required to remove a second electron from an atom is greater than that required to remove the first electron and the energy so required increases with each succeeding electron that is removed. In other words, the potential energy that holds some electrons in an atom is much greater than the energy that holds other electrons in the same atom. From the results of the detailed observations, Pauli formulated a principle, the Pauli Exclusion Principle, which states that no two electrons within the same atom may have exactly the same wave function and, on this basis, that no two electrons in the same atom may have the same set of quantum numbers. Thus, if a particular configuration state in an atom is occupied by an electron, that state is forbidden to all other electrons. If each electron falls into the lowest possible energy state, the next electron to enter must remain in some higher energy state. Acceptance of this principle allows us to classify observed spectral characteristics of the radiation emitted by atoms in such a way that we can determine within reasonable limits the number of electrons in each shell or subshell of the atom producing the radiation. The electron configurations in the known atomic species are shown in Table 5, in which the atoms are ordered in accordance with their atomic numbers Z. Generally the innermost (lower quantum number) shells are filled with all the electrons allowed. For example, neon has two $1s$ electrons, two $2s$ electrons, and six $2p$ electrons, such that its K ($n = 1$) and L ($n = 2$) shells are both filled. An atom with Z having a magnitude one greater than neon, which is sodium, also has both the K and L shells filled; thus there is no space for another electron to go into either of these shells, and its additional electron must go into the M ($n = 3$) shell. Shells with higher values of the orbital angular momentum quantum number l are sometimes partially shielded electrically from the nucleus by other electrons in such a way that their binding energies are not as great as the lower orbital angular momentum subshells associated with the next higher principal quantum number. Thus, as can be seen in Table 5, the $5s$ subshell is filled in atomic species of lower Z than any of those that have any $4f$ electrons.

TABLE 4. IDENTIFICATION OF ATOMIC SHELLS

X-ray notation	Corresponding quantum numbers n	l	j	X-ray notation	Corresponding quantum numbers n	l	j

L_{III}	2	1	$\frac{1}{2}$	N_{III}	4	1	$\frac{3}{2}$
M_I	3	0	$\frac{1}{2}$	N_{IV}	4	2	$\frac{3}{2}$
M_{II}	3	1	$\frac{1}{2}$	N_V	4	2	$\frac{5}{2}$
M_{III}	3	1	$\frac{3}{2}$	N_{VI}	4	3	$\frac{5}{2}$
M_{IV}	3	2	$\frac{3}{2}$	N_{VII}	4	3	$\frac{5}{2}$

The periodic table of elements can be described in terms of the similarities and differences of the angular momentum characteristics of the various atomic species. For example, similar but not identical chemical properties are observed for a number of elements that have all but one of their electrons in filled shells, with the extra electron being a single s electron. In the periodic table, lithium, sodium, potassium, rubidium, and cesium all have this characteristic and thus are placed in a single column. Other groups of atomic species that have similar electron configurations in their outermost shell are arranged in the periodic table in the same chemical grouping. See also **Periodic Table of the Elements**.

Motions of charged particles are expected to establish magnetic fields that interact with each other. As a result, coupling between spin and orbital angular momenta of a single electron or coupling between angular momenta of different electrons in a single atom is expected. The spin-orbit coupling of a single electron results in a total angular momentum state, described by a total quantum number j, such that either $j = l + \frac{1}{2}$ or $j = l - \frac{1}{2}$. Quantum-mechanical solutions show that the magnitude of the orbital angular momentum is $l^*h = [l(l + 1)]^{1/2}h$, not l, as would be expected if we had followed the simpler assumption of the Bohr model. *Similarly, the* magnitude of the spin and total angular momenta are $s^* = [s(s + 1)]^{1/2}$

and $j^* = [j(j+1)]1/2$, respectively. Coupled spin and orbital angular momenta thus do not align themselves in a linear pattern but in such a way that the spin and orbital angular momenta precess around the direction of the total angular momentum, as shown in Fig. 3. A similar precession around the direction of the resultant angular momentum state is found, as we shall find later, in the coupling of any two or more angular momentum states into a single common system.

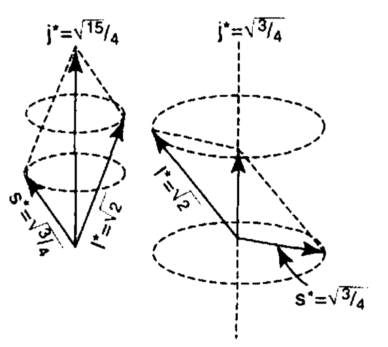

Fig. 3. Magnitudes and directions of the angular momentum vectors for an $l = 1$, $s = \frac{1}{2}$ electron in an atomic energy state

Without some external influence, angular momentum states have no preferred orientation in space because the only interacting magnetic fields are entirely within the individual atom. An external magnetic field, however, may couple to the magnetic field of an atomic angular momentum state of the type described in the preceding paragraphs. In coupling to the total angular momentum, for example, only a limited number of orientations of j^*h are possible, these being such that their projections in the direction of the magnetic field have magnitudes m_j in which m_j, a magnetic quantum number, can have only those whole-number values for which $m_j \leq j$. Thus $2j + 1$ orientations, as illustrated in Fig. 4 for $j = \frac{3}{2}$, are possible. Note that the vector representing the total angular momentum is not parallel to the direction of the applied magnetic field. As a result, the total angular momentum vector processes around the direction of the magnetic field such that the component of the total angular momentum that is perpendicular to the direction of the magnetic field has a time-averaged value of zero and the only component that can be observed with an external detecting device is that component parallel to the direction of the external magnetic field. A magnetic field of this type splits a set of levels characterized by a quantum number j, all of which initially have the same energy, into $2j + 1$ components. The nature of this level splitting is deduced from observations of the splitting of characteristic line spectra, in which case an originally monoenergetic radiation is split by the magnetic field into several components that are usually relatively closely spaced in wave length. The observed effect is known as the Zeeman effect. See also **Zeeman Effect**.

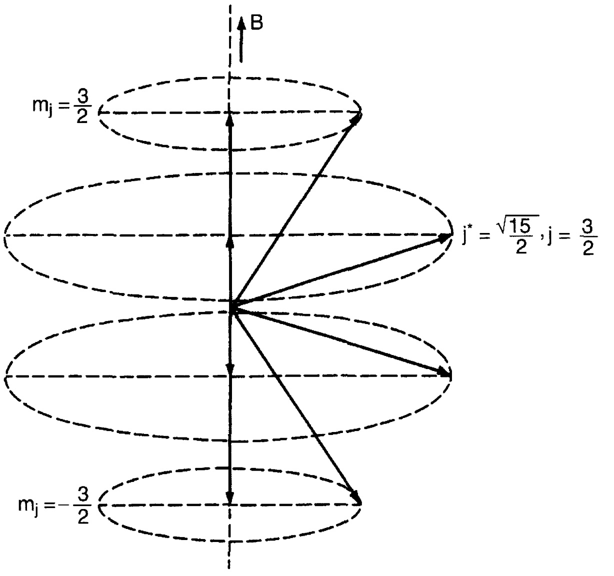

Fig. 4. Possible orientations of the total angular momentum vector **i** relative to the direction of an externally applied magnetic field B and the magnitudes of the associated magnetic quantum state vectors $\mathbf{m}_j$

The use of axial vectors to describe states of an atom in terms of a coupling between the angular momentum inherent in the electrons of the atom forms what is commonly called the *vector model* of the atom. The type of coupling just described forms the basis for the j-j coupling model. Such coupling is found between electrons that produce the optical radiation in the higher Z atomic systems. In these systems the total angular momentum j^* formed by the coupling of the spin and orbital angular momentum states of individual electrons are further coupled within any single shell of an atom to form a total angular momentum j^*, characterized by a quantum number J, which then is the angular momentum for the system of several electrons. According to customary usage, a lower case letter as a designator for a quantum number indicates that the quantum number is that of a single electron, while a capital letter indicates that the quantum number represents a state formed by several electrons.

For the lower Z part of the periodic table of elements, the appropriate coupling system for angular momentum states in an atom is the L-S, or Russell-Saunders, coupling. In this description, the orbital angular momenta of individual electrons in any single shell of an atom are coupled to form a resultant orbital angular momentum, described by the quantum number L, and the spin angular momenta of the same individual electrons are coupled to form a resultant spin angular momentum, described by the quantum number S. Coupling of the individual orbital angular momentum states is not shown but possible coupling schemes for the spins of 2, 3, and 4 electrons are shown in Fig. 5. Note that as many possible couplings exist as there are electrons. Only one of these possible schemes will be the lowest energy state, the others being at higher energies. The resultant spin and orbital angular momentum vectors for a group of electrons in a single shell of an atom can then be used to describe the coupling that gives the total angular momentum J^* for these electrons. In Fig. 6 is shown the coupling according to the vector model between the orbital and spin angular momenta for which $L = 2$ and $S = 1$. There are $2J + 1$ possible states. All $2J + 1$ states have the same energy unless under the influence of an external magnetic field, in which case they are broken into components, each of which is designated by a magnetic quantum number M_j. In principle this splitting is the same as for the splitting of the total angular momentum states for a single electron, as shown in Fig. 3, except for the use of capital letters M_j and J.

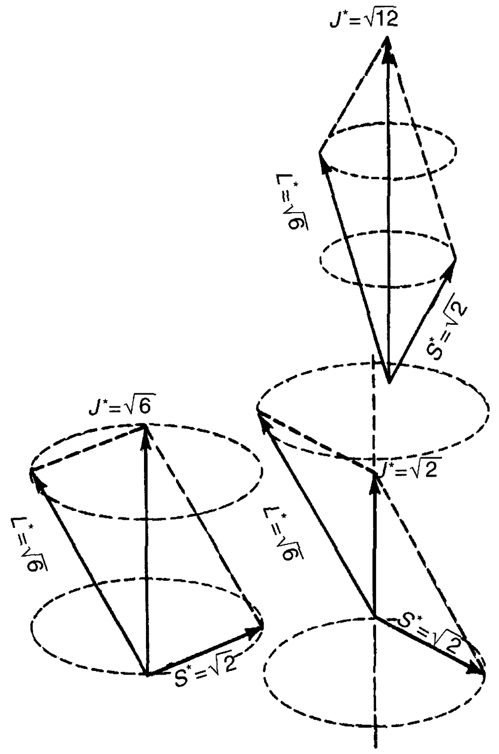

Fig. 6. Vector model coupling of spin and orbital angular momenta for which $L = 2$, $S = 1$

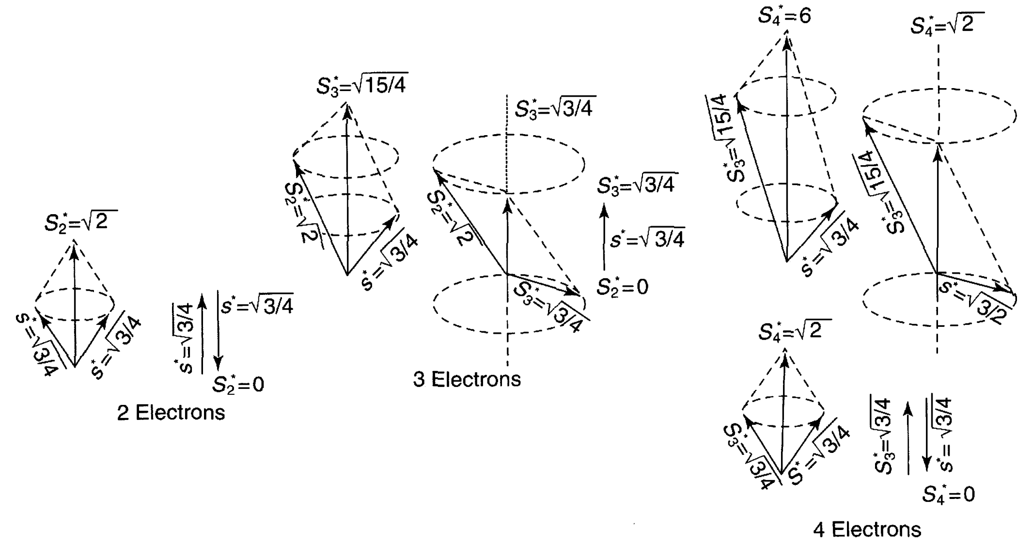

Fig. 5. Vector model coupling of the spin angular momenta of two, three, and four electrons

The Pauli Exclusion Principle states that no two electrons of any single atom may simultaneously occupy a state described by only a single set of quantum numbers. Five such numbers are needed to describe fully the quantum-mechanical conditions of an electron. For j-j coupling this set is generally n, l, s, j, m_j, and for L-S it is n, l, s, m_l, m_s. From the coupling of the angular momentum associated with the latter sets a full description of the multielectron state, described by n, L, S, J, M_J, is determined.

Part of the outgrowth of the determination that atomic particles have wave properties, and of the subsequent development of quantum mechanics, is the Heisenberg Uncertainty Principle, which states that an electron cannot be located exactly in terms of both its space and momentum coordinates, or in terms of both its time and energy coordinates. See also **Uncertainty Principle**. If the energy of a particular atomic state is precisely defined, the time at which an electron is found in that energy state cannot be so defined. Likewise, if the momentum of an electron is precisely defined, its position in space cannot be so defined. On the other hand, the probability for finding an electron in a particular location relative to the atomic nucleus can be determined. After substitution of the appropriate potential energy terms needed to describe the atomic system, these probability density distributions may be found from solutions of the Schroedinger wave equation, which is a quantum-mechanical description of the system. This distribution, which is directly related to the wave function that describes the atomic state in a quantum-mechanical manner, must be distributed through a region of space and is hence a function of all three spatial variables, which are r, θ and ϕ in the spherical coordinate system. Because only two variables are available on the plane of a page to describe these functions, they are usually described by a series of graphs, which must then be assembled in the imagination of the reader to picture the complete three-dimensional distribution. The radial part of the distribution is dependent only on the quantum numbers n and l and is usually represented by the terminology R_{nl}^2. The radial distribution for selected states of a hydrogen atom are shown in Fig. 7. The dashed lines are proportional to the probability of finding the electron in the appropriate nl state in an incremental volume dv of constant magnitude at the indicated radial distance from the atomic nucleus. The solid lines are proportional to the probability of finding the electron in an incremental shell between the radial distances r and $r + dr$, with a volume $4\pi r^2 dr$ at the indicated radius. Radial distances in Fig. 7 are given in units of Bohr radii, the distance from the nucleus of the $n = 1$ orbit in the Bohr planetary model of the hydrogen atom.

In the quantum-mechanical description of a hydrogen atom, the radial portion of the probability density distribution is the same in all directions from the nucleus, but only for the case $l = 0$ is the magnitude of the distribution the same in all radial directions. For all other values of l, the magnitude of the distribution is a function of the angular direction, defined

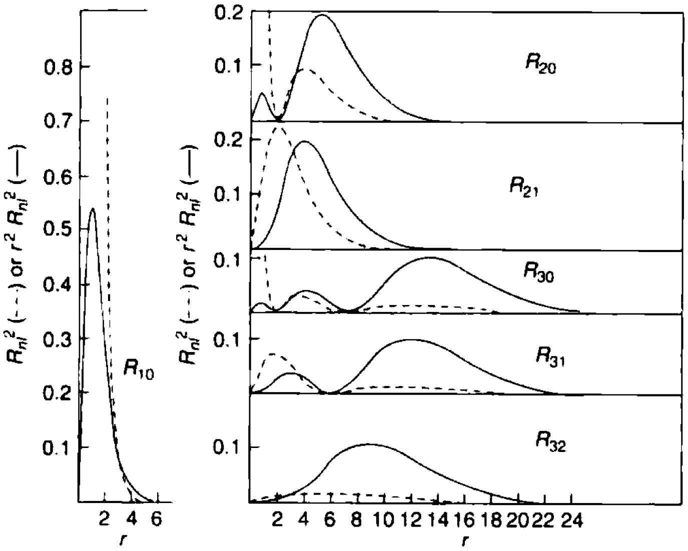

Fig. 7. Probability density distributions as a function of radial distance from the nucleus for several states of a hydrogen atom. The dashed lines are proportional to the probability of finding the electron in an incremental volume dv at the indicated radial distance. The solid lines are proportional to the probability for finding the electron in an incremental shell of volume $4\pi r^2 dr$ at the indicated radius

by the coordinates θ and ϕ. However, as in the case of the discussion of the vector model of an atom, we cannot define an angular direction unless an axis exists to provide a reference direction. To provide this axis some force or torque external to the electron configuration must be found. The only external force strong enough to interact with the electron configuration is that provided by certain magnetic fields. The interaction with the magnetic moment of the electron configuration can then be described in terms of a magnetic quantum number m_l, which is the magnetic quantum number associated with orbital angular momentum quantum number. When $l = 1$, m_l may have any of three values, +1, 0, or −1. Three possible angular distributions are then possible for the electrons described by a quantum number $l = 1$, but the distributions for $m_l = +1$ and $m_l = -1$ are identical, thereby providing some simplification. If we define $\theta = 0$ in the direction of the applied magnetic field, the probability density distribution in the $r\theta$-plane for an electron of a hydrogen atom described by $l = 1$, $m_l = 0$ is given in the $2p$, $m = 0$ part of Fig. 8. This distribution is symmetric in ϕ; it may thus be rotated around an axis perpendicularly directed through the center of the figure (the $\theta = 0$ axis) to give the full three-dimensional distribution. For either $m_l = +1$ or $m_l = -1$ the distribution is given by that part of Fig. 8 labeled $2p$, $m = 1$. When rotated about the $\theta = 0$ axis the $m_l = 0$ distribution gives a dumbbell-like distribution and the $m_l = 1$ distributions give ring-like distributions, all of which fade away to negligible magnitude at large distances from the center of the distribution. For the $2p$, $m_l = 0$ configuration, the angular distribution in the $r\theta$-plane is given by the equation $\frac{3}{2}\cos^2\theta$, and for the $2p$, $m_l = \pm 1$ configuration by the equation $\frac{3}{4}\sin^2\theta$. Since two $m_l = 1$ configurations exist for each $l = 1$, the distributions for all three m_l configurations, when summed, give a resultant distribution that is independent of the angle θ, as well as of the angle ϕ. This condition is reached when all possible electron states in the $2p$ subshell are filled. A similar situation, a complete symmetry of the electron distribution, exists for all filled subshells. Hence an external magnetic field interacts only with partially filled shells. In multielectron atoms only one shell is usually partially filled; thus interactions with external magnetic fields, such as those introduced artificially, by the atomic nucleus, or by neighboring atoms, occur only in one shell of the atom, sometimes called in chemical terminology the valence shell. For specific elements, the unfilled shell can be determined from Table 5. Probability density distributions for several other electron configurations besides $2p$ is given in Fig. 8.

The radial probability density distributions for individual electron configurations in atoms other than hydrogen are generally similar to those of Fig. 7, but, since the nuclear charge Z of these atoms is larger than for hydrogen, the electrostatic attractive force exerted by the nucleus on the innermost electron is stronger than for hydrogen and hence pulls its distribution closer to the nucleus. Outer electrons, however, are partially shielded electrostatically from the nucleus by the inner electrons and hence are influenced by a weaker force than that which would be provided by a bare nucleus. The least tightly-bound electron is held by a force that has an effective Z of about 1 but for the more tightly bound electrons the effective Z is much higher. The probability density distribution for the least tightly bound electron then extends to a distance comparable to the distribution for hydrogen, but the main part of the distribution is much closer to the nucleus. A typical distribution for all the electrons of a multielectron atom, in this case rubidium, is shown in Fig. 9.

As stated earlier in this entry, there are three p orbitals, with magnetic quantum numbers of 0, 1 and −1. The orbital for which $m = 0$ corresponds to the direction of the applied magnetic field, so that its effect is zero. This direction is conventionally taken as that of the z-axis, so that p_z, which is symmetrical about that axis, coincides with p_0. The other p orbitals, p_x and p_y, are perpendicular to p_z and to each other and correspond to standing waves built up by mixing of p_{+1} and p_{-1} which are oppositely directed waves.

An analogous situation for the d orbitals, for which $l = 2$, and hence $m_l = 2, 1, 0, -1$ and -2, gives rise to five d orbitals, designated as d_{xy}, d_{yz}, $d_{x^2-y^2}$ and d_{z^2}.

For further discussion of atomic orbitals see also **Orbitals**.

It follows from the earlier discussion that each orbital may be occupied, in accordance with the Pauli Exclusion Principle, by two electrons of opposed spin.

See also **Pauli Exclusion Principle**.

Atomic Radius

The radius of an atom may be defined as the distance of closest approach to another atom; it is the distance at which the mutual repulsion of the electron clouds and the mutual attraction of the nuclear charge of each for the electrons of the other are in equilibrium under specified circumstances. If the two atoms are the same, the radius of each is one half the internuclear distance; if they are unlike, the internuclear distance is the sum of the individual radii. Atomic radii fall roughly into four categories, which, however, merge into one another. These are Van der Waals and ionic radii, which are radii of equilibrium approach for mutually nonbonded atoms (neutral and charged, respectively), and covalent and metallic radii, which are for mutually bonded atoms (where the bonding electrons are, respectively, largely localized between the bonded atoms, or highly delocalized). Radii of all types vary in essentially the same manner from one part of the periodic table to another. In general, the radii decrease from the beginning to the end of any period, the rate of decrease being less the higher the number of the period. There are discontinuities in the decrease at points at which the quantum levels become half or completely filled. For example, Mn^{2+} (r = 0.83 Å) is larger than either Cr^{2+} (0.80 Å) or Fe^{2+} (0.80 Å), and Zn^{2+} (0.75 Å) is larger than Cu^{2+} (0.72 Å). (In this description, angstroms, Å, are used for convenience of notation. 1 angstrom = 10^{-10} meter.) Again, in general, the radii increase going down any column in the periodic table except in the region of hafnium. This last exception is caused by the lanthanide contraction occurring for the series of 14 elements between lanthanum and hafnium, which results in a far greater decrease between these two elements (average metallic radii: La 1.87 Å, Hf 1.58 Å) than between yttrium and zirconium (Y 1.80 Å, Zr 1.60 Å), where no such series intervenes. Because of the slower rate of decrease of the radius in the sixth period as compared to the fifth, however, the radii in the sixth period soon become larger again than those in the fifth (cf. Nb 1.429 Å, Ta 1.43 Å; Mo 1.36 Å, W 1.37 Å).

Van der Waals Radius

This is the radius of closest approach of one atom to another with which it does not form a chemical bond. It represents the distance at which the mutual repulsion of the nonbonding electrons of each exactly balances the attraction of the nucleus of each for the electrons of the other.

Ionic Radius

This is the radius of closest approach of a charged atom or group (i.e., an ion) to another atom or group with which it does not form a covalent bond. It represents the distance at which the mutual repulsion of the nonbonding electrons of each exactly balances the mutual attraction of oppositely charged ions, or the attraction of a positive ion for the electrons of a neutral atom or group or the attraction of a negative ion for the nucleus or nuclei of a neutral atom or group. Ionic radii for the cations of the least electronegative metals and of the most electronegative nonmetals are clearly defined, but for the elements of intermediate electronegativity (including the transition elements) they are much more doubtful because of the varying degrees of covalency in the compounds of these elements. Published ionic radii for these latter elements can therefore not be considered to be accurate measures of the true sizes of the ions, but are useful for comparison of relative sizes. In particular, there are certainly no simple cations of charge greater than 4+, and the simple tetrapositive cations are limited to Th^{4+}, probably the other tetrapositive actinide cations, and possibly Ce^{4+}. "Ionic radii" cited for such "cations" as Si^{4+}, P^{5+}, S^{6+}, Cl^{7+}, etc., are fictions arrived at by subtracting from an observed interatomic distance an arbitrary anionic radius for the second atom or else are extrapolated or theoretically calculated radii. However, inasmuch as all compounds of such elements have a high degree of covalency, such radii have no real meaning in normal compounds. Simple anions of absolute charge greater than 3 undoubtedly do not exist and the existence of monatomic trinegative ions is open to question. However, in their binary compounds with the lanthanide elements, phosphorus, arsenic, antimony and possibly nitrogen and bismuth apparently have radii very close to their Van der Waals radii and may therefore be considered essentially ionic. (See Table 6.)

The monatomic ionic radii of a given element become smaller as the oxidation state increases, provided this implies actual removal of electrons. For example, the radius of Fe^{2+} is 0.80 Å, whereas that of Fe^{3+} is 0.67 Å; Cu^{+} = 0.96, Cu^{2+} = 0.72.

The ionic radii discussed above are properly "crystal radii," i.e., the radii exhibited by the ions in ionic crystals. Although these radii are probably reasonable representations of the radii of contact of the ions in solution with the nearest atoms of solvate molecules, especially for ions of low charge density, nevertheless, most ions in solution have far larger effective radii because they carry with them a sheath of solvent molecules, the tenacity

* 1 angstrom = 10^{-10} meter.

and thickness of which is a function of the charge density and electronic structure of the ion. In consequence, ions of small crystal radius (e.g., Li^{+}) may act larger (e.g., have lower mobility) in solution than ions of large crystal radius (e.g., Cs^{+}).

The effective radius of an ion changes with coordination number. An ion of coordination number 4 (tetrahedral) has a radius 0.93–0.95 times as large as the same ion with coordination number 6, while an ion of coordination number 8 is about 1.03 times as large as the same ion with coordination number 6.

Effective spherical crystal radii for some polyatomic ions are given in Table 7.

Metallic Radius

Metals may be considered to be composed of cations bonded together by a cement of mobile electrons which are located in the conduction bands. Since the number of available energy levels in the conduction bands is a function of the number of available orbitals of the atoms making up the metal, and since the electron population of the nonbonding orbitals of the atoms and of the conduction band is a function of the number of valence electrons of the metal, the number and distance of nearest neighbors and the strength of the metal-metal bond varies in a fairly regular way

* 1 angstrom = 10^{-10} meter.

across the periodic table. In particular, bond lengths are shortest and bond strengths are greatest in the vicinity of cobalt, rhodium and iridium, where the number of valence electrons and the number of available orbitals (nine) exactly match. Below this number there are too few electrons and above, too many, for maximum sharing and use of the bonding orbitals. The interatomic distances and coordination numbers of the elements in their metallic states are given in Table 8.

Covalent Radius. This is the radius of closest approach for atoms bonded together by electrons that are localized in the region between the atoms. It represents the distance at which the attraction of each nucleus for the bonding electrons is in equilibrium with the mutual repulsion of the two nuclei and the repulsion of the inner electrons of each atom for the inner electrons of the other.

The length of the covalent radius is a function of several factors, among which are (1) bond order (multiplicity), (2) electronegativity, (3) hybridization, (4) orbital overlap, (5) steric factors, and (6) special electronic effects.

(1) The effect of bond order is exemplified by the familiar shortening of the carbon-carbon bond in ethane (1.543 Å), graphite (1.4210 Å), benzene (1.397 Å), ethylene (1.353 Å), and acetylene (1.207 Å) as the bond order goes from 1 to $1\frac{1}{3}$ to $1\frac{1}{2}$ to 2 to 3. Bond orders affect the covalent radii of other elements similarly.

The determination of the standard single bond radius is not always a simple matter. In those cases where two like atoms are joined by an unquestionable single bond (as the carbon atoms in ethane) the standard single bond radius is one-half the internuclear distance. Similarly the single bond radii for nitrogen, oxygen, and fluorine are half the interatomic distances in N_2H_4, H_2O_2 and F_2. On the other hand, acceptance of half the interatomic distances in P_4, H_2S_2 and Cl_2 for the corresponding single bond radii is open to question, since in these and similar cases the possibility exists of multiple bond formation by overlap of the electron-filled p-orbitals

TABLE 8. INTERATOMIC DISTANCES IN METALS (IN ANGSTROM UNITS)*

* 1 angstrom = 10^{-10} meter.

of each atom with the empty d-orbitals of the other. This will result in an increase in strength and a decrease in length for these bonds compared with what they would have if they were exactly single bonds. In support of this idea, it can be seen from Table 9 that, although the homoatomic bond energy for silicon (where no electrons are available for multiple bonding) is less than that for carbon, the bond energies for phosphorus, sulfur, and chlorine are significantly greater than for nitrogen, oxygen, and fluorine, respectively. Representative bond strength s are given in Table 10.

In consequence of this effect, the single bond radii for such elements are better derived from the alkyl derivatives (with an electronegativity correction) in which only single bonding is possible. The single bond radii in Table 11, Covalent Radii of the Elements, were derived insofar as possible from such compounds. The multiple bond radii were derived similarly. For example, the oxygen double bond radius may be obtained from acetone by using the double bond radius for carbon taken from ethylene and applying the electronegativity correction discussed in the following paragraph.

(2) When two atoms of different electronegativity are connected by a covalent bond, the bond length is always shorter than the sum of the individual homoatomic covalent radii for the atoms in question. The shortening is proportional to the difference in electronegativity of the two elements and is expressed by the relationship due to Stevenson and Schomaker.

$$R = (r_A - r_B) - 0.09|x_A - x_B|$$

where R = observed bond length
r_A, r_B = standard covalent radii of atoms A and B
x_A, x_B = electronegativities of A and B.

(3) It has been pointed out by a number of workers that for bonds of the same multiplicity, the lower the average value of the l quantum number in a hybrid bonding orbital, the shorter the bond should be. For example, the carbon-carbon single bond in HC≡C−C≡CH which involves orbitals of sp hybridization is 1.37 Å long compared with the carbon-carbon bond in ethane (sp^3 hybridization) which is 1.543 Å long. Similarly the B−C bond in $B(C_6H_5)_3$ ((sp^2) is shorter than in $B(C_6H_5)_4^-$ (sp^3). Thus it is found that a bond of given multiplicity has a length which is characteristic not only of the bond order, but also of the individual states of hybridization of the atoms. For example, the C−C bond in CH_3CN ($sp^3 + sp$) (1.46 Å) is almost exactly the average of the bonds in CH_3CH_3 (sp^3) and N≡C−C≡N (sp) (1.37 Å). Though the data for other elements are less extensive than for carbon, and the interpretation frequently is much more complicated, the same general principles seem to apply to other elements as well.

(4) The effectiveness of overlap of bonding orbitals of the same symmetry appears to decrease as the principal quantum number increases and as the difference between the principal quantum numbers increases. This is reflected in the bond strengths shown in Table 10. The covalent radius of hydrogen is especially subject to effects of this kind, and has the values 0.3707, 0.362, 0.306, 0.284 and 0.293 Å respectively in H2, HF, HCl, HBr and HI. The apparent anomaly of the P−P, S−S, and Cl−Cl bonds being stronger than the N−N, O−O, and F−F bonds has been considered in paragraph (1).

(5) In the case of very large atoms or groups bonded to small atoms, the spatial requirements of the large groups may result in a bond lengthening. For example, it is probable that the C−I bond in CI_4 is longer and weaker than in CH_3I because of the steric repulsions of the large iodine atoms. Again, the N−N bond in $[(CH_3)_3NN(CH_3)_3]^{2+}$ may be longer than in $H_3NNH_3^{2+}$.

(6) Special effects of electronic or orbital structure may result in either lengthening or shortening a bond. The first situation is exemplified by such compounds as $O_2N{-}NO_2$, $O_2N{-}X$, $(C_6H_5)_3C{-}C(C_6H_5)_3$ and the like, where the long bond is indicated in the formula. Cases of this sort involve molecules having a pi-electron system capable of accepting additional electrons (frequently in low-lying antibonding orbitals) so that the electrons required for the bond in question are partially drained away from it, leaving the bond weak and long. Thus the N−N bond in N_2O_4 has a length of 1.75 Å and a dissociation energy of 12.9 kcal compared with 1.47 Å and 60 kcal for N_2H_4.

Bond shortening, on the other hand, may occur in compounds of the most electronegative elements, notably fluorine. Typical examples are the fluoromethanes, in which the C−F bond lengths are: CH_3F 1.391 Å, CH_2F_2 1.358 Å, CHF_3 1.332 Å, and CF_4 1.323 Å. This has been explained in terms of electronegativity; i.e., that the polar C−F bond requires a high degree of p-character, thus releasing the s-orbital for the bonds to the less electronegative atoms, making them shorter and stronger. As more fluorine atoms are added, the s-orbital is more equally divided among the bonds, resulting in a regular shortening of the C−F bonds. This theory has been used to explain the supposed shortening of the C−C bond from 1.543 Å in C_2H_6 to 1.52 Å in C_2F_6. However, the experimental error attached to the latter value does not allow it to be considered really different from the former (a more recent value is 1.56 Å), and furthermore, the effect is not observed in other halo-substituted ethanes for which more accurate data are available: e.g., the C−C bond length in CF_3CN (1.464 Å) is if anything slightly longer than that in CH_3CN (1.458 Å), and microwave determinations on, C_2H_5 Br, C_2H_5Cl and C_2H_5 give 1.5508, 1.5508 and 1.540, respectively, for the C−C bonds. In addition, the C−H bond lengths in the fluoromethanes appear to be essentially constant: CH_4 1.092, CH_3F 1.109, CH_2F_2 1.092 and CHF_3 1.093. It should also be noted that the C−C stretching force constants in the two cyanides (4.50×10^{-5} and 4.55×10^{-5} dyne cm^{-1}, respectively) do not differ appreciably.

A theory that more satisfactorily explains all the known facts has been suggested by J.F.A. Williams (*Trans. Faraday Soc.*, **57**, 2089 (1961)). This proposes that the highly electronegative fluorine atom drains electron density away from the carbon atom in a C−F group sufficiently to make the lobe of the σ-antibonding (σ^*) orbital which is concentrated beyond the carbon atom available for π-bonding. In CH_3F where the hydrogen atoms have no nonbonding electrons to interact with the σ^* orbital, there is little or no effect. However, in CH_2F_2, where each fluorine atom has nonbonding electrons in p-orbitals of favorable disposition, the p-electrons of each interact with the σ^* orbital associated with the other to give a $p_\pi - \sigma_\pi{}^*$ bond, which results in a strengthening and shortening of both bonds.

This effect is observed in the shortening of such bonds as C−N in CCl_3NO_2 and $(CF_3)_3N$, C−P in $(CF_3)_3P$, C−S in $(CF_3)_2S$ and so forth.

* 1 angstrom – 10^{-10} meter.

Such a mechanism, on the other hand, could not result in a shortening of the C–C bond in C_2F_6.

Table 11 gives standard covalent radii for most of the elements of the periodic table. Most of these have been calculated from the best data available in the literature using the considerations of paragraphs 1–3 above. Thus when radii of the appropriate multiplicity and hybridization are added and corrected for difference in electronegativity by the Stevenson and Schomaker relationship, the observed bond length will be obtained. For example, the O–F bond in OF_2 would have the value $0.745 + 0.709 - 0.9(0.5) = 1.409$ Å. The experimental value is 1.41 Å.

The sp^3 double bond radii for Si, P, S and Cl are taken from the paper of D.W.J. Cruickshank, *J. Chem. Soc.*, **5486** (1961). A calculation of the Cl<C:/eqbond>O bond length gives

$$0.681 + 0.654 - 0.9(0.5) = 1.290\text{A}$$

while for the Cl–O bond we calculate

$$1.050 + 0.745 - 0.9(0.5) = 1.750\text{A}$$

The observed Cl–O bond length in ClO_4^- (1.48 Å) indicates that it has a bond order somewhat greater than 1.5.

The hybridization designations given in the table are not intended to be exact. In particular it must be recognized that the nitrogen bonding orbitals in the ammonia molecule, for example, have considerable s character. Nevertheless, such orbitals, for simplicity's sake, have been designated merely as p. This practice has been used uniformly when a nonbonding pair of electrons is found in the valence level. In the case of "sp^3d" hybridization, the radii are given as "sp^3d" if only average lengths were available, but are separated into sp^2 and pd if the data differentiated the two types of bonds. The values given for radii of the transition elements and for the less common hybridization states of the other elements, especially where the bond order is not accurately known, must be considered to be only approximate.

Valence

Valence is the capacity of an atom to combine with other atoms to form a molecule. Valence is specified as the number of hydrogen atoms or twice the number of oxygen atoms with which one atom of the element under question will combine. Thus, nitrogen has the valence 3,2,4,5 in the compounds NH_3, NO, NO_2, N_2O_5. A further distinction is made by considering positive and negative valences. If the hydrogen is assigned the valence of plus one, and oxygen that of minus two, and if the valences in a compound are made to total up to zero, we have a formal scheme of positive and negative valences. In ammonia, NH_3, the three hydrogen atoms each with a valence of plus one exactly balance the one nitrogen atom with the valence of negative three. Many atoms possess more than one valence but the principal valence is correlated with the periodic table and the atomic structure of the atom. The principal positive valence is the number of the group in which the element falls in the periodic table. Thus hydrogen is one, lithium also one, boron three, etc. The negative valence is eight minus the number of the group in the periodic table. Negative valences greater than four do not occur. For example, oxygen has the valence of eight minus six, that is two negative in H_2O (water): and nitrogen has the valence of eight minus five, that is three negative in NH_3 (ammonia).

On the basis of contemporary electronic theory of atomic structure we can classify the different types of valence. The guiding principle is that the atoms tend to assume an inert gas electronic structure of eight electrons in the outer shell (in the case of hydrogen it is two). To do this, the atom either loses to, gains from, or shares with other atoms, electrons. This process leads to molecule formation. The following are the principal types of valences and their electronic interpretation.

Electrovalence or polar valence is associated with a transfer of an electron from one element to the other in order to complete by such a transfer the octet of each element. Thus in sodium chloride the sodium atom has one valence electron outside a closed octet of eight. By loss of this electron the sodium atom becomes positively charged sodium ion because the nuclear positive charge exceeds that of the electrons by one. On the other hand, the chlorine atom has a grouping of seven electrons in the outer shell. It picks up another electron to complete its outer shell to an octet, but in so doing obtains a total charge of one minus, becoming a chloride ion. The result is that in sodium chloride we are not dealing with sodium atoms and chlorine atoms but with sodium and chloride ions. This is experimentally substantiated. The forces holding the ions together are the electrostatic forces, which are equal to the product of the electronic charges on the ions divided by the product of the separation squared times the dielectric constant of the medium. Thus when the sodium chloride crystal is placed in solvent of high dielectric constant such as water, the forces between the ions are weakened and the ions float away from each other. In other words, electrolytic dissociation takes place. It must be noted that polar valences have no specific directional effects in space. The electrostatic attraction is best satisfied by a close packing of the ions. Inasmuch as there are large stray electric fields present in polar compounds, they possess a high melting point and considerable hardness.

Homopolar or covalent bonds are formed by a different mechanism. Here again we have as the basis the tendency of each atom to complete its outer shell of electrons to eight, or in the case of hydrogen to a doublet. In contrast to polar valence, in covalence we have no direct transfer of electrons, but merely a sharing. In the case of molecular hydrogen each hydrogen atom with its one electron shares this electron with the other hydrogen. The result is that each atom in the molecule has at least part of the time a complete shell of two electrons. The electrons can be visualized as traveling in orbits encompassing the two hydrogen nuclei. It is a property of the covalent bond that it is not weakened by electrolytic solvents and that it has a definite direction in space. These directional effects of covalent bonds are expressed in stereochemistry. Thus, for example, the four valence bonds of the carbon atoms are arranged to extend from the center of a tetrahedron to the four corners. Furthermore, since there is a one-to-one saturation of the electron forces, the stray electric fields are negligible, the melting points are low, and the crystals are soft.

Intermediate in properties between the electrovalent and covalent bonds discussed above is the *semi-covalent bond* (also called *dative* or *polarized ionic bond*). It is formed when both electrons that constitute the bonding pair are supplied by one of the atoms. An example is the formation of amine oxides between tertiary amines and oxygen, in which both electrons are donated by the nitrogen atom. Such bonds naturally exhibit electrical polarity. They are members of the large class of heteropolar bonds characterized by an unequal distribution of charge due to a displacement of

the electron-pair so that the effect of the bond is to make the atoms differ in polarity. In fact, atomic bonds are best described, not qualitatively, but in terms of bond angles and distances. In water, for example, the bond angle is 109.5°, indicating that the lines joining the two hydrogen atoms to the oxygen atom meet at this angle. However, there are two special types of bonds that deserve individual mention.

The *hydrogen bond* is actually two bonds, whereby two electronegative atoms are joined through a hydrogen atom. Since a stable hydrogen atom cannot be associated with more than two electrons, the hydrogen bond may be regarded as a resonance phenomenon, whereby the hydrogen atom is periodically attached to each of the two other atoms in turn, so that its behavior is a composite of the two structures.

Another type of bond that occurs in solids is the metallic bond. It can be considered as an extreme case of sharing of electrons in that an electron gas (present in the crystal lattice) is shared not by two ions but by all the ions in the lattice. This electron gas is responsible for the metallic properties of certain solids, especially for thermal and electrical conductivity.

As a consequence of the fact that many valence bonds leave residual electrical fields, many molecules in which the "primary" valences are satisfied can combine further with other molecules or with atoms. These higher combinations enter into many important areas of chemical science. They are the basis of the formation of coordination compounds, discussed under that heading. They cause molecular association. They are responsible for the formation of hydrates. They are in many cases the binding forces in nonionic solids, and are of great importance in explaining the structure of larger material aggregates.

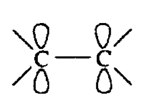
The foregoing discussion of valence is, of course, a simplified one. From the development of the quantum theory and its application to the structure of the atom, there has ensued a quantum theory of valence and of the structure of the molecule, discussed in this book under **Molecule**. Topics that are basically important to modern views of molecular structure include, in addition to those already indicated: the Schroedinger wave equation; the molecular orbital method (introduced in the article on **Molecule**) as well as directed valence bonds; bond energies, hybrid orbitals, the effect of Van der Waals forces; and electron-deficient molecules. Some of these subjects are clearly beyond the space available in this book and its scope of treatment. Even more so is their use in interpretation of molecular structure. (However, see **Crystal Field Theory**; and **Ligand**.)

There are a number of terms used in describing the individual valence bonds. The *bond angle* is the angle between two bonds in a molecule, e.g., in water the bond angle is 109.5°, indicating that the lines joining the two hydrogen atoms to the oxygen atom meet at this angle.

The term *bond direction* arises from the fact that certain covalent bonds prefer to lie in particular directions with respect to the bonded atoms. For example, the bonds from carbon point from the center to the vertices of a regular tetrahedron.

Atoms sharing the two pairs of electrons are described as connected by a *double bond*. The bond energy of the C–C bond is 80 kcal and that of the C=C bond is 145 kcal. The second bond is formed by p-electrons and, while its energy effect is considerable, it does not produce a double bond having twice the energy of the single bond. Moreover, its electrons, being less firmly held between the carbon atoms, are available for addition reactions. These bonds between p-electrons, or π-bonds, tend to delocalize in many cases, i.e., the electronic charges "spread" over other atoms than those furnishing them.

The diagram below, which shows the bonding of the carbon atoms in the ethylene molecule, shows the carbon atoms connected by one of the sp^2 hybrid bonds (solid line), the other two being used for the hydrogen atoms. The dotted lines show the π-bond formed between the two p-electrons. Since they occupy p-orbitals that are perpendicular to the plane of the sp^2 bonds, they cannot form a bond without considerable overlapping. From the figures of 80 and 145 kcal for single and double bonds, the π-bond accounts for 44% of the energy of the double bond, indicating extensive overlapping.



Conjugated double bonds are two double bonds in positions connecting alternate pairs of carbon atoms. For example, the compound

$$CH_2{=}CH{-}CH{=}CH_2$$

has conjugated double bonds. In addition reactions, the conjugated double bond system commonly changes to a single double bond between the second and third carbon atoms, accompanied by the addition of atoms or groups to the first and fourth carbon atoms.

Triple Bond

A single C–C bond involves sp-sp overlapping of orbitals, while a C–H bond is the result of sp-s overlapping. The other two valences on carbon atoms are represented by two remaining π-electrons, occupying mutually perpendicular p-orbitals. In the case of *triple bonding*, –C≡C–, overlapping of these four p-orbitals gives two π molecular orbitals. Thus the carbon-carbon *triple bond* is conveniently represented as –C:C–, in which the π-electrons are shown occupying positions on the periphery of the carbon-carbon single bond. Their mutual repulsion reduces their bonding effectiveness, so that the bond energies for single, double and triple carbon-carbon bonds are 80, 145, and 198 calories, respectively.

Bond Energies

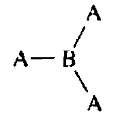
It has been suggested that ΔH^0_{298}, the heat of formation of a molecule from its constituent atoms (see also **Atomic Heat of Formation**), could be computed from a table of average bond energies, and the assumption of additivity:

$$\Delta H^0_{298} = \sum_{\substack{\text{all types} \\ \text{of bonds}}} n_{X_i-X_j} \cdot E_{X_i-X_j}$$

where $n_{X_i-X_j}$ is the number of bonds between the two atomic species, X_i and X_j, in the molecule. $E_{X_i-X_j}$ is the average bond energy associated with each of these bonds. Fairly accurate predictions of the heats of formations of organic molecules can be made in this way, particularly for the *larger* hydrocarbons, alcohols and other aliphatic derivatives.

The differences between the observed heats of formation of *cis-trans* isomers and of branched and unbranched hydrocarbon chains show that the additivity rule is not strictly rigorous. Various improvements have been suggested.

Single bond energies are given directly by the heat of dissociation of the corresponding molecules into neutral atoms. In cases where the molecule has no independent existence, other data may often be used. For example, the complete dissociation energy of a binary compound containing more than two atoms may be divided by the number of bonds broken in the dissociation, that is, the energy of the A–B bond may be taken as $\frac{1}{2}$ the dissociation energy of A–B–A into 2A and B, or as $\frac{1}{3}$ the dissociation energy of



into 3A and B. This multiple bond calculation yields, of course, an average value for the energy of the bonds involved. In the simple case of the H_2O molecule, the dissociation energies of the two successive steps $H_2O \longrightarrow H + OH \longrightarrow H + H + O$ differ by about 10%.

Representative single bond values were given in Table 10. Summation of such energies to obtain *average* values for molecules applies only when the constituent atoms exhibit their normal covalences and is subject to the exceptions already stated.

Pseudopotential Theory

It has been assumed for many years that the properties of matter (the chemical elements and the compounds that are built up from the atoms of the specific chemical elements) will follow the laws of quantum mechanics. Although the fundamental principles have been acknowledged, until recently it has been difficult to scale up these principles to aggregates of particles and to effectively apply fundamental theory to the prediction of materials properties, such as electrical conductivity, optical reflectivity, hardness, malleability, elasticity, and a number of chemical qualities. With a simple atom like hydrogen where its single electron is obviously a valence electron, calculations can be based on the potential energy of the electron. However, for atoms that contain two or more electrons, quantum scientists have found a mathematical approach impractical because the potential energy of a valence electron is affected by interactions with the more tightly

bound core electrons of the atom. Further, these interactions are governed by the potential energy of each core electron. Consider, for example, the calculations that would be needed in connection with an electronic structure that may contain upward of 10^{20} particles or more. Some researchers have found that the interactions of the core and valence electrons have little effect outside the core. Thus, there is no requirement to know the true potential energy of all the electrons.

What is needed is a good approximation to the configuration of the valence electrons. Thus, as pointed out in a scholarly and detailed paper, Cohen, Heine, and Phillips observe, "The new method regards the core electrons and the atomic nucleus as if they constitute a single particle without internal structure. The method is called the *pseudopotential theory*." In their article, the authors review early computational strategy and problems, electron waves and standing wave patterns, the Fermi momentum, quantum momentum change, scattering in crystals, and applications to elemental solids and binary compounds. The authors conclude, "Perhaps the most remarkable aspect of pseudopotential theory is its capacity for steady growth through increasing physical and mathematical sophistication. The cumulative development has enabled pseudopotential theorists to keep basic physical issues as well as technical details in mind in describing the quantum structure of materials."

Among recent practical accomplishments from applying the theory are: (1) explanation of the properties of interfaces between metals and semiconductors and between two semiconductors; (2) calculation of the total energy of semiconducting materials with an accuracy of about 0.2 eV per atom for a variety of densities or volumes; and (3) forecasting the properties of light or heavy elements and covalent, ionic or metallic compounds throughout the periodic table more accurately, more rapidly, and more reliably than appraisal of any one light element a quarter of a century ago.

In the late twentieth century, a number of new instrumental techniques were developed for determining atomic properties with increased precision and reliability. Of marked importance is the increased facility for measuring minute dimensions and units of time at the respective nanometer and nanosecond levels. Laboratory techniques include laser atom probes, cold neutron research, scanning-tunneling microscopy, and atom trapping, among others.

CHEMICAL EQUATION. By means of chemical formulas, the changes occurring during a chemical reaction can be expressed as an equation. Thus the reaction of 1 mole of sulfur with 1 mole of oxygen to produce 1 mole of sulfur dioxide is written as

$$S + O_2 \longrightarrow SO_2$$

The arrow is preferred to the equality sign, which does not emphasize the direction of the reaction. In addition to the identity of the reactants and products, the equation shows the number of atoms entering into the reaction, either in the atomic state or as constituents of molecules. It also shows the number of moles of each reactant and product, so that by use of the table of atomic weights, the relative masses can be computed.

Since the principle of conservation of masses applies to chemical reactions, coefficients must often be used in writing chemical reactions so that the number of atoms of products is equal to the number of atoms of reactants. An example is the reaction of *two* moles of hydrogen with *one* mole of oxygen to form *two* moles of water

$$2\ H_2 + O_2 \longrightarrow 2\ H_2O$$

In writing such equations, a convenient procedure is to write first an expression containing only the formulas, and then to add the smallest coefficients that will give the same number of atoms of products as of reactants. This operation is called balancing the equation.

Equilibrium reactions, such as that of acetic acid and ethyl alcohol to form ethyl acetate and water, which is cited in the entry on **Chemical Reaction Rate**, are indicated by use of the double arrow:

$$CH_3COOH + C_2H_5OH \rightleftharpoons HOH + CH_3COOC_2H_5$$

Reactions that result in the precipitation of a solid or the evolution of a gas are sometimes denoted by vertical arrows:

$$AgNO_3 + NaCl \longrightarrow AgCl \downarrow + NaNO_3$$

$$Na_2CO_3 + 2\ HCl \longrightarrow CO_2 \uparrow + H_2O + 2\ NaCl$$

This information about the state of the products may also be denoted by writing after their formulas the expressions (s), (l), or (g).

In some cases, as in reactions in electrochemical cells or other reactions involving oxidation-reduction, the half reactions of the ions are useful. Consider the Daniell cell, which consists of a zinc electrode in a zinc sulfate solution, and a copper electrode in a copper solution, the two solutions being separated by a porous partition. The half reactions are

$$Zn \longrightarrow Zn^{2+} + 2e^-$$

$$Cu^{2+} + 2e^- \longrightarrow Cu$$

so that the overall reaction is

$$CuSO_4 + Zn(s) \longrightarrow ZnSO_4 + Cu(s)$$

The more difficult oxidation-reduction equations can often be written more easily by use of the Stock system of oxidation numbers, which are positive or negative valences or charges. Consider the reaction of potassium dichromate, $K_2Cr_2O_7$, with potassium sulfite, K_2SO_3, in acid solution to form chromium(III) sulfate, $Cr_2(SO_4)_3$, and potassium sulfate, K_2SO_4. The unbalanced expression for the ionic reaction is

$$Cr_2O_7^{2-} + SO_3^{2-} \longrightarrow 2\ Cr^{3+} + SO_4^{2-}$$

Since the oxidation number of the combined oxygen atom is 2− throughout, that of the chromium atom in $Cr_2O_7^{2-}$ is 6+, that of the Cr^{3+} ion is obviously 3+, that of the sulfur atom in SO_3^{2-} is 4+, and that of the sulfur atom in SO_4^{2-} is 6+. The total loss in oxidation number by the two chromium atoms is therefore $(2 \times 6) - (2 \times 3) = 6+$. Since this loss must be offset by a gain made by the sulfur atoms, and since one sulfur atom gains 2+, the reaction must require 3 sulfur atoms. Therefore, the next partially balanced equation is written as

$$Cr_2O_7^{2-} + 3\ SO_3^{2-} \longrightarrow 2\ Cr^{3+} + 3\ SO_4^{2-}$$

Counting the charges in this expression shows that there are 8 negative charges on the left-hand side and a net total of 0 charges on the right-hand side. Therefore, since the reaction occurs in acid solution, requiring that hydrogen ions be present, $8H^+$ are added to the right-hand side to balance the expression electronically, giving

$$Cr_2O_7^{2-} + 3\ SO_3^{2-} + 8\ H^+ \longrightarrow 2\ Cr^{3+} + 3\ SO_4^{2-}$$

Now it is balanced in number of atoms by counting the hydrogen ions (8 on the left-hand side), and the oxygen atoms (an excess of 4 on the left-hand side). Therefore 4 H_2O is added to the right-hand side:

$$Cr_2O_7^{2-} + 3\ SO_3^{2-} + 8\ H^+ \longrightarrow 2\ Cr^{3+} + 3\ SO_4^{2-} + 4\ H_2O$$

If the molecular equation is wanted, it can be written by grouping the ions, and adding those that did not enter into the ionic equations, i.e., the potassium ions of the salts and the anions of the acid:

$$K_2Cr_2O_7 + 3\ K_2SO_3 + 4\ H_2SO_4 \longrightarrow Cr_2(SO_4)_3 + 4\ H_2O + 4\ K_2SO_4$$

CHEMICAL EQUILIBRIUM. The fundamental law of chemical equilibrium was enunciated by Le Châtelier (1884), and may be stated as follows: If any stress or force is brought to bear upon a system in equilibrium, the equilibrium is displaced in a direction which tends to diminish the intensity of the stress or force. This is equivalent to the principle of least action. Its great value to the chemist is that it enables him to predict the effect upon systems in equilibrium of changes in temperature, pressure, and concentration.

The chemical system hydrogen-nitrogen-ammonia furnishes a notable example of the application of the principle:

$$\underbrace{\underset{1\text{vol.}}{\text{nitrogen}} + \underset{3\text{vol.}}{\text{hydrogen}}}_{4\text{ vol.}} \rightleftharpoons \underset{2\text{ vol.}}{\text{ammonia}} + \underset{\text{12,000 carlories per mole ammonia}}{\text{heat}}$$

At the temperature 700°C and pressure 1 atmosphere, the equilibrium percentage of ammonia is 0.03 in the above system, and at 100 atmospheres 2.5. Increase of pressure shifts the equilibrium toward the side of the smaller total volume, at a constant temperature. Decrease of pressure shifts the equilibrium toward the side of the larger total volume, at a constant temperature. Systems of the same initial and final volumes are unaffected, as to equilibrium amounts of materials, by change of pressure.

At the pressure 100 atmospheres, and temperature 700°C, the equilibrium percentage of ammonia is 2.5 in the above system, at 600°C it is 5, at 500°C it is 10. Increase of temperature shifts the equilibrium in the direction which absorbs heat, at a constant pressure. Decrease of temperature shifts the equilibrium in the direction which evolves heat (van't Hoff's principle, 1884).

At constant pressure and temperature, the equilibrium is shifted away from the side subjected to an increase in concentration of any constituent, or toward the side subjected to a decrease in concentration of any constituent. (See also **Chemical Reaction Rate**.) For the qualitative effect of temperature change, one may visualize the heat of an equilibrium reaction as material, and an increase of temperature (heat intensity) as operating to increase the concentration of "heat material," thus shifting the equilibrium away from the side of its increased concentration, and conversely. It is possible, knowing the heat of reaction, Q, on the assumption that the heat of reaction is constant between two given (absolute) temperatures, T_1 and T_2, to calculate the equilibrium constant K_2 (at T_2) when the equilibrium constant K_1 (at T_1) and the gas constant, R (equals 2 calories per mole) are known, by the application of van't Hoff's equation:

$$\log_{10} K_2 - \log_{10} K_1 = \frac{Q}{2.3 \times R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

In this way the quantitative effect of temperature change on the state of equilibrium may be calculated.

In reactions of the ammonia synthesis type, to which sulfur trioxide from sulfur dioxide plus oxygen also belongs, the rate of reaction decreases with lowering of the temperature as the conversion is increased. There is, in such types of reactions, a limit to the practicable lowering of the temperature. The finding of a positive catalyzer for a given reaction of this sort permits the operation to gain the advantage of equilibrium conversion at the lower temperature as well as the increased rate of reaction at that temperature due to the presence of the catalyzer. (See also **Chemical Reaction Rate**.) The time yield of product is, therefore, very important, and, with a catalyzer, the space-time yield.

Systems in equilibrium are divided into two great divisions, according to whether they are (A) homogeneous, that is, chemically and physically uniform throughout, or (B) heterogeneous, that is, not uniform throughout but consisting of two or more phases. Each phase is a homogeneous, physically distinct, and mechanically separable portion of a system. For example, ice, water, water vapor are three different phases (solid, liquid, gas) of the substance water. There can be only one gas phase of a system, and only one liquid phase where a *single* homogeneous solution is present. But the number of liquid and of solid phases in general is limited by the number of components (not constituents) of a system. The number of components is the least number of constituents *independently* variable and requisite to compose each and every phase. For example, the system consisting of saturated solution in water, H_2O, of sodium sulfate, Na_2SO_4, plus solid sodium sulfate decahydrate, $Na_2SO_4 \bullet 10H_2O$, plus water vapor consists of three phases, (a) gas, (b) solution, (c) solid sodium decahydrate. The *least* number of constituents independently variable in amount *and* requisite to compose each and every phase is two, namely, Na_2SO_4 and H_2O. These, therefore, are the two components of this system. Since zero and negative as well as positive amounts of compounds are permitted in expressing the composition of each phase of any system, the three phases of this system are composed of the following components:

gas phase, zero	Na_2SO_4 plus H_2O
liquid phase,	Na_2SO_4 plus H_2O
solid phase,	Na_2SO_4 plus H_2O

The number of components in the ice-water-water-vapor system is one, namely, H_2O.

To systems in which equilibrium depends solely upon the variables, (1) composition of each and every phase, (2) temperature, and (3) pressure, the phase rule (Willard Gibbs, 1874) applies: The number of variables, that is (1) the number of components, C, plus (2) temperature plus (3) pressure, above, equals the number of phases, P, plus the number of degrees of freedom, F. The number of degrees of freedom of a system is the least

number of the above variables which must be arbitrarily fixed in order to define the condition of the system:

$$C + 2 = P + F$$

The phase rule applies to true equilibrium systems, where the equilibrium can be reached from either side, and, furthermore, takes no account of the time involved to attain equilibrium. The phase rule is a qualitative statement, whereas the law of mass action (concentration effect) is quantitatively applicable to those equilibrium systems where the reaction which occurs may be considered to take place in a homogeneous system, e.g., gas phase, or solution phase. (See also **Chemical Reaction Rate**.).

In a one-component system, $P + F = 3$, and physical changes only occur. When only one phase is present, for example, liquid water (no vapor, no solid), the system is bivariant. That is, two variables—temperature and pressure—may be independently changed over a range. When a second phase, either vapor or solid, appears through a sufficient change of temperature or pressure or both, or when two phases are originally present, the system is univariant. That is, one variable—either temperature or pressure—may be independently changed over a range. When the third phase appears or when three phases are originally present, the system is invariant. That is, a change of either temperature or pressure destroys the equilibrium, and the disappearance of one of the phases occurs. A system of one component in three phases is invariant and the conditions are represented by a point known as the triple point. The triple point for water is 0.007°C, 4.6 millimeters mercury pressure. When the total pressure is one atmosphere (760 millimeters) the equilibrium temperature of water-ice is 0.000°C, and when the water vapor pressure is one atmosphere the equilibrium temperature of water-water vapor is 100.000°C.

If, in dealing with any system, the gas phase or pressure may be neglected, on account of constancy or slightness of effect, the phase rule is simplified for practical purposes to $C + 1 = P + F$, and, if both may be neglected, to $C = P + F$.

Many two- and three-component systems have been studied and recorded in detail. The iron-carbon system is one that has attracted much attention and been of great value in iron metallurgy.

In 1977, Professor Ilya Prigogine of the Free University of Brussels, Belgium, was awarded the Nobel Prize in chemistry for his central role in the advances made in irreversible thermodynamics over the last three decades. Prigogine and his associates investigated the properties of systems far from equilibrium where a variety of phenomena exist that are not possible near or at equilibrium. These include chemical systems with multiple stationary states, chemical hysteresis, nucleation processes which give rise to transitions between multiple stationary states, oscillatory systems, the formation of stable and oscillatory macroscopic spatial structures, chemical waves, and the critical behavior of fluctuations. As pointed out by I. Procaccia and J. Ross (*Science*, **198**, 716–717, 1977), the central question concerns the conditions of instability of the thermodynamic branch. The theory of stability of ordinary differential equations is well established. The problem that confronted Prigogine and his collaborators was to develop a thermodynamic theory of stability that spans the whole range of equilibrium and nonequilibrium phenomena.

CHEMICAL FORMULA. The formulas of chemistry constitute a shorthand notation used to represent the composition by weight, the molecular properties, the characteristic chemical reactions or at times even the ordering of the atoms in space of the elements which go to make up the chemical compound. Chemical formulas are classified into empirical, molecular, structural, or configurational, the order given being that of increasing content of information. The meaning of empirical and the molecular formulas is explained in the entry on **Chemical Composition**, which also describes methods for determining the formulas for some simple compounds. See also **Atomic Mass (Atomic Weight)**. Their determination for compounds in general, especially if they are present in mixtures, requires considerable experimental work. The first step consists of the isolation of a pure chemical compound. Chemical purification can be obtained by methods such as crystallization, distillation, adsorption, and sublimation. Some of the criteria of purity a substance must satisfy are constancy and sharpness of melting point and boiling point on repeated purification. As an example, let us assume that we have succeeded in purifying a solid compound which we shall call tartaric acid and whose formula we wish to determine.

The second step consists in a qualitative and quantitative analysis of the compound. In the case of tartaric acid, qualitative analysis tells us that the compound contains carbon, oxygen and hydrogen, while quantitative analysis shows that the proportions are 48 parts by weight of carbon, 96 of oxygen, and 6 of hydrogen. To obtain the empirical formula, one divides each proportion by the atomic weight of the particular element, obtaining in this way a set of numbers that can be represented by a ratio of small integers. The simplest ratio of integers is commonly used to indicate as subscripts on the right of the chemical symbol of the element to represent the empirical formula. In the case of tartaric acid, the atomic weights are approximately 12 for carbon, 16 for oxygen, and 1 for hydrogen. Dividing the percentages as determined by analysis by the atomic weights, we get:

$$\text{carbon } \frac{48}{12} = 4.00$$

$$\text{oxygen } \frac{96}{16} = 6.00$$

$$\text{hydrogen } \frac{6}{1} = 6.00$$

The set of numbers is 4,6,6 and can be presented, in this case, by the ratio of integers 2:3:3. The empirical formula is therefore $C_2O_3H_3$. Empirical formula is thus only a convenient method for representing the percentage composition by weight of the different elements in the compound. The third step is the determination of the molecular weight of the compound in question. This allows us to assign to the compound a molecular formula. The molecular weight can be determined in a variety of methods, such as by the determination of the weight of 22.242 liters of the vapor of the substance at 1 atmosphere pressure and 0°C, temperature. Other methods are based on the differences in the boiling point or freezing point of solutions of known concentration and those of the pure solvent. To determine the molecular formula from the knowledge of the empirical formula and the molecular weight, the following procedure must be followed: Multiply the atomic weight of each element by its subscript, as indicated in the empirical formula, and add the result. On comparison of such a sum with the molecular weight it will be found that the molecular weight is equal to the sum times an integer. To obtain the molecular formula, multiply each subscript in the empirical formula by this integer and obtain a new set of subscripts. We found the empirical formula of tartaric acid was $C_2O_3H_3$. The sum mentioned above is

$$12 \times 2 + 16 \times 3 + 1 \times 3 = 75$$

The molecular weight determined experimentally is 150. The integer multiple is 2, and the molecular formula becomes $C_4O_6H_6$.

The molecular weight of the compound can be obtained from the molecular formula by summing the products obtained by multiplication of the atomic weights of the elements times their subscripts in the molecular formula. The latter contains all the information that the empirical formula contains but in addition specifies the number of atoms in the molecule and also the molecular weight of the substance.

Important as the molecular formula is, it does not describe fully the properties, or even in some cases the identity, of chemical compounds. For example, there are two compounds that have the molecular formula C_2H_6O. They are different in all their properties, both chemical and physical. This difference is due to a difference in the manner in which the atoms are connected in the molecules of the two substances. These differences can be shown only by the use of structural formulas, such as those shown in Fig. 1, in which the valence bonds between the atom are shown. These structural formulas are determined circumstantially, that is, by the chemical reactions into which the compounds enter. (However, their arrangements have been confirmed in many cases by a direct instrumental means such as spectrometric methods, x-ray studies, etc.) These reactions differ markedly for ethyl alcohol and methyl ether. Such compounds which have the same molecular formula but differ due to the arrangements or positions of their atoms are called isomers, and the type just cited, in which the difference is in the grouping of the atoms, are called *functional isomers*. These, and many other types of isomers, are treated in the entry on **Isomerism**.

The structural formula is also a shorthand notation for the important chemical reactions of the compound. It can be considered as being built up of a group of organic radicals, i.e., groups of atoms that retain their individuality in the course of certain reactions. Each radical has reactions which are characteristic of its presence in the molecule.

For instance, the carboxyl radical will react with alkali such as sodium hydroxide to form salts with phosphorus pentachloride to form acid

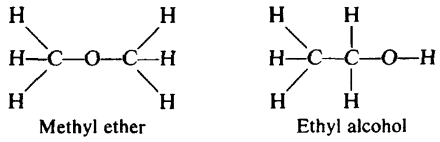

Fig. 1. Examples of structural formulas

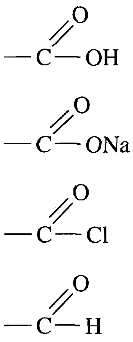
chlorides with alcohols to form esters; with reducing agents under certain conditions to form successively the aldehyde radical and the alcohol radical. Any pound that undergoes such reactions is said to contain a carboxyl group. The number of such carboxyl groups in a molecule can be determined by studying the above reactions quantitatively. On the other hand, if the compound will react: with sodium to give off hydrogen; with phosphorus trichloride to give a halogen substitution product which can be reduced to hydrocarbon; with an oxidizing agent to give an aldehyde or ketone, with organic acids to form esters; and with alcohols to form ethers; then the molecule is said to contain a hydroxyl group—OH. Analogously, there are similar characteristic reactions for a variety of radicals. It often happens that the presence of one type of a radical near another type mutually influences their reactivity, but one can consider to the first approximation that the radicals act independently of each other. The structural formula is considered completely established if one can synthesize the compound by simple clear-cut reactions involving no rearrangements on the basis of the proposed formula.



Just as it was stated above that two compounds may have the same molecular formula and yet have quite different structural formulas and properties, so there are also many instances in chemistry of compounds which have the same planar structural formula and yet differ in properties. In such cases their differences in structure can be shown only by three-dimensional formulas or their projections which portray differences in the arrangement in space of the atoms or radicals that make up the molecules of the two compounds.

Thus, in cases where four different atoms or groups are attached to the same atom, it is possible to have two arrangements in space that cannot be made to coincide geometrically. This situation can be demonstrated by use of a special type of formula, shown in Fig. 2 for the two forms of the compound fluorochlorobromomethane. This existence of two forms due to a difference in orientation in space is called *stereoisomerism*, and is discussed in the entry on **Isomerism**. It also follows that for compounds containing more than one atom bonded to four unlike groups, the number of different forms increases rapidly, as is shown by the three possible forms of tartaric acid, HOOC–CH–OH–CHOH–COOH, as portrayed by the three formulas shown in Fig. 3.

Still other types of formulas showing the spatial positions of atoms and groups are perspective and projection formulas, as shown in Fig. 4 for the

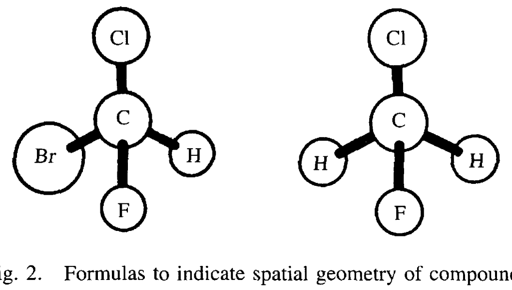


Fig. 2. Formulas to indicate spatial geometry of compounds

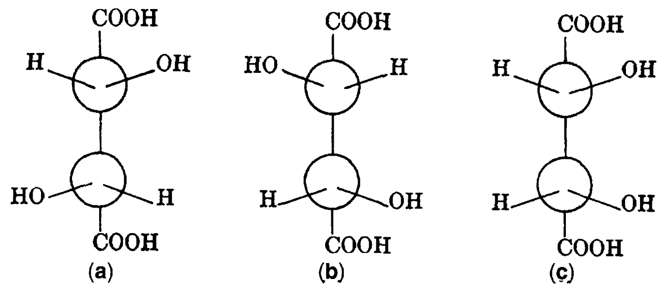

Fig. 3. Formulas to demonstrate stereoisomerism

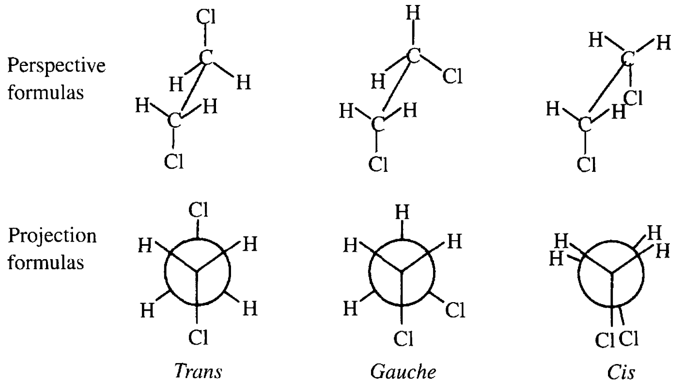

Fig. 4. Perspective and projection type formulas

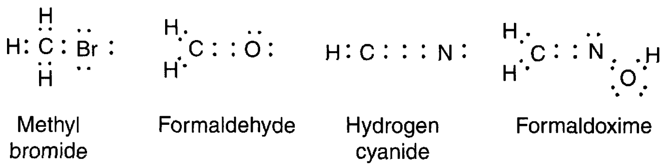

Fig. 5. Formulas to demonstrate bonding

compound 1,2-dichloroethane. These differences are due to differences in conformation, that is, to the various configurations of a molecule, which differ in space by the rotation of two atoms about a single bond.

Another type of formula often written for compounds is the electronic formula, showing the distribution of the valence electrons among the atoms of the molecule, as shown in Fig. 5 and explained under valence and molecule.

CHEMICAL MANUFACTURERS ASSOCIATION (CMA). Founded in 1863, this nonprofit trade association of chemical manufacture represents more than 90% of the chemical industry of the U.S. and Canada. It is located at 2501 M St., N. W., Washington, DC 20037. It is particularly active in the fields of packaging, transportation, and safe handling of hazardous chemicals and wording of precautionary labels, as well as in general chemical education and all aspects of pollution control. It has instituted an emergency telephone information service called *ChemTrec* to provide instant information for safety precautions in accidents involving chemicals.

CHEMICAL POTENTIALS. Chemical potentials are defined in terms of the entropy by the relationship

$$\mu_i = -T\left(\frac{\partial S}{\partial n_i}\right)_{U,V} \tag{1}$$

Apart from the factor T (the absolute temperature) the chemical potential is equal to the change of the entropy due to the introduction of the mole number **i** into the system, at constant total energy U and volume V. The parentheses in the above equation contain the partial derivative representing this rate of change.

Other independent variables are often much more convenient. One has also

$$\mu_i = \left(\frac{\partial U}{\partial n_i}\right)_{S,V} = \left(\frac{\partial G}{\partial n_i}\right)_{S,p} = \left(\frac{\partial A}{\partial n_i}\right)_{T,V} = \left(\frac{\partial G}{\partial n_i}\right)_{T,p} \quad (2)$$

The last member of Equation (2) shows that μ_i is the partial molar quantity associated with the Gibbs free energy, G. Euler's theorem gives then

$$G = \sum_i n_i \mu_i \quad (3)$$

The relation to chemical affinity is also very direct

$$\mathrm{A} = -\sum_i v_i \mu_i \quad (4)$$

Note that the roman capital A represents chemical affinity, while the italic capital A symbolizes the Helmholtz free energy (also called work function). It follows that the condition for chemical equilibrium is

$$\sum_i v_i \mu_i = 0 \quad (5)$$

where the v_i are stoichiometric coefficients. This formula expresses the law of mass action. Similarly the condition for two phases α and β to be in equilibrium with respect to species i is

$$\mu_i^{\alpha} - \mu_i^{\beta} \quad (6)$$

The chemical potential has then the same value in the two phases. See also **Thermodynamics**.

CHEMICAL REACTION RATE. The chemical composition of a substance is subject to various changes under various conditions, depending upon (1) the nature of the specific substance, (2) the nature of other substances present, and (3) the environment in which it exists (the physical and chemical ambient conditions). Similarly, chemical reaction rates are affected.

The majority of reactions take place between two substances—occasionally one substance only, and sometimes three or more different substances. There are many cases when simple contact of the substances is sufficient to bring about the chemical change, e.g., the rusting of iron in oxygen. In many other cases, the change is not spontaneous, but must be induced, frequently by raising the temperature, as in the burning of fuels. The conditions that are considered important and fundamental are (1) temperature, (2) pressure, (3) medium, if any, (4) catalyzer, if any (5) electric direct current, (6) light. In a given reaction, the change in composition of the substance or substances involved is inherently connected with a change in energy. Thermal, electrical or light energy of a certain potential or intensity and in definite amounts, is requisite to initiate and carry on the reaction, and thermal, electrical or light energy of definite amount is liberated or consumed in the reaction. Every reaction, properly speaking, has both a matter and an energy aspect. While the energy aspect is frequently neglected directly, the conditions must always be in accord with the energy demand, even if apparently not considered. Chemical changes require consideration of three topics, namely, (1) natural rate of chemical reactions, (2) acceleration of the natural rate in the presence of a catalyzer, and (3) the endpoint of chemical reactions. See also **Electrochemistry**; **Photochemistry and Photolysis**; and **Thermochemistry**.

Contemporary Investigations of Reactions and Reaction Rates

The near term and continuing into the early 2000s will witness outstanding progress in the development of a better understanding of chemical reactions and the time frames within which they occur. In this excellent paper (1985), the late Frederick Kaufman (University of Pittsburgh) stated, "The experimental science of measuring the rates of elementary chemical reactions has advanced to a point where hundreds of such rates either have been determined or are within reach. In a sense, these data give us a global view of chemical reactivity for gas-phase reactions. What this information lacks in detailed, state-to-state insight it more than makes up for in chemical diversity. It is essential that this research be pursued for its own sake rather than just for the sake of providing input data for atmospheric and combustion chemistry (traditional areas of interest), however important these applications are. The existing data bases of elementary-reaction rate constants have not yet been systematically examined for what they tell us about chemical reactivity. In the light of present advances in the techniques for the generation and detection of reactive species, the number of accessible reactions and the range of temperatures and pressures being studied are rapidly increasing and the accuracy of rate measurements is rapidly improving. Strong interaction between theorists and experimentalists has developed but needs to be expanded. What is needed more than anything else is the full realization by the academic community that elementary reaction kinetics is an intellectually exciting field that gives insight into why, how, and how fast chemical reactions take place."

Modern experimental techniques for measuring rate parameters of elementary reactions have transformed the field of gas-phase reaction kinetics from one of indirect inference to one of direct determination. Two general kinds of experimental methods may be cited: (1) In the flash- or laser-photolysis (FP) method, reactive species are produced in a short (10^{-6} to 10^{-8} second) light flash, and their decay resulting from a reaction is monitored in real time by spectroscopic means. (2) In the flow reactor (flowing afterglow) discharge-flow (DF) method, the reactive species are produced continuously in steadily flowing carrier gas (helium or argon) and mixed with other reactants. The rate is determined either by changing the distance over which the reactants are in contact (reaction time) or by changing the concentration of one reactant at constant reaction time. Detailed diagrams of the apparatus used for these experimental methods are beyond the scope of this encyclopedia. They are carefully depicted in the Kaufman (1985) paper listed under additional reading.

As reported by Leone (1985), available laser sources for selective excitation and detection makes it possible to infer many things concerning the dynamics of reactions, such as the particular motions that molecules are likely to undergo during a reaction. The technique makes it possible to interrogate or probe the specific forms of excitation that best lead to chemical reaction, such as vibrational, rotational, or translational motion, or electronic and photo-excitation.

Under ideal circumstances, reactions under investigation are carried out under what is called "single-collision" conditions. These typically require low pressures, so that a product molecule born in a particular state is not modified by subsequent collisions before the time of interrogation has expired. Very short laser pulses usually are used, thus making the time between excitation and interrogation less than 10^{-8} second. However, at this speed, higher pressures can be used so that collisions occurring between formation of a product and its detection and identification can be minimized or essentially eliminated.

One of the fastest reactions reported to date resulted from research at Pennsylvania State University in 1986. It was reported that the time required for the rhodium helide ion ($RhHe^{2+}$) to dissociate into Rh and He was approximately 10^{-13} second, i.e., eight ten-trillionths of a second. Because this kind of interval cannot be resolved by present electronic timer technology, the investigators modified their apparatus to stretch out the reaction time by orders of magnitude. One part of the solution was to use a 4.2 meter evacuated flight tube that lead into an ion detector. Time was determined on the basis of the slight difference in kinetic energy (velocity) of the rhodium ions detected at the end of the flight tube.

Natural Rate of Chemical Reactions

Various factors operate to affect the rate of chemical reactions. By natural rate is understood the rate of a reaction in the absence of a catalyzer. Excluding electrochemical and photochemical reactions, and giving attention to thermochemical reactions only, there are four factors or conditions to be considered, namely, (1) concentration of constituents, (2) temperature, and (3) pressure—important where a gas is involved, (4) nature of the medium, if any.

The general mathematical definition of the rate of a chemical reaction v is

$$v = \frac{d\xi}{dt} \quad (1)$$

where ξ (Greek letter xi) is the extent of reaction, t is time, and the derivative thus represents the rate of change of the extent of reaction.

1. Relation between concentration of reactants and rate of *reaction*. The rate of a given reaction, at constant temperature and pressure under stated conditions of concentration of the reacting substances, is quantitatively

expressible by a velocity constant, which is the fraction of the substances transformed in a unit of time. Many reactions occur instantaneously—true for most reactions in solution in inorganic chemistry—and many others are complicated in subsidiary reactions, so that the velocity constant is measurable in comparatively few cases. The principle, however, holds as stated, whether or not the desired value can be ascertained experimentally.

A simple reaction that was studied by Wilhelmy, and since then by various investigators, is the transformation (hydrolysis) of sucrose $C_{12}H_{22}O_{11}$ in water solution into glucose ($C_6H_{12}O_6$, a polyhydroxy aldehyde) plus fructose ($C_6H_{12}O_6$, a polyhydroxy ketone), which proceeds at a measurable, steady rate in the presence of acid (hydrogen ion). The rate of reaction at any instant is found to be proportional to the amount of sucrose present at that instant.

When a dilute water solution of an ester, such as methyl acetate, is similarly hydrolyzed in the presence of hydrogen ion, the reaction is of the same type. And this statement also applies to the decay of radioactive elements. One of the important radioactive constants is the half-life, that is, the time required for the decay of one-half of the element present at a given instant.

The preceding cases are instances of *first order reactions*, that is, reactions in which the rate depends only upon the concentration of a single molecular or atomic species. They are also *monomolecular reactions*, that is, reactions in which the initial reactant is only of one species, that is, sucrose, or an ester, or a radioactive element. Note that first order reactions are not necessarily monomolecular; thus $H_2 + D_2 \rightleftharpoons 2HD$, is a first order reaction, even though it is called bimolecular because a hydrogen-1 molecule reacts with a hydrogen-2 (deuterium) molecule to form hydrogen deuteride molecules.

We can now introduce a general treatment of the concept of the order of a chemical reaction. A chemical reaction is said to be of the *n*th order if its rate is directly proportional to the product of n concentrations. Therefore the decomposition of A, if described by the equation

$$\frac{dC_A}{dt} = -kC_A \tag{2}$$

is a *first order reaction*. Similarly if it is described by the equation

$$\frac{dC_A}{dt} = -kC_AC_B \text{ or } \frac{dC_A}{dt} = -kC_A^2 \tag{3}$$

it is a *second order reaction*.

The coefficient k, which appears in (2) or (3), is called the *rate constant*. Generally the temperature variation of a rate constant may be expressed by

$$k = Pe^{-Q/kT} \tag{4}$$

where k is the rate constant and k is the Boltzmann constant. This equation is called the *Arrhenius equation*.

We now introduce a general treatment of rate of reaction, which is often called the *absolute reaction rate theory*, because its purpose is to calculate the rate in terms of molecular quantities only.

Consider the reaction

$$A + BC \longrightarrow : AB + C \tag{5}$$

To simplify the discussion, assume that A, B, and C always remain in a straight line. The course of the reaction may then be followed by noting the values of the two interatomic distances r_{AB} and r_{BC}. At the beginning of the reaction r_{AB} is large and r_{BC} is small while at the end of the reaction r_{AB} is small and r_{BC} is large.

Let us introduce the potential energy surface. The representative point of the system moves on this surface along the so-called *reaction coordinate*. The potential energy along the reaction coordinate is represented schematically in Fig. 1. The maximum of the curve corresponds to a situation where three atoms are very close to one another. Moreover this point is a *maximum* along the reaction coordinate but a *minimum* for the direction normal to the reaction coordinate. Indeed the most probable path is the path involving the minimum potential energy in going from the initial to the final state.

Therefore the point considered corresponds to a *saddle point* of the energy surface. It is called the *activated complex*.

One may now assume that the reaction rate is the product of the following three factors: (1) the average number of activated complexes; (2) the characteristic frequency of the activated complex (that is, the inverse of its lifetime); and (3) the *transmission coefficient*, K, which is

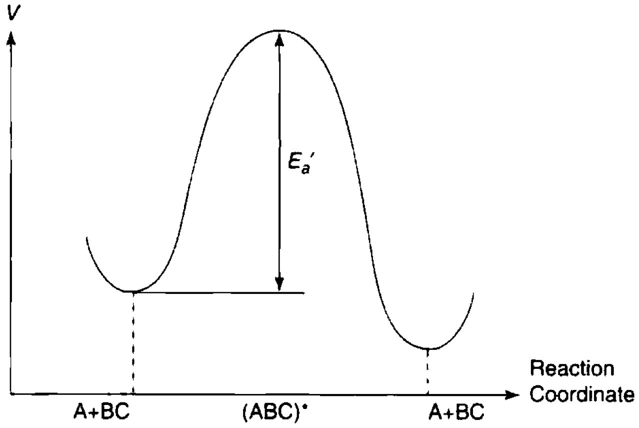

Fig. 1. Potential energy along the reaction coordinate

the probability that a chemical reaction takes place after the system has reached the activated state.

Moreover, the number of activated complexes is calculated by the equilibrium assumption.

Using this description of the reaction process one derives the following expression for the reaction constant

$$k = K\frac{\phi(T)}{\phi_A(T)\phi_{BC}(T)}\frac{kT}{h}\exp\left(-\frac{E'}{kT}\right) \tag{6}$$

Here the ϕ terms are the partition function $f(T, V)$, the volume factor being removed

$$f = V\phi \tag{7}$$

ϕ_t corresponds to the activated complex, the degree of freedom associated with the reaction coordinate being removed; k is Boltzmann's constant, h is Planck's constant, E' is the energy associated with activated complex, or *activation energy* of the reaction.

This expression may also be written in the thermodynamic form

$$\begin{aligned} k &= K\frac{kT}{h}\exp\left(-\frac{\Delta G^{\ddagger}}{kT}\right) \\ &= K\frac{kT}{h}\exp[-(\Delta H^{\ddagger} - T\Delta S^{\ddagger})/kT] \end{aligned} \tag{8}$$

where $\Delta G^{\ddagger}$ is a suitable free energy of activation and $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ the corresponding enthalpy and entropy of activation.

When a reaction involves two different phases, that is, when the system is not homogeneous but heterogeneous, as in reactions between a solid phase, such as zinc or calcium carbonate, and a liquid phase, such as hydrochloric acid solution, the rate of reaction involves consideration of (1) the area of the surface of contact of the solid with the solution, and (2) the rate of diffusion from the surface of the solid, as well as (3) the concentration of hydrogen ion of the acid solution.

When the rate of a chemical process is dependent upon (1) two or more *consecutive* reactions, the observed rate is limited by the rate of the slowest reaction in the series, or (2) two or more *concurrent* reactions, the products are in the same ratio at any instant only when the reactions themselves are of the same rate.

2. Relation between temperature of reactants and rate of reaction. The rate of chemical reaction is increased by an increase in temperature, as is evident from the fact that temperature occurs in the numerators in the foregoing equations.

3. Relation between pressure of reactants, if gaseous, and rate of reaction. Since pressure changes amount to concentration changes in such systems, the behavior is as described above under concentration.

4. Relation between nature of the medium and rate of reaction. Very slight changes in the nature of the medium greatly affect the rate of a chemical reaction, but attempts to relate any physical property of a solvent with the effect observed on the rate of a given reaction appear to have proved unsuccessful.

One should mention here that in reactions involving ions, the effects of electrolytes can be put into two principal categories: (a) primary salt effect and (b) secondary salt effects.

Primary salt effects refer to the effects of electrolyte concentration on the activity coefficients. Secondary salt effects are those concerned with the actual changes in concentration of the reacting species resulting from the addition of electrolytes.

BrØnsted has shown that the variation in specific rate with ionic strength depends on the magnitude and sign of the ionic charges. Thus three main types of primary salt effect in reactions of two species can be distinguished. If the products of the signs of the charges are positive, the velocity of the reaction increases with increasing ionic strength:

$$Co[(NH_3)_5Br]^{2+} + Hg^{2+} (+2 \times +2 = +4)$$

or

$$S_2O_8^{2-} + I^- \quad (-2 \times -1 = +2)$$

or

$$BrCH_2COO^- + S_2O_3^{2-} \quad (-1 \times -2 = +2)$$

If the products of the charges are negative the velocity of the reaction decreases with increasing ionic strength:

$$Co[(NH_3)_5Br]^{2+} + OH^- (+2 \times -1 = -2)$$

or

$$H_2O_2 + H^+ + Br^- (+1 \times -1 = -1)$$

In the third category where the product of the ionic charges is zero, the ionic concentration has no or very little effect on the velocity of the reaction, particularly in dilute solution, as in the case of

$$[Cr(NH_2CONH_2)_6]^{3+} + 6H_2O \longrightarrow [Cr(H_2O)_6]^{3+} + 6\ NH_2CONH_2 (+3 \times 0 = 0)$$

BrØnsted showed the inadequacy of both the classical and the activity theories of rate of certain reactions. He proposed a new theory postulating that when ions or molecules react, they first form an unstable critical complex, which then decomposes to give the reaction products. The reaction that determines the velocity of a chemical change consists in the formation of that unstable critical complex.

Summarizing, the rates of chemical reactions are subject to highly specific influences in each case, as has been abundantly demonstrated by experimental investigations, and recognized in numerous legal battles in chemical patent suits.

Acceleration of the Natural Rate of Chemical Reactions in the presence of a positive or negative catalyzer. When, in the presence of a given substance, the natural rate of a chemical reaction is changed, either increased or decreased, the given substance is called a catalyzer. Examples are numerous. (1) When a gas-lighter of the type known as platinum black, the active part of which consists of very finely divided platinum, is held in a stream of hydrogen or city gas, the gas is ignited in air. Platinum is a catalyzer for this reaction, and causes ignition to take place at a temperature much lower than by subjecting to fire. (2) The changing of sulfur dioxide into sulfur trioxide is accomplished by passing a mixture of sulfur dioxide and air (one-fifth oxygen) over asbestos coated with finely divided platinum. The temperature required is much lower by the use of platinum catalyzer than without its use. (3) Solutions of sulfites are subject to oxidation to sulfates by oxygen upon allowing to stand in air. The addition of sugar or glycerol retards the speed of this reaction. These substances act in this case as negative catalyzers. (4) The combination of nitrogen and hydrogen gases under high pressure to form ammonia gas is accomplished at a lower temperature in the presence of a catalyzer than in its absence, thus increasing the yield of ammonia (see also **Equilibrium**). One of the catalyzers is composed of iron, intimately mixed with 1% aluminum oxide and 1% potassium oxide. Iron is a catalyzer for this reaction, but is more active as such in the presence of aluminum oxide and potassium oxide, which are spoken of as promoters, a sort of catalyzer of a catalyzer. (5) The hydrogenation of liquid fatty oils and of oleic acid is conducted in the presence of finely divided nickel as a catalyzer. (6) Enzymes are very specific catalyzers, "the most selective and delicate of all known catalysts (Hilditch)," at ordinary temperatures, say 25 to 30°C. Dextroglucose is converted into ethyl alcohol in the presence of the enzyme (zymase) of yeast, and ethyl alcohol into acetic acid (vinegar) in the presence of the enzyme of *Mycoderma aceti*. (7) Nitric acid reacts slowly with copper metal, but the rate of reaction is accelerated more and more as nitrogen tetroxide (catalyzer) is formed in the solution. This is an example of autocatalysis, wherein the reaction brings about the formation of its own catalyzer. (8) Arsenic-containing substances are extreme negative catalyzers, called inhibitors or poisons, of platinum catalyzer.

When the catalyzer is a solid substance, the greatest difficulty in use is to maintain a clean surface. The presence of a positive catalyzer enables a reaction to proceed more rapidly at a lower temperature than corresponds to the natural rate of the reaction. This increases the amount of substances converted in a given time, decreases the demands as to temperature resistance of materials of construction of the apparatus, and frequently makes possible a state of equilibrium more favorable to the yield of desired material.

The End-point of Chemical Reactions

If a chemically reactive system is isolated from the rest of the universe at a constant temperature and pressure, a definite end-point is often attained short of the complete transmutation of reactants into resultants. In order to be certain that this end-point (short of complete transmutation) is what is known as the equilibrium point, the equilibrium must be approached from both directions, e.g., $A + B \longrightarrow C + D$ and $C + D \longrightarrow A + B$. If the equilibrium constant (see treatment below) is the same when approached from both directions, then the reaction is one of true chemical equilibrium. Such equilibrium reactions are also referred to as balanced or reversible reactions. In such reactions the extent of the chemical change is proportional to the concentrations of all the reactants—reactants and resultants being interchangeable, depending upon the direction of the reaction. (Generalization of Guldberg and Waage, 1864, called Law of Mass Action, or more correctly Law of Concentration Effect. Reaction studied by Guldberg and Waage (1867): Barium sulfate plus potassium carbonate plus barium carbonate plus potassium sulfate.)

A classical case, frequently cited, is that investigated by Berthelot in 1963. When 1 mole (60 grams) of acetic acid CH_3COOH and 1 mole (46 grams) of ethyl alcohol C_2H_5OH, both of which substances are soluble in water, are mixed, a reaction takes place which results in the formation of water and ethyl acetate ester, which is likewise in the ratio of 1 mole (18 grams) of water, and 1 mole (88 grams) of ethyl acetate $CH_3COOC_2H_5$. On the other hand, when 1 mole of water and 1 mole of ethyl acetate ester are mixed, a reaction takes place which results in the formation of acetic acid and ethyl alcohol in the ratio of 1 mole of acetic acid and 1 mole of ethyl alcohol. Three important observations have resulted from the detailed study of this reaction, namely: (1) the reaction between acetic acid and ethyl alcohol as reactants proceeds at such a rate that the fraction $\frac{0.005}{5}$ of the amount present at any instant reacts, at 6 to 9°C, in 1 day to form equivalent amounts of water and ethyl acetate ester; (2) the reaction between water and ethyl ester as reactants proceeds at such a rate that the fraction 0.00144 of the amount present at any instant reacts, at 6 to 9°C, in 1 day to form equivalent amounts of acetic acid and ethyl alcohol; and (3) the end-point of each reaction is the same, that is, the reaction is one of true chemical equilibrium, and the resulting equilibrium mixture contains, in each case, 0.33 mole acetic acid plus 0.33 mole ethyl alcohol plus 0.67 mole water plus 0.67 mole ethyl acetate ester. This system attains practical equilibrium, at 6 to 9°C in about 1 year, at 100°C in about 8 days, and at 200°C in about 24 hours.

The equilibrium constant is calculated numerically as follows:

Equation:	CH_3COOH +	C_2H_5OH ⇌	HOH +	$CH_3COOC_2H_5$
Reaction weights:	60	46	18	88
Molar ratio at equilibrium:	0.33	0.33	0.67	0.67
Weights at equilibrium:	0.33 × 60	0.33 × 46	0.67 × 18	0.67 × 88

$$\left.\begin{array}{r}\text{Equilibrium}\\ \text{constant at } 9^\circ\text{C}\end{array}\right\} = \frac{\text{conc. } HOH \times \text{conc. } CH_3COOC_2H_5}{\text{conc. } CH_3COOH \times \text{conc. } C_2H_5OH} = \frac{0.67 \times 0.67}{0.33 \times 0.33}$$

Knowing the equilibrium constant at any stated temperature enables one to calculate the equilibrium end-point at that temperature for any ratio of reactants. Thus, when 1 mole (60) grams of acetic acid and 10 moles (460)

grams of ethyl alcohol at 9°C are taken:

$$\text{Equilibrium constant at } 9^\circ C = 4 = \frac{X \times X}{(1 - X) \times (10 - X)}$$

where X is the number of moles of water and also the number of moles of ethyl acetate ester formed (1 mole of each is formed by reaction of 1 mole acetic acid plus 1 mole ethyl alcohol). Solution of this equation shows $X = 0.97$. Therefore, by taking the above ratio of acetic acid (1 mole) to ethyl alcohol (10 moles) 0.97 (or 97%) of the acetic acid, the excess reactant being ethyl alcohol (9 moles), is converted at equilibrium into water plus ethyl acetate ester. In practice, the reaction is conducted by the use of a catalyzer, e.g., sulfuric acid concentrated, zinc chloride.

In cases where one of two resultants can be separated from the reactants and the other resultant, by precipitation as a solid, by condensation as a liquid, or by volatilization as a gas or vapor, the yield of the desired substance from a given amount of reactants can sometimes be materially increased. In the case of heterogeneous systems, whenever a solid participant is present, the *concentration* of said solid is considered constant. The precipitation and solution of solids are in this category, as well as the reactions between a gas and a solid, e.g., the system ferroferric oxide plus hydrogen gas plus iron plus water vapor.

The effect of change of temperature on a system in chemical equilibrium is that the equilibrium point is shifted (1) toward the side *away* from that which evolves heat when the temperature is *raised*, and (2) toward the side which evolves heat when the temperature is lowered. It is *as if* the amount of heat were a *material* reactant and its concentration (temperature or intensity of heat) increased, in respect to the *direction* of the shift of the equilibrium point. The amount of the shift at constant pressure can be calculated in cases where one possesses the proper data.

The effect of change of pressure on a system in chemical equilibrium is that the equilibrium point is shifted (1) towards the side possessing the smaller aggregate volume when the pressure is increased, and (2) towards the side possessing the larger aggregate volume when the pressure is decreased. The amount of the shift at constant temperature can be calculated by means of the equilibrium constant (above), recalling that increase of pressure is equivalent to increase of concentration of gases (temperature constant). When the volume of resultants equals the volume of reactants, no effect is produced on the equilibrium point by change of pressure. See also **Chemical Equilibrium**.

In some chemical reactions, the use of concentrations does not give calculated results that agree with those observed, because of the departure from ideality of real gases and solutions. In such reactions, concentrations are replaced by apparent effective concentrations, or activities, as explained in that entry.

CHEMICALS (Number of). With over 100 chemical elements from which chemical compounds can be built, the large numbers of atoms which may be present in various compounds, and the many ways in which the atoms can be linked (straight chains, branching chains, rings, half-rings, etc.), the number of "possible" chemical compounds is a very high number indeed, and, of course, is much larger than the millions of "known" compounds, which can be described fully in terms of constituents and structure. Keeping track of so many compounds—in the interest of fundamental research and, in more recent years, the identification of chemical compounds in terms of both beneficial and adverse effects on biological systems, health, and the environment—commenced many years ago. Thousands of compounds are described in numerous handbooks, various societies have compiled lists and tabulations, as for example the Chemical Abstracts Service (CAS) of the American Chemical Society, and special encyclopedias which describe inorganic and organic compounds. Possibly the most outstanding example is the "Handbuch der Organische Chemie," first undertaken in Germany in 1918. The first 27 volumes of this book were published between 1928 and 1938. Supplements have been released periodically since that time. Part II, consisting of 29 volumes, was published between 1941 and 1957; Part III, 14 volumes, was published between 1958 and 1973. Part IV was commenced in 1972 and continues. Publisher is Springer-Verlag, Berlin. The "Dictionary of Organic Compounds," 5th Edition (J. Buckingham, Executive Editor), published by Chapman and Hall Ltd, London, describes some 150,000 compounds. The book is published in seven volumes, which comprise a total of approximately 7900 printed pages. The "Main Work" was published in October 1982, with supplements scheduled for publication periodically. The First Supplement was released in 1938.

The CAS registry listings run into the millions of compounds, a very high percentage of which contain carbon. The majority are synthesized for specific research use. It is estimated that about three-fourths of the compounds listed are mentioned only once or very few times in the literature. Large numbers of listed materials are coordination compounds, the structure of which has not been fully defined. The registry also lists alloys, polymers, and mixtures with definite names. The registry embraces only papers published since 1965.

The ACS also offers the "Beilstein Online Database." This is claimed to be the most complete and systematic collection of evaluated data on organic compounds. The database is reviewed in a ten-chapter, "The Beilstein Online Database: Implementation, Content, and Retrieval," available from American Chemical Society, Washington, DC.

CHEMISORPTION. The binding of a liquid or gas on the surface or in the interior of a solid by chemical bonds or forces.

CHEMOTHERAPEUTICS, ANTICANCER. Cancer is second only to cardiovascular disease as the principal cause of human mortality. As the median age of populations has risen, total deaths from cancer have increased. Treatment of cancer includes surgery, radiation, and chemotherapy, the last encompassing the use of both cytotoxic agents and relatively nontoxic hormonal agents for the control of tumor growth.

Drugs used in cancer chemotherapy or clinical trials are classified according to primary underlying mechanisms of action. However, many drugs operate through multiple mechanisms. Mechanisms include those of antimetabolites, DNA alkylating and/or cross-linking agents, DNA binding/cleaving agents, DNA topoisomerase interactive compounds, agents that act on tubulin structure, and hormones (Fig. 1). In addition to those drugs already approved by the FDA, a number of investigational drugs are undergoing clinical evaluation and many others are in the pipeline.

Antimetabolites. Antimetabolites, which represent one of the earliest groups of anticancer agents, are listed in Table 1.

DNA Alkylating/Cross-Linking Agents. This category includes compounds of diverse chemical classes (Table 2).

DNA Binding/Cleaving Agents. DNA binding and/or cleaving agents that have anticancer activity are listed in Table 3. All of the natural products and analogues of natural products in this category (Table 3) are able to bind DNA either as intercalators or as minor groove binders, hence inhibiting DNA-dependant RNA synthesis. Both bleomycin and esperamicin A_1 cleave DNA by forming free radicals in the immediate vicinity of the sugar—phosphate backbone. Activity as antitumor agents is related to the ability to induce irreparable lesions in DNA. Bleomycin generates oxygen free-radical species whereas esperamicin A_1 and a number of related natural products that include neocarzinostatin, dynemicin, and the calicheamicins generate aryl diradical species, which abstract hydrogen

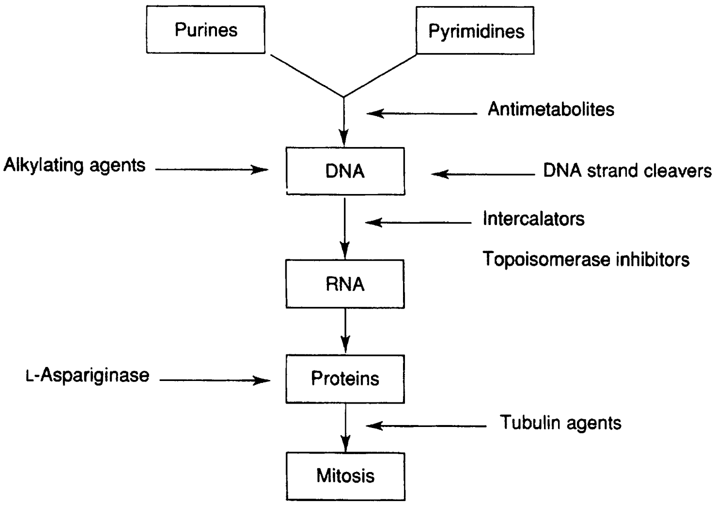

Fig. 1. Schematic of nucleic acid and protein synthesis and the steps leading to mitosis showing the common mechanisms of action and various classes of chemotherapeutic agents

atoms directly from the deoxyribose backbone. An analogue of the natural product CC1065 has the unique property of being a DNA alkylating agent which recognizes poly-AT regions of the minor groove of DNA. It remains to be seen if the high potency and unique modes of action ascribed to these novel classes of agents can translate into clinically useful drugs.

Topoisomerase Interactive Drugs. Topoisomerases I and II have emerged as interesting targets for the design of new anticancer agents (Table 4).

Tubulin Active Drugs. Tubulin active drugs are listed in Table 5.

Hormones. Although not strictly cytotoxic, hormones have been used to control the environment of hormone-dependent tumors such as those of the prostate, breast, and endometrium, i.e., androgens are used to control the growth of estrogen-dependent breast tumors, whereas estrogens control androgen-dependent tumors of the prostate. Hormones that have anticancer activities are listed in Table 6.

Miscellaneous Agents. Those chemotherapeutic agents that do not fit into any of the classifications discussed are listed in Table 7.

Toxicity

As a result of the life-threatening nature of cancer and the general lack of therapeutically effective drugs for most cancers, doses of chemotherapeutic drugs in Phase I clinical trials are escalated until the emergence of a dose-limiting toxicity. The efficacy of these compounds in one or more tumor types is then established in Phase II/III clinical trials. The commonly observed dose-limiting toxicities include myelosuppression, gastrointestinal upset, and renal, hepatic, and cardiotoxicities.

TABLE 1. ANTIMETABOLITES

Drug (trade name)	Molecular formula	Molecular weight	Disease	Toxic effects
5-azacitidine[a] (Mylosar)	$C_8H_{12}N_4O_5$	244.21	acute myelogenous leukemia	nausea, vomiting; hepatic dysfunction; myelosuppression
cytarabine USP[a] (Cytosar)	$C_9H_{13}N_3O_5$	243.22	acute granulocytic leukemia (adults); acute lymphocytic leukemia (children); Hodgkin's disease	bone marrow depression; hepatic toxicity; megaloblastosis; nausea; vomiting; diarrhea
gemcitabine[b]	$C_9H_{11}F_2N_3O_4$	263.20	investigational drug; responses seen in Phase I trials in colon and nonsmall cell lung cancer	myelosuppression observed as dose-limiting toxicity
floxuridine USP[c] (FUDR)	$C_9H_{11}FN_2O_5$	246.21	palliative treatment of gastrointestinal adenocarcinoma with liver metastases	severe hematological toxicity; gastrointestinal hemorrhage; nausea; vomiting; diarrhea; enteritis; stomatitis; erythema
fluorouracil USP[c] (Fluorouracil)	$C_4H_3FN_2O_2$	130.08	palliative treatment of carcinoma of colon, rectum, breast, stomach, and pancreas	bone marrow depression; dermatitis; alopecia; nausea; vomiting; diarrhea; stomatitis; anorexia; GI ulcers; skin pigmentation
mercaptopurine USP[d] (Purinethol)	$C_5H_4N_4S$	152.19	acute leukemia (more effective in children than in adults); chronic granulocytic leukemia	bone marrow depression; hepatic toxicity; anemia; gastrointestinal (GI) ulceration; nausea; vomiting
thioguanine USP[d] (Tabloid)	$C_5H_5N_5S \cdot XH_2O$	167.19	acute leukemia; chronic granulocytic leukemia	bone marrow depression; stomatitis; anorexia; nausea; vomiting
methotrexate USP[e] (Methotrexate)	$C_{20}H_{22}N_8O_5$	454.46	acute lymphocytic leukemia; meningeal leukemia; choriocarcinoma; chorioadenoma destruens; lymphosarcoma; osteogenic sarcoma; cancer of lung, neck, head, cervix; mycosis fungoides; hydatidiform mole high dose MTX followed by leucovorin rescue in nonmetastatic osteosarcoma	bone marrow depression; renal and hepatic toxicity; enteritis; stomatitis; alopecia; abdominal distress; erythematous rash; oral and GI ulceration; diarrhea; nausea; vomiting
leucovorin[e] (calcium USP)	$C_{20}H_{21}CaN_7O_7$	511.51	high dose methotrexate rescue therapy in osteosarcoma	allergic sensitization
DDATHF[b] (Ly237147) (Lometrexol sodium)	$C_{21}H_{23}N_5Na_2O_6$	487.42	investigational drug	
trimetrexate[f]	$C_{19}H_{23}N_5O_3$	369.42	investigational drug; partial remissions in soft tissue sarcomas observed	myelosuppression; mucositis; nausea; vomiting; skin rash
hydroxyurea USP[g] (Hydrea)	$CH_4N_2O_2$	76.05	chronic granulocytic leukemia; melanoma; cancer of ovary, head, neck	vomiting; anorexia; fever; bone marrow depression; nausea; diarrhea

TABLE 2. DNA ALKYLATING/CROSS-LINKING AGENTS

Drug (trade name)	Molecular formula	Molecular weight	Disease	Toxic effects
carmustine USP[a] (BiCNU)	$C_5H_9Cl_2N_3O_2$	214.05	Hodgkin's disease; non-Hodgkin's lymphomas; meningeal leukemia; brain tumor; multiple myeloma	bone marrow depression; hepatic toxicity; nausea; vomiting
lomustine USP[a] (CeeNU)	$C_9H_{16}ClN_3O_2$	233.70	malignant brain tumors; Hodgkin's disease	bone marrow depression; hepatic toxicity
tauromustine[b]	$C_7H_{15}ClN_4O_4S$	286.73	investigational drug responses observed in malignant melanoma	gastrointestinal; thrombocytopenia
streptozocin USP[c] (Zanosar)	$C_8H_{15}N_3O_7$	265.22	metastatic islet cell carcinoma of the pancreas	bone marrow depression; renal and hepatic toxicity; nausea; vomiting
busulfan USP[d] (Myleran)	$C_6H_{14}O_6S_2$	246.29	chronic granulocytic leukemia; other myeloproliferative disorders	bone marrow depression; hyperuricemia; gynecomastia; amenorrhea; skin hyperpigmentation
cyclophosphamide USP[a] (Cytoxan)	$C_7H_{15}Cl_2N_2O_2P$	279.10	acute and chronic lymphocytic leukemia; lung cancer; rhabdomyosarcoma; neuroblastoma; ovarian and mammary carcinoma; multiple myeloma; lymphosarcoma; Burkitt's lymphoma; Hodgkin's disease; retinoblastoma; mycosis fungoides	bone marrow depression; hepatic toxicity; cystitis; alopecia; nausea; vomiting
ifosphamide USP[a] (Ifex)	$C_7H_{15}Cl_2N_2O_2P$	261.09	germ cell testicular cancer; used in combination with mesna	myelosuppression; urotoxicity; alopecia; nausea; vomiting; CNS toxicities
mesna USP[a] (Mesnex)	$C_2H_5NaO_3S_2$	164.17	prophylactic prevention of hemorrhagic cystitis	
mechlorethamine hydrochloride USP[e] (Mustargen)	$C_5H_{11}Cl_2N \cdot HCl$	192.52	Hodgkin's disease; non-Hodgkin's lymphomas; lymphosarcoma; cancer of breast, ovary, lung; neoplastic effusion	bone marrow depression; nausea; vomiting; anorexia; diarrhea; local irritation
chlorambucil USP[d]	$C_{14}H_{19}Cl_2NO_2$	304.23	chronic lymphocytic leukemia; cancer of ovary, breast, testis; Hodgkin's disease; non-Hodgkin's lymphomas	bone marrow depression; nausea; vomiting
melphalan USP[d] (Alkeran)	$C_{13}H_{18}Cl_2N_2O_2$	305.20	multiple myeloma; plasmacytic myeloma; cancer of breast and ovary	bone marrow depression; nausea; vomiting; anorexia
thiotepa USP[f] (Thiotepa)	$C_6H_{12}N_3PS$	189.21	cancer of breast, ovary, lung, bladder; Hodgkin's disease; non-Hodgkin's lymphomas; neoplastic effusion	bone marrow depression; amenorrhea; anorexia; nausea; vomiting
mitomycin C USP[a] (Mutamycin)	$C_{15}H_{18}N_4O_5$	334.33	chronic myelogenous leukemia; reticulum cell sarcoma; Hodgkin's disease; non-Hodgkin's lymphomas; cancer of stomach, pancreas, lung; epithelial tumors	bone marrow depression; renal toxicity; alopecia; stomatitis; anorexia; nausea; vomiting
BMY-25067[a]	$C_{23}H_{25}N_5O_7S_2$	547.60	investigational drug	
KW2149[g]	$C_{24}H_{34}N_6O_8S_2$	598.7	investigational drug	
cisplatin USP[a] (Platinol)	$Cl_2H_6N_2Pt$	300.06	metastatic testicular tumors; metastatic ovarian tumors; advanced bladder cancer	nephrotoxicity; ototoxicity; myelosuppression; nausea; vomiting; allergic reaction
carboplatin USP[a] (Paraplatin)	$C_6H_{12}N_2O_4Pt$	371.25	recurrent ovarian carcinoma	bone marrow suppression; emesis; allergic reactions
dacarbazine USP[h] (DTIC)	$C_6H_{10}N_6O$	182.18	malignant melanoma; Hodgkin's disease; soft tissue sarcomas	bone marrow depression; flulike syndrome; alopecia; nausea; vomiting; anorexia

Toxicity Amelioration

Research efforts to address the problem of toxicity amelioration has progressed in several directions. The three most prominent areas are analogue synthesis, chemoprotection, and drug targeting.

Drug Resistance

The most recognized and studied mechanisms of drug resistance are attributed to multidrug resistance (MDR), gene amplification, DNA repair, topoisomerase II activity, and glutathione and metallothionein levels. Even with advances in understanding the biology and mechanism of drug resistance among different classes of antitumor agents, no real breakthrough appears imminent.

Economics of Cancer Chemotherapy

The increased use of chemotherapy as a modality in the treatment of cancer has caused a corresponding increase in the market for anticancer

TABLE 3. DNA INTERACTIVE AGENTS

Drug (trade name)	Molecular formula	Molecular weight	Disease	Toxic effects
daunorubicin hydrochloride USP[a] (Cerubidine)	$C_{27}H_{29}NO_{10} \cdot HCl$	563.99	acute lymphocytic and granulocytic leukemia; lymphomas	bone marrow depression; cardiac toxicity; alopecia; stomatitis; GI disturbance
doxorubicin USP[b] (Adriamycin)	$C_{27}H_{29}NO_{11}$	543.53	soft-tissue and osteogenic sarcomas; Hodgkin's disease; non-Hodgkin's lymphomas; acute leukemia; cancer of thyroid, breast, lung, genitourinary (GU) tract; Wilm's tumor; neuroblastoma	bone marrow depression; cardiac toxicity; alopecia; stomatitis; GI disturbance
idarubicin hydrochloride[b] (Idamycin)	$C_{26}H_{27}NO_9 \cdot HCl$	533.96	acute myeloid leukemia in adults	bone marrow suppression; cardiotoxicity; nausea; vomiting; alopecia
mitoxanthrone hydrochloride USP[c] (Novantrone)	$C_{22}H_{28}N_4O_6 \cdot 2HCl$	517.41	acute nonlymphocytic leukemia, including myelogenous promyelocytic, monocytic, and erythroid acute leukemias	nausea; vomiting; alopecia; mucositis; stomatitus; myelosuppression; cardiotoxicity; allergic reaction; phlebitis
bleomycin sulfate USP[d] (Blenoxane)	mixture of bleomycin A_2, B_2 as primary components		squamous cell carcinoma of head, neck, esophagus, skin, GU tract; testicular tumor; Hodgkin's lymphomas	pulmonary fibrosis; skin reactions; alopecia; nausea; vomiting; anorexia; fever; stomatitis
esperamicin A_1[d]	$C_{59}H_{80}N_4O_{22}S_4$	1324.41	investigational drug	
Adozelesin[e] (U73,975)	$C_{30}H_{22}N_4O_4$	502.30	investigational drug	
dactinomycin USP[f] (Cosmegen)	$C_{62}H_{86}N_{12}O_{16}$	1255.43	Wilm's tumor; Ewing's tumor; choriocarcinoma; testicular carcinoma; rhabdomyosarcoma; neuroblastoma; melanoma; soft-tissue and osteogenic sarcomas	bone-marrow depression; renal and hepatic toxicity; alopecia; mental depression; stomatitis; nausea; vomiting; diarrhea; anorexia; local irritation
plicamycin USP[a] (Mithracin)	$C_{52}H_{76}O_{24}$	1085.16	testicular tumors; hypercalcemia and hypercalciuria associated with advanced malignancies	bone marrow depression; hepatic and renal toxicity; hypocalcemia; hemorrhage; stomatitis; nausea; vomiting; anorexia; diarrhea
procarbazine hydrochloride USP[g] (Matulane)	$C_{12}H_{19}N_3O \cdot HCl$	257.76	Hodgkin's disease; non-Hodgkin's lymphomas; lung cancer	bone marrow depression; neurological and dermatological toxicity; nausea; vomiting

[c] Smith Kline Beecham.
[d] Parke-Davis.

agents. Only a few anticancer drugs have achieved sales in excess of $100 million per year and many of the drugs discussed herein sell less than $10 million per year. Those agents that have achieved greater economic importance are newer, frequently used in combination chemotherapy, and of use in the treatment of solid tumors which comprise the bulk of reported cancer incidence. A number of the agents in clinical trials, such as taxol and camptothecin analogues, are expected to have considerable economic impact based on activity in the treatment of the more common human

TABLE 5. TUBULIN ACTIVE DRUGS

Drug (trade name)	Molecular formula	Molecular weight	Disease	Toxic effects
vinblastin sulfate USP[a] (Velban)	$C_{46}H_{58}N_4O_9 \cdot H_2SO_4$	909.06	Hodgkin's disease; lymphosarcoma; reticulum cell sarcoma; neuroblastoma; choriocarcinoma; carcinoma of breast, lung, oral cavity, testis, bladder; acute and chronic leukemia; histiocytosis; mycosis fungoides	leukopenia; neurological toxicity (paresthesias, mental depression, loss of deep tendon reflexes, etc); dysfunction of autonomic nervous system (ileus, constipation, urinary retention, etc); alopecia; stomatitis; nausea; vomiting; local irritation
vincristin sulfate USP[a] (Oncovin)	$C_{46}H_{56}N_4O_{10} \cdot H_2SO_4$	923.04	acute leukemia in children; lymphocytic leukemia; Hodgkin's disease; non-Hodgkin's lymphomas; Wilm's tumor; neuroblastoma; rhabdomyosarcoma.	neurological toxicity (paresthesias, foot drop, double vision, etc); constipation; ileus; alopecia; leukopenia (occasional);
vindesine sulfate[a] (Eldisine)	$C_{43}H_{55}N_5O_7 \cdot H_2SO_4$	852.01	investigational drug	
navelbine[b] (Vinorelbine)	$C^{45}H^{54}N^4O_8$	778.45	investigational drug; nonsmall cell lung cancer	
taxol[c] (Paclitaxol)	$C_{47}H_{51}NO_{14}$	853.92	refractory ovarian cancer; refractory breast cancer; melanoma; lung cancer; head and neck cancer	alopecia; neutropenia; hypersensitivity; mucositis; neuropathy
taxotere[d] (Docetaxol)	$C_{43}H_{53}NO_{14}$	807.43	investigational drug

CHERT. An impure, flinty hard rock composed chiefly of cryptocrystalline silica. Chert varies in color from gray through brown to black according to the kind and amount of coloring matter. It occurs principally as concretions, nodules or bands in limestones and dolomites, and unlike flint its fracture tends to be splintery instead of conchoidal. A great deal has been written on the occurrence and origin of chert and there is no doubt but that it may be formed in several different ways. Many of the nodular and concretionary cherts have grown around siliceous sponge spicules or radiolaria. Chert may be either sygenetic or epigenetic. The former type is supposed by some authors to be chemically precipitated from river waters on the bottom of the sea as a colloid contemporaneously with the limestones or dolomites. On the other hand certain cherts are obviously secondary although they may have been formed previous to the final lithification of the formations in which they occur. Cherts containing relatively large amounts of iron are called Jasper.

CHINA CLAY. A commercial term, more or less identical with kaolin, as applied to the relatively pure clay concentrated by washing from a thoroughly kaolinized granite. England is the chief exporter of china clay. France has unique clays from which are made the famous Sèvres and Limoges potteries.

China-clay rock is a kaolinized granite made up chiefly of quartz and kaolin, with sometimes the presence of muscovite and tourmaline. The rock crumbles easily in the fingers. *China stone* is (1) a partially kaolinized granite, which contains quartz, kaolin, and sometimes mica and fluorite, is harder than china-clay rock and is used as a glaze in the production of china; or (2) a fine-grained, compact mudstone or limestone found in England and Wales.

CHIRAL SEPARATIONS. Chiral separations are concerned with separating molecules that can exist as nonsuperimposable mirror images. Examples of these types of molecules, called *enantiomers* or *optical isomers*, are illustrated in Figure 1. Although chirality is often associated with compounds containing a tetrahedral carbon with four different substituents, other atoms, such as phosphorus or sulfur, may also be chiral. In addition,

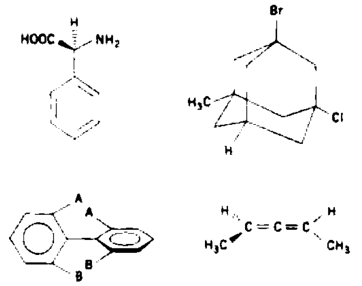

Fig. 1. Examples of chiral molecules

molecules containing a center of asymmetry, such as hexahelicene, tetrasubstituted adamantanes, and substituted allenes or molecules with hindered rotation, such as some 2, 2′ disubstituted binaphthyls, may also be chiral. Compounds exhibiting a center of asymmetry are called *atropisomers*.

Although scientists have known since the time of Louis Pasteur that optical isomers can behave differently in a chiral environment (e.g., in the presence of polarized light), it has only been since about 1980 that there has been a growing awareness of the implications arising from the fact that many drugs are chiral and that living systems constitute chiral environments. Hence, the optical isomers of chiral drugs may exhibit different bioactivities and/or biotoxicities.

In the case of enantiomerically pure chiral drugs, the possibility of racemization or inversion either *in vivo* or during storage cannot be ruled out. Ibuprofen is an example of a chiral drug which undergoes rapid inversion *in vivo*. In addition, there are several examples of achiral (or *prochiral*) drugs being biotransformed into chiral entities. In some cases, the enantiomeric ratios produced by laboratory animals may differ from that produced in humans. This raises the question of the suitability of laboratory animals as appropriate test models for a certain drug.

For those drugs that are administered as the racemate, each enantiomer needs to be monitored separately yet simultaneously, since metabolism, excretion or clearance may be radically different for the two enantiomers. Further complicating drug profiles for chiral drugs is that often the pharmacodynamics and pharmacokinetics of the racemic drug is not just the sum of the profiles of the individual enantiomers.

Although a great deal of the work currently being done in chiral separations is related to pharmaceuticals, the agricultural and the food and beverage industries are affected as well. For instance, several chiral pesticides are used commercially. It is possible that the enantiomers may differ in their persistence in the environment and their effectiveness against specific pests. In the food and beverage industry, many of the constituents that confer flavor or aroma in foods and beverages are chiral. For instance, the configuration of the 4-alkyl-substituted γ-lactones responsible for much of the flavor in fruits is almost exclusively *R*. Often, the two enantiomers have very different aromas or flavors. The presence of any of the "unnatural" enantiomer may confer an "off-flavor" to the substance and may be indicative of racemization under adverse storage conditions, adulteration, or formulation from nonnatural sources.

The growing awareness of the implications of chirality to the pharmaceutical industry has spurred tremendous effort toward stereoselective

synthetic strategies and the development of new chiral catalysts. However, the enantiomeric purity of these substances or their chiral precursors needs to be determined. Also, there are many chiral compounds for which no stereospecific synthetic pathways have been devised. Thus, there is a tremendous need not only for analytical scale (<5–10 mg), but bulk-scale chiral separations as well.

Whether analyzing drugs or synthetic precursors for enantiomeric purity, monitoring biological or environmental samples for chiral discrimination or trying to enantioresolve kilogram quantities of a racemic drug, there are a variety of reasons for performing chiral separations. The purpose of the separation dictates, to some extent, the method employed.

Traditionally, chiral separations have been considered among the most difficult of all separations.

A variety of strategies have been devised to obtain them. Although the focus of this article is on chromatographically based chiral separations, other methods include crystallization and stereospecific enzymatic-catalyzed synthesis or degradation. In crystallization methods, racemic chiral ions are typically resolved by the addition of an optically pure counterion, thus, forming diastereomeric complexes.

Enzymatically based methods depend upon the stereospecificity of an enzyme-catalyzed reaction, such as lipase-catalyzed esterification, to degrade enantioselectively the unwanted enantiomer or to produce the desired enantiomer. Because only one enantiomer undergoes the reaction, the subsequent separation is reduced to separating two different species. One disadvantage of enzymatically based methods is that only one enantiomer is obtained and there is usually no analogous method for producing the opposite enantiomer.

An alternative method of creating a chiral environmental is to derivatize a chiral analyte with an optically pure reagent, thus, producing diastereomers. The resultant diastereomers, containing more than one chiral center, have slightly different melting and boiling points and can often be separated using conventional methods. A number of chiral derivatizing agents, as well as the types of compounds for which they are useful, have been developed and are listed in Table 1. Limitations of this approach include lack of suitable functionality in the analyte that can be derivatized with an appropriate enantiomerically pure derivatizing agent, unavailability of a suitable derivatizing agent of sufficiently high or at least known optical purity, difficulty of removing the derivatizing group after the desired separation has been accomplished, enantiodiscrimination during derivatization, potential racemization either during derivatization or removal or the chiral derivatizing group (which is not always possible), and the additional validation required to confirm that the enantiomeric ratio of the final product corresponds to the original enantiomeric ratio.

TABLE 1. ANALYTE FUNCTIONAL GROUPS AND CHIRAL DERIVATIZING REAGENTS

Analyte functional group	Derivatizing agent	Product	Examples of derivatizing agents
carboxylic acid (acid or base catalyzed)	alcohol	ester	(−)-menthol
	amine	amide	1-phenylethylamine 1-(1-naphthyl)ethylamine
amine (1°)	aldehyde	isoindole	*o*-phthaldialdehyde–2-mercaptoethanol
amine (1° and 2°)	anhydrides	amide	γ-butyloxycarbonyl-L-leucine anhydride *O,O*-dibenzoyltartaric anhydride
	acyl halides	amide	(*R*)-(−)-methylmandelic acid chloride α-methoxy-α-trifluoromethylphenylacetyl chloride
	isocyanates	urea	α-methylbenzyl isocyanate 1-(1-naphthyl)ethyl isocyanate
	isothiocyanate	thiourea	2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl isothiocyanate α-methylbenzyl isothiocyanate
(1°, 2°; can *N*-dealkylate 3°)	chloroformates	carbamate	(−)-menthyl chloroformate (+)-1-(9-fluorenyl)ethylchloroformate
alcohols	acyl halides	ester	(−)-menthoxy acid chloride (*S*)-*O*-propionylmandelyl chloride
	anhydrides	ester	(*S,S*)-tartaric anhydride
	chloroformate	carbonate	(−)-menthyl chloroformate
	isocyanate	carbamate	α-methylbenzyl isocyanate

Use of Chiral Additives

Another method for creating a chiral environment is to add an optically pure chiral selector to a bulk liquid phase. Chiral additives have several advantages over chiral stationary phases and continue to be the predominant mode for chiral separations by tlc and capillary electrophoresis (ce). First of all, the chiral selector added to a bulk liquid phase can be readily changed. The use of chiral additives allows chiral separations to be done using less expensive, conventional stationary phases. A wider variety of chiral selectors are available to be used as chiral additives than are available as chiral stationary phases, thus, providing the analyst with considerable flexibility. Finally, the use of chiral additives may provide valuable insight into the chromatographic conditions and/or likelihood of success with a potential chiral stationary-phase chiral selector. This is particularly important for the development of new chiral stationary phases because of the difficulty and cost involved.

Chiral additives, however, do pose some unique problems. Many chiral agents are expensive or are not commercially available, and therefore, must be synthesized. The presence of the chiral additive in the bulk liquid phase may also interfere with detection or recovery of the analytes. Finally, the presence of enantiomeric impurity in the chiral additive may add analytical complications.

Thin-Layer Chromatography. Thin-layer chromatography (tlc) offers several advantages for chiral separations and in the development of new chiral stationary phases. Besides being inexpensive, tlc can be used to screen mobile-phase conditions rapidly (i.e., organic modifier content, pH, etc.), chiral selectors, and analytes. Several different analytes may be run simultaneously on the same plate. Usually, no preequilibration of the mobile phase and stationary phase is required. In addition, only small amounts of mobile phase, and therefore, chiral mobile-phase additive, are required. Another significant advantage is that the analyte can always be unambiguously found on the tlc plate.

Two mechanisms for chiral separations using chiral mobile-phase additives, analogous to models developed for ion-pair chromatography, have been proposed to explain the chiral selectivity obtained using chiral mobile-phase additives. In one model, the chiral mobile-phase additive and the analyte enantiomers form "diastereomeric complexes" in solution. As noted previously, diastereomers may have slightly different physical properties such as mobile phase solubilities or slightly different affinities for the stationary phase. Thus, the chiral separation can be achieved with conventional columns.

An alternative model has been proposed in which the chiral mobile-phase additive is thought to modify the conventional, achiral stationary phase *in situ*, thus, dynamically generating a chiral stationary phase. In this case, the enantioseparation is governed by the differences in the association between the enantiomers and the chiral selector in the stationary phase.

Several different types of chiral additives have been used including (1*R*)-(−)-ammonium-10-camphorsulfonic acid, cyclodextrins, proteins, and various amino acid derivatives such as *N*-benzoxycarbonyl-glycyl-L-proline as well as macrocyclic antibiotics.

Chiral separation validation in tlc may be accomplished by recovering the individual analyte spots from the plate and subjecting them to some type of chiroptical spectroscopy such as circular dichroism or optical rotary dispersion. Alternatively, the plates may be analyzed using a scanning densitometer.

Capillary Electrophoresis. Capillary electrophoresis (ce) or capillary zone electrophoresis (cze), a relatively recent addition to the arsenal of

analytical techniques, has also been demonstrated as a powerful chiral separation method. Its high resolution capability and lower sample loading relative to hplc makes it ideal for the separation of minute amounts of components in complex biological mixtures.

In a ce experiment, a thin capillary is filled with a run buffer and a voltage is applied across the capillary. The underlying impetus for separations in ce is, in general, derived from the fact that charged species migrate in response to an applied electric field proportionately to their charge and inversely proportionately to their size.

Chiral separations by ce have been performed almost exclusively using chiral additives to the run buffer. The advantages of this approach are identical to the advantages mentioned previously with regard to using chiral mobile-phase additives in tlc. Many of the chiral selectors used successfully as mobile-phase additives in tlc and as immobilized ligands in hplc have been used successfully in ce including proteins, native and functionalized cyclodextrins, various carbohydrates, assorted functionalized amino acids, chiralion pairing agents, and macrocyclic antibiotics.

Although chiral ce is most commonly performed using aqueous buffers, there has been some work using organic solvents such as methanol, formamide, *N*-methylformamide or *N,N*-dimethylformamide with chiral additives such as quinine or cyclodextrins. Nonaqueous ce requires that the background electrolyte be prepared using organic acids (e.g., citric acid or acetic acid) and organic bases (e.g., tetraalkylammonium halides or tris(hydroxymethyl)aminomethane).

Chiral Stationary Phases

Most chiral chromatographic separations are accomplished using chromatographic stationary phases that incorporate a chiral selector. The chiral separation mechanisms are generally thought to involve the formation of transient diastereomeric complexes between the enantiomers and the stationary phase chiral ligand. Differences in the stabilities of these complexes account for the differences in the retention observed for the two enantiomers. Often, the use of a chiral stationary phase allows for the direct separation of the enantiomers without the need for derivatization. One advantage offered by the use of chiral stationary phases is that the chiral selector need not be enantiomerically pure, only enriched. In addition, for chiral stationary phases having a well understood chiral recognition mechanism, assignment of configuration (e.g., *R* or *S*) may be possible even in the absence of optically pure standards. However, chiral stationary phases have some limitations. The specificity required for chiral discrimination limits the broad applicability of most chiral stationary phases; thus there is no "universal" chiral stationary phase. The cost of most chiral columns are typically much higher (~3×) than for conventional columns. In contrast to conventional chromatographic columns, chiral stationary phases are generally not as robust, require more careful handling than conventional columns and usually, once column performance has begun to deteriorate, cannot be returned to their original performance levels. In many cases, chromatographic column choice or mobile phase optimization for chiral stationary phases is not as straightforward as with conventional stationary phases. For many of the chiral stationary phases, adequate chiral recognition models, used to guide selection of the appropriate column for a given separation, have yet to be developed. Column selection, therefore, is often reduced to identifying structurally similar analytes for which chiral resolution methods have been reported in the scientific literature or chromatographic supply catalogues and adapting a reported method for the chiral pair to be resolved.

An additional complication, sometimes arising with the use of chiral stationary phases, may occur when the analytes either exist as *conformers* or can undergo inversion during the chromatographic analysis.

Thin-Layer Chromatography. Chiral stationary phases in tlc have been primarily limited to phases based on normal or microcrystalline cellulose, triacetylcellulose sorbents or silica-based sorbents that have been chemically modified or physically coated to incorporate chiral selectors such as amino acids or macrocyclic antibiotics into the stationary phase. The cost of many chiral selectors, as well as the accessibility and success of chiral additives, may have inhibited widespread commercialization.

Of the silica-based materials, only the ligand-exchange phases are commercially available (Chiralplate, tlc plates are available through Alltech Associates, Inc.) Supelco, Inc., the Aldrich Chemical Company, and Bodman Industries are all based on ligand exchange. Typically in the case of the ligand-exchange type tlc plates, the ligand-exchange selector is comprised of an amino acid residue to which a long hydrocarbon chain has been attached (e.g., (2*S*, 4*R*, 2′*RS*)4-hydroxy-1-(2-hydroxydodecyl)proline). The hydrocarbon chain of the functionalized amino acid is either chemically bonded to the substrate or intercalates in between the chains of a reversed phase-stationary phase thus immobilizing the chiral selector. The bidentate amino acid chiral selector is thought to reside close to the surface of the stationary phase and participates as a ligand in the formation of a bi-ligand complex with a divalent metal ion (e.g., Cu^{2+}) and the chiral bidentate analyte. Analytes enantioresolvable using ligand exchange are usually restricted to 1,2-diols, α-amino acids, α-amino alcohols, and α-hydroxyacids. Again, differences in the stabilities of the diastereomeric complexes thus formed give rise to the chiral separation.

High Performance Liquid Chromatography. The last decade has seen the commercialization of a large number of different types of chiral stationary phases including the cyclodextrin phases, the chirobiotic phases, the π-π interaction phases, the protein phases as well as the cellulosic and amylosic phases and chiral crown ether phases. Currently, there are over 50 different chiral columns that are commercially available for hplc. Table 2 briefly summarizes the types of columns available as well as typical applications and mobile-phase conditions. Each of these chiral stationary phases are very successful at separating large numbers of enantiomers, which in many cases, are unresolvable using any of the other chiral stationary phases. Unfortunately, despite the large number and variety of chiral stationary phases currently available, there remains a large number of enantiomeric compounds that are unresolvable by any of the existing chiral, stationary phases. In addition, incomplete understanding of the chiral recognition mechanisms of many of these chiral stationary phases limits the realization of the full potential of the existing chiral stationary phases and hampers development of new chiral stationary phases.

Ligand-Exchange Phases

Among the earliest reports of chiral separations by liquid chromatography were based on work done by Davankov using ligand exchange. These types of columns are available from Phenomenex, J. T. Baker, and Regis Technologies, Inc. Although almost any amino acid can form the basis for the chiral selector, proline and hydroxyproline exhibit the most widespread utility. Also, although other metals can be used, copper(II) is usually the metal of choice and is added to the aqueous buffer mobile phase.

The dependence of chiral recognition on the formation of the diastereomeric complex imposes constraints on the proximity of the metal binding sites, usually either an hydroxy or an amine α to a carboxylic acid, in the analyte. Principal advantages of this technique include the ability to: assign configuration in the absence of standards; enantioresolve

TABLE 2. CLASSES OF HPLC CHIRAL STATIONARY PHASES

Column chiral selector	Typical mobile phase conditions	Typical analyte features required
pirkle	nonpolar organic; 2-propanol-hexane	π-acid or π-basic moieties for charge transfer complex; hydrogen-bonding or dipole stacking capability near chiral center
protein	phosphate buffers	aromatic near chiral center; organic acids or bases; cationic drugs
cyclodextrin	aqueous buffers; polar organic	good "fit" between chiral cavity or chiral mouth of cyclodextrin and hydrophobic moiety; hydrogen-bonding capability near chiral center
ligand exchange	aqueous buffers	α-hydroxy or α-amino acids near chiral center; can do nonaromatic
chiral crown ether	0.01 *N* perchloric acid	primary amines near chiral center; can do nonaromatic
macrocyclic antibiotics	aqueous buffers, nonpolar and polar organic	amines, amides, acids, esters; aromatic; hydrophobic moiety
cellulosic and amylosic	nonpolar organic	aromatic

nonaromatic analytes; use aqueous mobile phases; acquire a stationary phase with the opposite enantioselectivity; and predict the likelihood of successful chiral resolution for a given analyte based on a well-understood chiral recognition mechanism.

Pirkle Phases

Of all of the commercially available chiral stationary phases for liquid chromatography, the chiral recognition mechanism for the "Pirkle" phases are among the best understood. Chiral recognition on Pirkle phases is thought to depend upon complimentary interactions between the analyte and the selector. These interactions may be π-π, steric, hydrogen-bonding, or dipole—dipole interactions and contribute to the overall stability of the diastereomeric association complexes that form between the individual enantiomers and the chiral selector in the stationary phase.

Nonpolar organic mobile phases, such as hexane with ethanol or 2-propanol as typical polar modifiers, are most commonly used with these types of phases. Under these conditions, retention seems to follow normal phase-type behavior (e.g., increased mobile phase polarity produces decreased retention). The normal mobile phase components only weakly interact with the stationary phase and are easily displaced by the chiral analytes thereby promoting enantiospecific interactions. Some of the Pirkle-types of phases have also been used, to a lesser extent, in the reversed phase mode.

Reciprocity, an important concept introduced by Pirkle, exploited the notion that analytes that were well resolved using a particular chiral selector would likely be good candidates for chiral selectors to enantioresolve analytes similar to the original chiral selector. This insight spawned a second generation of Pirkle phases based on *N*-(2-naphthyl)-α-amino acids. These phases were very successful at enantio-resolving analytes containing a 3,5-dinitrobenzoyl group, such as 3,5-dinitrophenyl carbamates, and ureas of chiral alcohols and amines. These columns are available through a variety of sources including Phenomenex, Regis Technologies, Inc., J. T. Baker, Inc., and Supelco, Inc.

The structure of the Whelk-O-1 phase, the most recent addition to this type of chiral stationary phase, is illustrated in Figure 2. The presence of both π-acid and π-base features, as well as the inherent rigidity of the chiral selector, confers greater versatility than any of the previous Pirkle-type phases, imposing fewer constraints on both analyte structural features required for successful enantioresolution and mobile phase conditions. Indeed, this chiral stationary phase has demonstrated considerable chiral selectivity for naproxen, warfarin, and its *p*-chloro analogue under nonaqueous reversed-phase conditions and reversed-phase conditions. An additional advantageous feature of this phase is its availability with either the (*R,R*) or (*S,S*) configuration, thus, permitting the enantiomeric elution order to be readily changed. The small size of the chiral selector also promotes fairly high bonded ligand densities in the stationary phase, which coupled with the high enantioselectivities often achieved with these phases, facilitates their use for preparative-scale separations.

Cyclodextrin Phases

Cyclodextrins are macrocyclic compounds comprised of D-glucose bonded through 1,4-α-linkages and produced enzymatically from starch. The greek letter which proceeds the name indicates the number of glucose units incorporated in the CD (e.g., $\alpha = 6$, $\beta = 7$, $\gamma = 8$, etc). Cyclodextrins are toroidal shaped molecules with a relatively hydrophobic internal cavity (Fig. 3).

Among the most successful of the liquid chromatographic reversed-phase chiral stationary phases have been the cyclodextrin-based phases, introduced by Armstrong and commercially available through Advanced

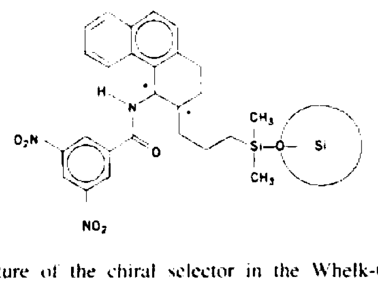

Fig. 2. The structure of the chiral selector in the Whelk-O-1 chiral stationary phase

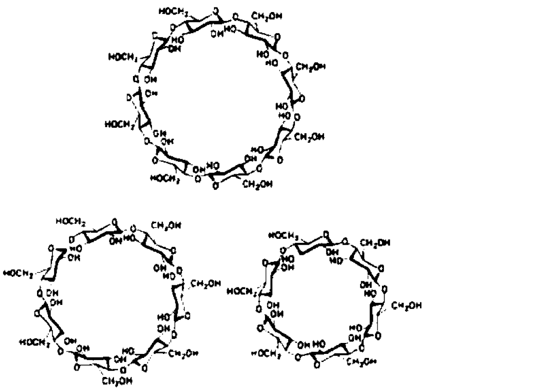

Fig. 3. The structure of the three most common cyclodextrins

Separation Technologies, Inc. or Alltech Associates. The most commonly used cyclodextrin in hplc is the β-cyclodextrin. In the bonded phases, the cyclodextrins are thought to be tethered to the silica substrate through one or two spacer ligands. The mechanism thought to be responsible for the chiral selectivity observed with these phases is based upon the formation of an inclusion complex between the hydrophobic moiety of the chiral analyte and the hydrophobic interior of the cyclodextrin cavity. Preferential complexation between one optical isomer and the cyclodextrin through stereospecific interactions with the secondary hydroxyls which line the mouth of the cyclodextrin cavity results in the enantiomeric separation. Unlike the Pirkle-type phases, enantiospecific interactions between the analyte and the cyclodextrin are not the result of a single, well-defined association, but more of a statistical averaging of all the potential interactions with each interaction weighted by its energy or strength of interaction.

Vast amounts of empirical data suggest that chiral recognition on cyclodextrin phases in the reversed phase mode require the presence of an aromatic moiety that can fit into the cyclodextrin cavity, that there be hydrogen bonding groups in the molecule, and that the hydrophobic and hydrogen-bonding moieties should be in close proximity to the stereogenic center. Chiral recognition seems to be enhanced if the stereogenic center is positioned between two π-systems or incorporated in a ring.

Most of the chiral separations reported to date using the native cyclodextrin-based phases have been accomplished in the reversed-phase mode using aqueous buffers containing small amounts of organic modifiers. However, polar organic mobile phases have gained in popularity recently because of their ease of removal from the sample and reduced tendency to accelerate column degradation relative to the hydroorganic mobile phases. In these cases, because the more nonpolar component of the mobile phase is thought to occupy the cyclodextrin cavity, the analyte is thought to sit atop the mouth of the cyclodextrin much like a "lid".

Limitations with the chiral selectivity of the native cyclodextrins fostered the development of various functionalized cyclodextrin-based chiral stationary phases, including acetylated, sulfated, 2-hydroxypropyl, 3,5-dimethylphenylcarbamoylated and 1-naphthylethylcaarbamoylated cyclodextrin. Each of the glucose residues contribute three hydroxyl groups to which a substituent may be appended; thus, each cyclodextrin contributes multiple sites for derivatization. The substituents of these functionalized cyclodextrins seem to play a variety of roles in enhancing chiral recognition.

Cellulosic and Amylosic Phases

Cellulose and amylose are comprised of the same glucose subunits as the cyclodextrins. In the case of cellulose, the glucose units are attached through 1,4-β-linkages resulting in a linear polymer. In the case of amylose, the 1,4-α-linkages, as are found in the cyclodextrins, are thought to confer helicity to the polymeric chain.

Cellulosic phases as well as amylosic phases have been used extensively for enantiomeric separations recently. Most of the work in this area has been with various derivatives of the native carbohydrate. The enantioresolving abilities of the derivatized cellulosic and amylosic phases are reported to be very dependent upon the types of substituents on the aromatic moieties that are appended onto the native carbohydrate. Table 3 lists some of the cellulosic and amylosic derivatives that have been used.

These columns are available through Chiral Technologies, Inc. and J. T. Baker, Inc.

Protein-Based Phases

Proteins, amino acids bonded through peptide linkages to form macromolecular biopolymers, used as chiral stationary phases for hplc include bovine and human serum albumin, α_1-acid glycoprotein, ovomucoid, avidin, and cellobiohydrolase. The bovine serum albumin column is marketed under the name Resolvosil and can be obtained from Phenomenex. The human serum albumin column can be obtained from Alltech Associates, Advanced Separation Technologies, Inc., and J. T. Baker. The α_1-acid glycoprotein and cellobiohydrolase can be obtained from Advanced Separation Technologies, Inc. or J. T. Baker, Inc.

In most cases, the protein is immobilized onto γ-aminopropyl silica and covalently attached using a cross-linking reagent such as *N,N′*-carbonyldiimidazole. The tertiary structure or three dimensional organization of proteins are thought to be important for their activity and chiral recognition. Therefore, mobile phase conditions that cause protein "denaturation" or loss of tertiary structure must be avoided.

Typically, the mobile phases used with the protein-based chiral stationary phases consist of aqueous phosphate buffers. Often small amounts of organic modifiers, such as methanol, ethanol, propanol, or acetonitrile, are added to reduce hydrophobic interactions with the analyte and to improve enantioselectivity. In some cases, dramatic changes in chiral recognition occur when small amounts of organic modifiers, such as *N,N*-dimethyloctylamine or octanoic acid are added to the mobile phase. As in the case of the cyclodextrin and amylosic and cellulosic phases, the chiral recognition mechanism for these protein-based phases is not well understood. Optimization of chromatographic conditions and selection of analytes that can be successfully resolved on these phases is usually done empirically. In addition, the large molecular weight of these biopolymers dictates that the amount of chiral selector that can be immobilized on the column packing material is very small.

An interesting application of the protein-based phases is various protein binding and displacement experiments which can be done fairly routinely. For instance, differences in the enantioselectivity, toward a particular drug, of a column derived from human serum albumin and a column derived from some other animal serum albumin might be indicative that a particular species might not be a good animal model during drug development, thus, obviating the need for animal testing. Chiral separations on protein-based phases may also provide useful information on drug interactions.

Chirobiotic Phases

The chirobiotic chiral stationary phases are based on macrocyclic antibiotics such as vancomycin and teicoplanin. These chiral selectors, originally used as chiral additives in capillary zone electrophoresis, incorporate aromatic and carbohydrate, as well as peptide and ionizable moieties. The presence of aromatic groups, allowing for π-π interactions, and the macrocyclic rings, offering potential inclusion complexation, give these phases some of the advantages of the protein-based phases (e.g., peptide and hydrogen bonding sites) and the carbohydrate-based phases but with greater sample capacity and greater mobile phase flexibility. Indeed, these phases seem to be truly "multimodal" in that they have demonstrated chiral selectivity in the normal, polar organic, and reversed-phase modes. In addition, the use of such well-defined chiral selectors facilitate method development and optimization. These columns are commercially available through Advanced Separation Technologies, Inc. and Alltech Associates.

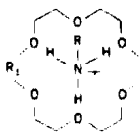

Fig. 4. An inclusion complex formed between a protonated primary amine and a chiral crown ether

Chiral Crown Ether Phases

Chiral crown ethers based on 18-crown-6 (Fig. 4) can form inclusion complexes with ammonium ions and protonated primary amines. Immobilization of these chiral crown ethers on a chromatographic support provides a chiral stationary phase which can resolve most primary amino acids, amines and amino alcohols. However, the stereogenic center must be in fairly close proximity to the primary amine for successful chiral separation. Significantly, the chiral crown ether phase is unique in that it is one of the few liquid chromatographic chiral stationary phases that does not require the presence of an aromatic ring to achieve chiral separations.

Mobile phases used with this stationary phase are typically 0.01 *N* perchloric acid with small amounts of methanol or acetonitrile. One significant advantage of these phases is that both configurations of the chiral stationary phase are commercially available and can be obtained from J. T. Baker Inc. and Chiral Technologies, Inc. (Crownpak CR).

Chiral Synthetic Polymer Phases

Chiral synthetic polymer phases can be classified into three types. In one type, a polymer matrix is formed in the presence of an optically pure compound to molecularly *imprint* the polymer matrix. Subsequent to the polymerization, the chiral template is removed, leaving the polymer matrix with chiral cavities. The selectivities achieved with these phases are generally excellent, thus, facilitating semipreparative separations. However, the applicability of these chiral stationary phases are generally limited to the analyte upon which the phase is based and a limited number of analogues. In addition, these types of phases generally exhibit poor efficiency in large part because the polymeric matrix contributes to nonsterespecific binding. Advantages of this approach include the ability to prepare reciprocal phases and the predictability of the enantiomeric elution order.

Another type of synthetic polymer-based chiral stationary phase is formed when chiral catalyst are used to initiate the polymerization. Columns of this type (e.g., Chiralpak OT) are available from Chiral Technologies, Inc., or J. T. Baker Inc.

A third type of synthetic polymer-based chiral stationary phase, developed by Blaschke, is produced when a chiral selector is either incorporated within the polymer network or attached as pendant groups onto the polymer matrix. Both are analogous to methods used to produce polymeric chiral stationary phases for gc.

In general, the synthetic polymeric phases seem to have polarities analogous to diol-type phases and a wide range of mobile phase conditions have been used including hexane, various alcohols, acetonitrile, tetrahydrofuran, dichloromethane and their mixtures, as well as aqueous buffers.

Chiral Separation Validation for Hplc

Chiral separations present special problems for validation. Typically, in the absence of spectroscopic confirmation (e.g., mass spectral or infrared data), conventional separations are validated by analyzing "pure" samples under identical chromatographic conditions. Often, two or more chromatographic stationary phases, which are known to interact with the analyte through different retention mechanisms, are used. If the pure sample and the unknown have identical retention times under each set of conditions, the identity of the unknown is assumed to be the same as the pure sample. However, often the chiral separation that is obtained with one type of column may not be achievable with any other type of chiral stationary phase. In addition, "pure" enantiomers are generally not available.

Most commonly, uv or uv–vis spectroscopy is used as the basis for detection in hplc. When using a chiral stationary phase, confirmation of a chiral separation may be obtained by either monitoring the column effluent at more than one wavelength or by running the sample more than once. Although not absolute proof of a chiral separation, this approach does provide strong supporting evidence.

As in tlc, another method to validate a chiral separation is to collect the individual peaks and subject them to some type of optical spectroscopy.

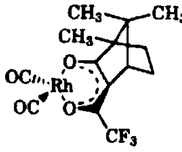
such as, circular dichroism or optical rotary dispersion. Alternatively, a chiroptical spectroscopy can be used as the basis for detection on-line using commercially available optical rotary dispersion or circular dichroism-based detectors. Another method for validating chiral separations by lc is to couple the chromatographic system to a mass spectrometer.

Chiral Stationary Phases for Gas Chromatography

Gc chiral stationary phases can be broadly classified into three categories: diamide, cyclodextrin, and metal complex.

Diamide Chiral Separations. The first commercially available chiral column was the Chiralsil-val, which was introduced in 1976 for the separation of amino acid type compounds by gas chromatography. It is based on a polysiloxane polymer containing chiral side chains incorporating L-valine-*t*-butylamide. The polysiloxane backbone improved the thermal stability of these chiral stationary phases relative to the original coated columns and extended the operating temperatures up to 220°C. The column is effective for the separation of perfluoroacylated and esterified amino acids, amino alcohols, and some chiral sulfoxides. Another polysiloxane-based chiral stationary phase incorporating L-valine-(*R*)-α-phenylethylamide appended onto hydrolyzed XE-60 was found to be particularly successful at resolving perfluoroacetylated amino alcohol derivatives. Through judicious choice of derivatizing agent, chiral separations were obtained for a wider range of compounds, including amino alcohols, α-hydroxy acids, diols and ketones, than had previously been obtainable using these types of stationary phases.

Metal Complex. Complexation gas chromatography was first introduced by V. Schurig in 1980 and employs transition metals (e.g., nickel, cobalt, manganese or rhodium) complexed with chiral terpenoid ketoenolate ligands such as 3-trifluoroacetyl-1*R*-camphorate (**1**), 1*R*-3-pentafluoro-benzoylcamphorate or 3-heptafluorobutanoyl-(1*R*, 2*S*)-pinanone-4-ate. This class of chiral columns is particularly adept at enantioresolving some olefins and oxygen-containing compounds such as ketones, ethers, alcohols, spiroacetals, oxiranes, and esters.



(1)

Cyclodextrins. As indicated previously, the native cyclodextrins, which are thermally stable, have been used extensively in liquid chromatographic chiral separations, but their utility in gc applications was hampered because their highly crystallinity and insolubility in most organic solvents made them difficult to formulate into a gc stationary phase. However, some functionalized cyclodextrins form viscous oils suitable for gc stationary-phase coatings and have been used either neat or diluted in a polysiloxane polymer as chiral stationary phases for gc.

Chiral Separation Validation for Gas Chromatography

The special problems for validation presented by chiral separations can be even more burdensome for gc because most methods of detection (e.g., flame ionization detection or electron capture detection) in gc destroy the sample. Even when nondestructive detection (e.g., thermal conductivity) is used, individual peak collection is generally more difficult than in lc or tlc. Thus, off-line chiroptical analysis is not usually an option. Fortunately, gc can be readily coupled to a mass spectrometer and is routinely used to validate a chiral separation.

CHLORAL. See **Chlorinated Organics.**

CHLORARGYRITE. Also known as horn silver, chlorargyrite is silver chloride, AgCl. The mineral crystallizes in the isometric system but is usually massive, appearing like wax or horn, hence the name. It has no cleavage, is highly sectile, yielding bright surfaces; hardness, 2.5; specific gravity, 5.55; luster, resinous to adamantine; color, gray, white to colorless. May be blue, violet-brown after exposure to light; transparent to translucent. Chlorargyrite is largely a secondary mineral, usually associated with other silver minerals as well as with compounds of lead, zinc, and copper. Saxony and the Harz Mountains are European localities. The Broken Hill district of New South Wales is a well-known occurrence, but probably the most important deposits are found in Atacama, Chile. The mineral also is found in Bolivia and Mexico. In the United States, chlorargyrite comes from Colorado, Idaho, Utah, Nevada, Arizona, and New Mexico.

CHLORIDE (Biological Aspects). Sodium chloride, potassium chloride, and other chloride salts, when ingested by animals from feedstuffs and humans from various food substances, reduce to a consideration of the cation involved (Na^+, K^+, etc.) and the Cl^- (chloride) ion. Generally, in terms of animal and human nutrition, more research has been conducted and more is known about the role of cations in metabolism than that of the chloride ion. Some physiologists and nutritionists in the past have described chloride as playing a "passive role" in maintaining the body's ionic and fluid balance. With exception of the "chloride shift" in venous blood, the movements of chloride have usually been considered secondary to those of the cations.

Much is known, of course, concerning the effects of excessive sodium chloride and of deficient sodium chloride in human and animal diets, but the physiological and nutritional roles of chloride have not been thoroughly studied and fully explained. C.E. Coppock, Department of Animal Science, Texas A & M University, College Station Texas; and M.J. Fettman, Cornell University College of Veterinary Medicine, undertook a study of chloride (targeted to chloride as a required nutrient for lactating dairy cows) and also carefully reviewed the prior work in this area of other researchers. (Interested readers are referred to the bibliography at end of article, "Chloride as a Required Nutrient for Lactating Dairy Cows," *Feedstuffs* (February 10, 1978).)

Despite important physiological functions and its presence in milk at about 0.11%, chloride is a neglected element in large animal nutrition. The practice of adding sodium chloride to concentrate mixtures and free-choice feeding seems to have precluded the possibility of a practical deficiency problem. When salt was omitted from the diet, researchers found that under the conditions used in their study, sodium was the first limiting element. This was true because sodium is present in most natural ingredients at much lower levels, relative to the cow's requirements, than is chloride.

Those who formulate diets usually ignore sodium levels in the natural ingredients (which are usually low in forages, but may be appreciable in certain concentrate ingredients) because of the traditional value of salt as a condiment. In addition, other sodium salts are often included in concrete mixtures: sodium sulfate as a sulfur replacement, the sodium phosphates as phosphorus supplements, and sodium bicarbonate as a buffer. Even when these supplements are used, salt is still often included because of tradition. Under many conditions, gross overfeed of both sodium and chloride occurs. High dietary levels of sodium and chloride do not increase the levels of these elements in milk. Excess will be excreted in urine and manure. Excess salt intake may result in greater water consumption, waste transport, bedding requirements, and transfer of sodium and chloride to the soil.

Of the seven macro mineral elements required by dairy cattle, five can be considered fertilizer elements (potassium, calcium, phosphorus, magnesium, and sulfur), but sodium and chloride are both toxic to plants at high concentrations and present practical problems in areas with saline soils. High salt intakes have also been shown to increase udder edema in heifers. Because of the importance of chloride in nutrition and metabolism, research is needed to define the chloride requirements of lactating cows and clarify mineral relationships, especially between chloride and potassium plus sodium.

Chloride and Plants

Chloride is one of the most recent elements to be shown essential for plant growth. Evidence shows that tomato plants grown in a low-chloride solution developed wilting of leaflet blade tips, which progressed to chlorosis, bronzing, and necrosis. Growth was proportional to chloride

concentration (up to a point) in the culture medium. Chloride additions to the medium prevented the deficiency symptoms and caused their disappearance in deficient plants. Later, the same team showed that often, other species, including barley and alfalfa, displayed severe deficiency symptoms when grown in a low-chloride medium. Although buckwheat, corn (maize), and beans did not exhibit these obvious symptoms, yield effects were apparent.

Despite the presence of 250 parts per million (ppm) in the leaves of chloride-deficient tomato plants compared to a 0.1 ppm for molybdenum, chloride was classified as a micronutrient by plant physiologists. The essentiality of chloride escaped detection for so long because of its wide distribution in nature, the high solubility of most chloride salts, and difficulties of purification. Because chloride is a principal ion of sea water, it is picked up by winds from sea spray and carried far inland. For example, Geneva, New York has been estimated to receive 18 kilograms/hectare of chloride annually; Mount Vernon, Iowa, 73 kilograms/hectare annually. Deposits of more than 45 kilograms/hectare have been reported near coastlines. It was also suggested that leaf structures were capable of capturing airborne chloride. The popularity of potassium chloride as a potassium fertilizer and manure from cows fed excessive levels of chloride relative to their requirement are additional sources of soil chloride.

Chloride differs from other nutrient elements present in native rocks because it is not fixed by colloids; it is repelled by negatively charged clay surfaces, and all chloride compounds formed in soils are highly soluble. In addition to leaching, chloride is lost from soils through crop removal.

Several factors affect chloride uptake by plants: (1) age or advancing maturity shown in avocado, apricot, and grape leaves; (2) chloride concentration in the soil; (3) soil oxygen levels; (4) plant species; and (5) competition from other anions. Research has shown a specific antagonism between nitrate-nitrogen and chloride; increasing chloride levels in the growth medium reduces nitrogen uptake, but this reduction is primarily in the nitrate-nitrogen fraction, with little if any effect on the protein-nitrogen fraction. The reciprocal effect was also observed between chloride and sulfate accumulation. Chloride is essential in the plant for photosynthetic reactions in chloroplasts, which produce oxygen.

Chloride is also treated as a toxic element as well as a part of saline toxicity. Over the toxic range, the reduction in growth is approximately linear. For example, at about 3500 ppm chloride in the cultural medium, alfalfa growth will be depressed to about 60% that of normal. Obviously, in areas with saline soils, there is concern about excessive levels of salt returned to the soil via manure.

Gastrointestinal Absorption of Chloride

Since 1952, when in goats, sheep, and dairy cattle, the observation was made that chloride could be absorbed from ruminal fluid into the blood against a tenfold concentration difference (normal rumen fluid chloride concentrations may range from 10 to 30 mEq/l, while those of the plasma may range from 100 to 110 mEq/l), numerous researchers have attempted to describe accurately and explain the processes by which chloride might move across the reticulorumen epithelium against its apparent chemical gradients. For a number of years, it was assumed by some workers that the observed electrical potential difference across the forestomach epithelium, making the plasma approximately 30 mV positive to the contents of the reticulorumen, could adequately account for the otherwise anomalous movements. If chloride's movement into the blood was truly attributable solely to the combined electrochemical gradient acting upon it, then its distribution across the gastric epithelium should have been describable by the Nernst equation.

In rumen-fistulated experimental animals, it has been observed that for certain distribution ratios of chloride in the ruminal fluids and blood plasma, the calculated equilibrium potential for chloride is relatively the same as that measured directly with KCl–agar bridges and calomel electrodes. However, in many circumstances, the calculated and measured values have been found to be significantly different, an observation that could only be accounted for by the presence of an active transport mechanism responsible for the movement of chloride out of its equilibrium distribution.

The active transport of chloride has also been demonstrated across the wall of the frog stomach, rat ileum, dog ileum, and the human ileum. Experiments have produced a double exchange model in which bicarbonate secretion and chloride absorption are linked by an isoelectric mechanism to hydrogen ion secretion and sodium absorption across the human ileum. In 1972, a group of researchers proposed a similar model of coupled transport across the reticulorumen epithelium, and further concluded that active anion and cation transport in the rumen cannot function efficiently unless both components are intact, i.e., the net transport of the body's major cations from the rumen to the blood, appeared to be dependent in part on the activity of chloride in the system.

Chloride in Cerebrospinal Fluid

A similar story has unfolded concerning the distribution and movement of chloride between the blood and cerebrospinal fluid (CSF). The first indication for the possible existence of an active mechanism responsible for the maintenance of chloride levels in the CSF in the mid-20th Century when, Hiatt demonstrated in dogs the persistence of CSF chloride concentrations at 44% of normal, despite the reduction of chloride levels to 30% of normal in all body fluids during a nitrate-induced diuresis. Over the next 20 years, researchers recorded chloride ion concentration and electrical potential differences across CSF-ECF (extracellular fluid) and CSF-blood barriers ranging from 15 to 20% and from 5 to 30 mV, respectively, in such varied subjects as dogfish, rats, cats, dogs, monkeys, and humans. In all cases, the CSF was both higher in chloride ion concentration and negative in potential with respect to the reference body fluid.

In 1970, researchers studied the distribution and kinetics of chloride in cats following the iso-osmotic replacement of body chloride with isethionate via extracorporeal hemodialysis. They found that when the plasma chloride concentration was reduced by approximately 93%, the cerebral cortex, corpus callosum, and CSF chloride concentrations were reduced by approximately only 26.5, 35, and 21%, respectively. Other body tissues and fluids showed reductions in chloride concentration closer to those of the plasma (skeletal muscle and liver, 73%). The influx of chloride into the CSF at various plasma chloride concentrations was then plotted as a Lineweaver-Burk plot, and was shown to behave as a carrier-mediated process, as described by Michaelis-Menten kinetics. This information, combined with the observations made by Abbot et al. that reduction of the plasma chloride concentration by isethionate replacement did not produce a change in electrical potential "commensurate with or even in the same direction" as that expected by Nernst equation predictions, led workers in the field to ascribe the bulk of chloride movement from the blood into the CSF to an active transport process. It is possible that control of the rate of chloride transport is a factor in the regulation of the secretion of CSF, the medium that bathes, protects, and nourishes the central nervous system.

Chloride in the Humoral Regulation of Sodium and Potassium

Conventional presentations of the regulatory mechanisms involved in body fluid and electrolyte homeostasis usually have considered maintenance of the sodium/potassium ratio in the ECF both the prime means and end toward a functional electrolyte balance. Certainly, the sodium/potassium ratio provides the axis about which the body's humoral mechanism of electrolyte homeostasis revolves, represented mainly by the renin-angiotensin-aldosterone system. Aldosterone increases the activity of sodium retaining processes in the body. These include the active uptake of sodium from the gastrointestinal tract and the reabsorption of sodium from the renal tubes in exchange for potassium or hydrogen ion.

Given chloride's role in ruminal absorption and CSF secretion, perhaps its participation in the aldosterone mechanism of regulating the sodium/potassium "axis" should come as no surprise.

Upon detection of decreased blood pressure, volume, and/or sodium, the juxtaglomerular apparatus in the kidney secretes renin, an enzyme which then cleaves a decapeptide, angiotensin I, from a plasma α 2-globulin, angiotensinogen. A converting enzyme present in the plasma, and most abundant in the pulmonic circulation, cleaves a dipeptide from angiotensin I, thus forming angiotensin II. The effect of angiotensin II, potentiated by ACTH and high plasma potassium, is to induce the secretion of aldosterone by cells in the zona glomerulosa (arcuata) of the adrenal gland cortex. Aldosterone than exerts its effects on the sweat glands, salivary glands, intestinal mucosa, and distal convoluted tubules of the kidneys, promoting sodium absorption and retention. Because of its potent vascoconstrictive properties (40 times that of norepinephrine) angiotensin II can effectively reduce both renal blood flow and glomerular filtration rate, leading to an immediate decrease in excretion of water and electrolytes, before aldosterone can affect tubular sodium reabsorption.

Research has demonstrated that chloride is not only responsible in part for angiotensin II formation, but also for its deactivation or catabolism by the major angiotensinase of the body. Furthermore, chloride ion's relation

to angiotensin II may not be its only route to affecting aldosterene secretion and sodium/potassium balance. Chloride's role in the metabolism of ACTH has led to support for the hypothesis that fluid and electrolyte homeostatic mechanisms may revolve not just around the sodium/potassium ratio, but also around the levels of chloride in the body.

CHLORINATED ORGANICS. Organic compounds containing chlorine are valued as reagents and intermediates in chemical synthesis and for their commercial and industrial importance. Several are produced in high tonnages. The large-volume market for these compounds is in plastics, including vinyl chloride for polyvinyl chloride (PVC), or as a copolymer with vinyl acetate; vinylidene chloride for *Saran*; and chloroprene for neoprene. Other important uses include agricultural chemicals, solvents, plasticizers, and medicines. Uses as intermediates to produce other chemicals also are important and varied. The largest-volume chlorine organic is ethylene dichloride (EDC). About 14 billion pounds (6.2 billion kilograms) per year of EDC are produced, but over half of this is consumed by the producers to make vinyl chloride monomer. Methyl chloride is the intermediate for many chemicals, as are benzyl chloride, phosgene, and chloroform.

The chlorine on certain compounds is used as a facile leaving group for the introduction of another functional group. The displacement of a halogen atom by a cyano group to form a nitrile is one of the most useful reactions of halogen compounds. This opens a route to carboxylic acids having one carbon atom more than the original halide, aside from the importance of the nitriles themselves. Adiponitrile, used in the manufacture of nylon, can be made by treatment of 1,4-dichlorobutane with cyanide:

$$\begin{array}{l} CH_2CH_2Cl \\ | \\ CH_2CH_2Cl \end{array} \xrightarrow{NaCN} \begin{array}{l} CH_2CH_2CN \\ | \\ CH_2CH_2CN \end{array}$$

Long-chain alkyl chlorides can be used for the synthesis of various amines, while benzyl chloride is used for production of quaternary ammonium compounds. Alkyl chlorides are used for the formation of organometallics, including the Grignard reagents as well as for alkylation of aromatics. One of the important reactions of phosgene is with diamines for production of diisocyanates (polyurethanes).

Synthesis of Chlorinated Organics

Chlorine derivatives of organic compounds are obtained by substitution, addition, or displacement. Substitution reactions of Cl on hydrocarbons involve radical attack to remove a hydrogen, forming the hydrocarbon radical as an intermediate: $R{-}H + Cl \longrightarrow R + HCl$. Since a tertiary carbon radical $-\overset{|}{\underset{|}{C}}\cdot$ is most stable, it chlorinates more readily than a secondary carbon $\overset{|}{-CH_2}$ and that more readily than a methyl group. Due to inductive effects, the presence of chlorine in a molecule reduces the activity of the hydrogens on adjacent carbons more than on the chlorinated carbon. Thus, a second radical (Cl·) will preferentially attack a hydrogen on the same carbon. For example, chlorination of ethyl chloride will produce nearly twice as much 1,1-dichloroethane as 1,2-dichloroethane. Specificity of this sort is decreased at higher temperatures, leading to more random substitution. Hydrogens further away on a longer-chained molecule are essentially unaffected by the first chlorine, therefore little selectivity occurs for subsequent substitutions.

The wide range of organic compounds that can be produced through chlorination is illustrated by the very abridged listing in Table 1.

Chlorine can be substituted onto an aromatic ring in the presence of a catalyst, such as ferric chloride, $FeCl_3$, or aluminum chloride, $AlCl_3$. The simplest case would be chlorination of benzene. Substitution of a second Cl onto the ring preferentially goes to the para position, but the ortho and meta isomers can be formed with the latter least favored. If the chlorination

TABLE 1. PROPERTIES OF SOME CHLORINATED ORGANICS

Compound	Specific gravity	Melting point, °C	Boiling point, °C
Acetyl chloride	1.105	−112	51
Acetylene dichloride	1.291	−80	60

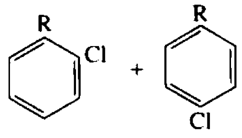
Pentachloroethane	1.671	−22	162
Vinyl chloride	0.908	−160	−12

is carried out in the presence of a radical source, such as ultraviolet light, addition occurs instead. See *Chlorinated Aromatics* described later in this entry. When a functional group is present on the aromatic ring, Cl attack will depend upon the type of group present. Phenol and benzoic acid will chlorinate on the ring to give chlorophenol and *p*-chlorobenzoic acid. Alkyl benzenes will chlorinate on the alkyl group if a radical source is present. In the presence of an iron catalyst, the product is a mixture of the ortho- and para-chloroalkyl-benzenes:



With higher aromatics, such as naphthalene, chlorine successively substitutes all of the hydrogens. The first product is α-chloronaphthalene and the final compound is perchloronaphthalene.

Chlorine addition occurs on unsaturated hydrocarbons having double or triple bonds. Addition can occur by use of Cl_2, HCl, or HOCl:

$$>C=C< + ClX \longrightarrow \begin{array}{c} |\;\;\; | \\ ClC-CX \\ |\;\;\; | \end{array}$$

where X=Cl, H, or OH.

With ethylene, the products would be 1,2-dichloroethane, ethyl chloride, or ethylene chlorohydrin. When the unsaturated molecule has three or more carbons, HCl will add, preferentially, with the Cl on the carbon having the fewest hydrogens. For addition of HOCl, the opposite is favored.

Displacement occurs when a functional group is replaced. Chlorine can displace groups, such as hydroxyl, OH, in an acid-catalyzed reaction. For example, methyl chloride can be prepared from the reaction of HCl on methanol. Other alkyl chlorides can be made from their corresponding alcohols. Another type of displacement would be the exchange of one halogen for another, e.g., Cl can be substituted for bromine or iodine in a molecule. An acyl chloride can be formed by the reaction of a strong dehydrating Cl carrier, such as PCl_3, PCl_5, POCl, or $SOCl_2$ with an organic acid or its salt.

Industrially, chlorinations are carried out in five ways: (1) radical substitution of hydrogens (protons); (2) addition across unsaturated (double or triple) bonds, using molecular Cl, HCl, or HOCl; (3) HCl reaction with an alcohol; (4) chlorinolysis, in which the oxidative power of Cl is

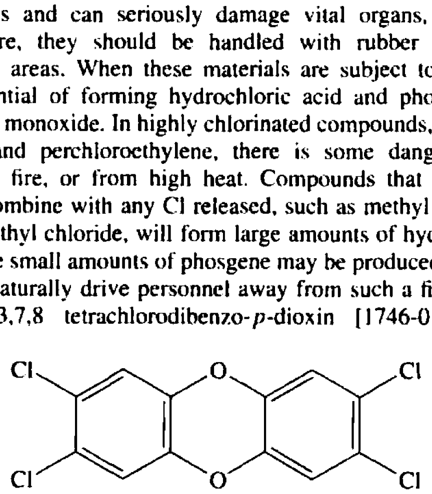
used at high temperature to cleave hydrocarbons, resulting in formation of smaller chlorinated fragments; and (5) oxychlorination. The latter reaction is similar to producing molecular chlorine, *in situ*, from HCl and air in the presence of a catalyst. An example of this is the production of ethylene dichloride, 1,2-dichloroethane, from ethylene, HCl, and oxygen.

Characteristics of Chlorinated Organics

The presence of Cl in an organic molecule increases the density, viscosity, and chemical reactivity, while decreasing the specific heat, solubility in water, and flammability. Chlorine is normally an excellent leaving group, particularly in base-catalyzed reactions, which makes it important for syntheses. Toxicity is the principal hazard. Threshold Limit Values, established by the American Conference of Governmental Industrial Hygienists, for tetra- and pentachloroethane are 5 ppm (vol.) in the atmosphere. Corresponding values for CCl_4, $CHCl_3$, and perchloroethylene are 10, 50, and 100 ppm, respectively. Chloroacetylenes are highly explosive, especially in contact with caustic, e.g., NaOH.

Safety and Handling. Chlorinated organics are absorbed through the skin and lungs and can seriously damage vital organs, especially the liver. Therefore, they should be handled with rubber gloves and in well-ventilated areas. When these materials are subject to burning, they have the potential of forming hydrochloric acid and phosgene, $COCl_2$, besides carbon monoxide. In highly chlorinated compounds, such as carbon tetrachloride and perchloroethylene, there is some danger of forming phosgene in a fire, or from high heat. Compounds that have sufficient hydrogen to combine with any Cl released, such as methyl chloride, vinyl chloride, and ethyl chloride, will form large amounts of hydrochloric acid. Although some small amounts of phosgene may be produced, the hydrogen chloride will naturally drive personnel away from such a fire.

Dioxin (2,3,7,8 tetrachlorodibenzo-*p*-dioxin [1746-01-61]), shown below,



is the extremely toxic byproduct of manufacture of certain chemicals, notably 2,4,5-T. Unfortunately, the name *dioxin* is used synonymously for other, non-chlorinated compounds, such as 2,6 dimethyl-1,3-dioxin-4-ol acetate [828-00-2], which do not deserve the notoriety.

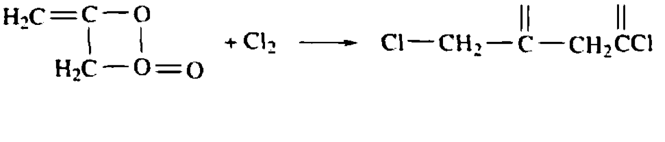
Types or Families of Chlorinated Organics

Chlorinated Paraffins. Cl will displace one, two, three, or more hydrogens from the paraffins. These substitution products are referred to as *mono* ($C_nH_{2n+1}Cl$), *di* ($C_nH_{2n}Cl_2$), *tri* ($C_nH_{2n-1}Cl_3$), and so on. *Monochloro* derivatives include methyl chloride, CH_3Cl, ethyl chloride, C_2H_5Cl, and propyl chloride, C_3H_7Cl. These are also called *alkyl chlorides*. Examples of *dichloro* compounds include methylene dichloride, CH_2Cl_2, and ethylene dichloride, $C_2H_4Cl_2$. Chloroform, $CHCl_3$, and 1,1,1-trichloroethane, $C_2H_3Cl_3$, are *trichloro* derivatives, while carbon tetrachloride, CCl_4, is a *tetrachloro* molecule. When all the hydrogens are substituted by Cl, the term *perchloro* is sometimes used.

Chlorinated Carbonyls. Chlorination of an aldehyde or ketone occurs most readily on a carbon next to the carbonyl function. This is due to proton interaction with the carbonyl and is acid catalyzed. Reaction of Cl with acetone yields chloroacetone. Substitution of a second Cl on chloroacetone occurs with no preference for sites. Thus, equal amounts of 1,1-dichloro- and 1,3-dichloroacetone are produced. (The opposite is true when brominating, since it is possible to form nine parts of 1,3-dibromo- to one of 1,1-dibromoacetone.) Chloral is produced from acetaldehyde. It is also produced by hydrolysis of trichlorodiethyl ether. Acrolein reacts with dry HCl at low temperatures to give β -chloropropionaldehyde.

The chlorinated acetones are strong lachrymators. Tear gas contains chloroacetophenone, which is also a component of the nonlethal disabling spray chemical *Mace*.

Chlorination of diketene yields α-chloroacetoacetyl chloride:



This product is both a vesicant (blistering agent) and a lachrymator.

Chlorinated Fatty Acids. Chlorination of carboxylic acids is much more difficult because the contribution of the carbonyl group toward proton removal is offset by the electron donation effect from the hydroxyl group. This hindrance is obviated by reaction with the acid chloride or anhydride. Chlorination is normally accomplished by use of a catalyst, such as phosphorus trichloride. Monochloroacetic acid is an important industrial chemical. Dichloro- and trichloroacetic acids can be produced by further chlorination, although the latter can be produced conveniently by nitric acid oxidation of chloral. Higher chlorinated fatty acids can be produced by treatment of the hydroxy carboxylic acid or ester with HCl or PCl_5:

$$CH_3CHOHCH_2COOR + PCl_5 \longrightarrow CH_3CHClCH_2COOR$$

Amino fatty acids can be treated with a mixture of nitric oxide and chlorine to produce the corresponding chloroacid. Mono- and dichlorosuccinic acids are examples of chlorinated dicarboxylic acids.

Chlorinated Ethers. Ethylene chlorohydrin reacts with sulfuric acid to form β,β'-dichloroethyl ether. It is a byproduct of ethylene glycol production. The chlorines on this ether are inert, making it a good solvent. Further chlorination at 20–30°C gives α,β,β'-trichloro diethyl ether which hydrolyzes to chloroacetaldehyde and ethylene chlorohydrin. Ethylene and sulfur monochloride react to give β,β'-dichlorodiethyl sulfide (mustard gas), which is a thioether.

Chlorinated Aromatics. Chlorination of benzene in the presence of a catalyst ($FeCl_3$ or $AlCl_3$) yields chlorobenzene as the first product. Substitution with a second Cl yields ortho, para, or meta dichlorobenzene. Eventually all the hydrogens can be substituted to give hexachlorobenzene, C_6Cl_6. In the presence of ultraviolet light, the chlorination of benzene yields benzene hexachloride, $C_6H_6Cl_6$, a derivative of cyclohexane. Under the same conditions toluene chlorinates on the methyl group to give one, two or three substitutions (benzyl chloride, benzal chloride or benzotrichloride), while in the presence of an iron catalyst, one obtains ortho- and parachlorotoluene.

Chlorinated Heterocyclics. Substitution in pyridine is more difficult than in benzene but Cl will enter the β position slowly. Chlorine will not add to furan to give stable addition products but substitution occurs to give 2-chloro- or 3-chlorofuran, 2,5-dichlorofuran, and 2,3,5-trichlorofuran.

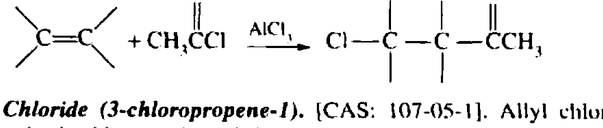
Important Specific Chlorinated Organic Compounds

Several thousand chlorine-containing compounds are known and have been synthesized. A select group is included for description here to provide a cross section of the most important of these compounds. The number in brackets following each heading, where appropriate, is the *Chemical Abstracts Service Registration* number.

Acetyl Chloride $\left(CH_3\overset{\overset{\displaystyle O}{\|}}{C}Cl\right)$. [CAS: 75-36-5]. Acetyl chloride can be prepared by treatment of acetic acid with various reagents, such as PCl_3, $SOCl_2$ or $COCl_2$. It can be prepared by chlorination of acetic anhydride in several different ways, by reaction of methyl chloride with carbon monoxide in the presence of catalysts, by reaction of ketene ($H_2C{=}C{=}O$) with HCl, or by partial hydrolysis of 1,1,1-trichloroethane. Acetyl chloride hydrolyzes in the presence of water to give acetic acid. It reacts with ammonia and amines to give acetamides:

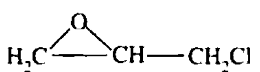
$$CH_3\overset{\overset{\displaystyle O}{\|}}{C}Cl + RNH_2 \rightarrow CH_3\overset{\overset{\displaystyle O}{\|}}{C}NHR$$

Reaction with alcohols gives the corresponding acetate esters. Acetyl chloride will add across unsaturated bonds in the presence of suitable catalysts to give halogenated ketones:



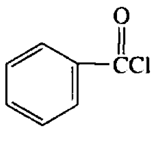
Allyl Chloride (3-chloropropene-1). [CAS: 107-05-1]. Allyl chloride can be synthesized by reaction of allyl alcohol with HCl or by treatment of allyl formate with HCl in the presence of a catalyst ($ZnCl_2$). Commercial production is by chlorination of propylene at high temperatures, about 500°C, using a large excess of propylene. It is used in the synthesis of

glycerol, allyl alcohol and epichlorohydrin. Since the chlorine is situated alpha to a double bond, it is particularly reactive. Thus, hydrolysis to allyl alcohol occurs rapidly in dilute caustic at about 150°C. Addition of HOCl followed by treatment with an alkali yields epichlorohydrin:

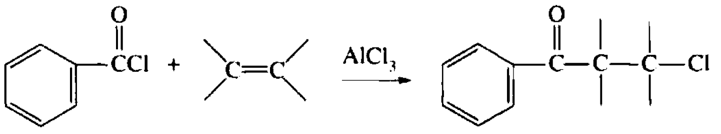


Addition of HBr in the presence of an oxidizing agent yields 1-chloro-3-bromopropane, which is used to prepare cyclopropane. Allyl chloride is one of the most toxic of the chlorinated organics.

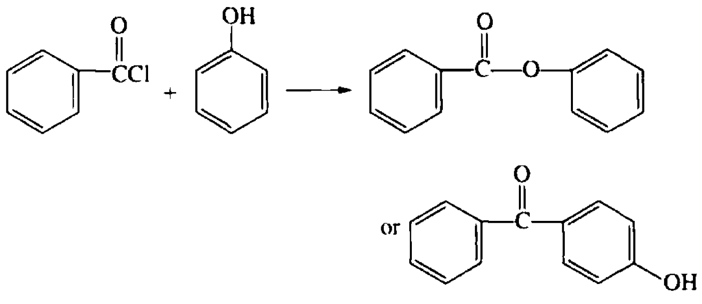
Benzoyl Chloride. [CAS: 98-88-4].



Benzoyl chloride can be prepared from benzoic acid by reaction with PCl_5 or $SOCl_2$, from benzaldehyde by treatment with $POCl_3$ or SO_2Cl_2, from benzotrichloride by partial hydrolysis in the presence of H_2SO_4 or $FeCl_3$, from benzal chloride by treatment with oxygen in a radical source, and from several other miscellaneous reactions. Benzoyl chloride can be reduced to benzaldehyde, oxidized to benzoyl peroxide, chlorinated to chlorobenzoyl chloride and sulfonated to *m*-sulfobenzoic acid. It will undergo various reactions with organic reagents. For example, it will add across an unsaturated (alkene or alkyne) bond in the presence of a catalyst to give the phenylchloroketone:

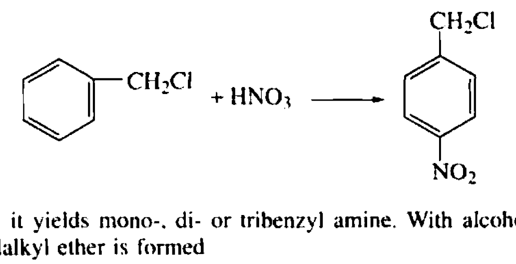


Reaction with benzene yields benzophenone while toulene gives phenyl-*p*-tolyl ketone. Reaction of benzoyl chloride with monohydric alcohols gives the corresponding alkyl ester, but with phenols the product can either be the phenylbenzoate or a phenolic ketone:

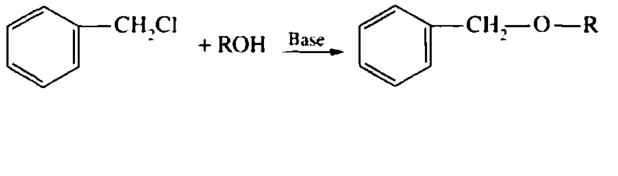


With ammonia and various primary and secondary amines the corresponding amide is formed.

Benzyl Chloride (α-chlorotoluene). [CAS: 100-44-7]. Benzyl chloride can be synthesized by chloromethylation of benzene in the presence of a catalyst ($ZnCl_2$) or by treatment of benzyl alcohol with SO_2Cl_2. Commercially it is produced by chlorination of boiling toluene in the presence of light. Benzyl chloride can be oxidized to benzoic acid or benzaldehyde, or substituted to give the halogenated, sulfonated or nitrated product:



With NH_3 it yields mono-, di- or tribenzyl amine. With alcohols in base the benzylalkyl ether is formed



With phenols either the phenolic or nuclear hydrogens can react to give benzylaryl ether or benzylated phenols. Reaction with NaCN gives benzyl cyanide (phenylacetonitrile); with aliphatic primary amines the product is the N-alkylbenzylamine, and with aromatic primary amines N-benzylaniline is formed. Benzyl chloride is converted to butyl benzyl phthalate plasticizer and other chemicals.

Carbon Tetrachloride (tetrachloromethane). [CAS:56-23-5]. Carbon tetrachloride can be synthesized by the chlorination of CS_2, acetylene and other higher hydrocarbons but the primary source is the exhaustive chlorination of methane. It can be pyrolyzed to yield hexachloroethane, oxidized to phosgene and carbonylated with CO in the presence of $AlCl_3$ to give trichloroacetylchloride:

$$CCl_4 + CO \xrightarrow{AlCl_3} Cl_3C{-}\overset{O}{\overset{\|}{C}}{-}Cl$$

Some of the more important commercial uses involve fluorine displacement to yield chlorofluoromethane refrigerants, such as trichlorofluoromethane (R-11) and dichlorodifluoromethane (R-12).

Chloroacetic Acid ($ClCH_2COOH$). [CAS: 79-11-8]. Chloroacetic acid can be synthesized by the radical chlorination of acetic acid, treatment of trichloroethylene with concentrated H_2SO_4, oxidation of 1,2-dichloro ethane or chloroacetaldehyde, amine displacement from glycine, or chlorination of ketene. It behaves as a very strong monobasic acid and is used as a strong acid catalyst for diverse reactions. The Cl function can be displaced in base-catalyzed reactions. For example, it condenses with alkoxides to yield alkoxyacetic acids: $ClCH_2COOH + KOR \longrightarrow ROCH_2COOH$. Oxidation of chloroacetic acid leads to formation of methylene chloride. Treatment with ammonia yields glycine ($ClCH_2COOH \xrightarrow{NH_3} H_2NCH_2COOH$) while use of amines leads to formation of substituted glycines. Commercially, chloroacetic acid is an intermediate in the production of herbicides (2,4-D, 2,4,5-T and others) and cellulose ethers.

Chloroacetylene ($HC \equiv CCl$). [CAS: 593-63-51]. This compound is a gas with a very unpleasant odor. It ignites spontaneously in air and may detonate during handling. It can be synthesized by dehydrochlorination of dichloroethylenes with a strong base. It will react with silver or mercury to give explosive salts. Addition occurs across the unsaturated bond-for example, bromination yields 1-chloro-1,1,2,2-tetrabromoethane.

Chloral (trichloroacetaldehyde). [CAS: 75-87-6]. Chloral can be prepared by action of Cl_2 on ethanol, chlorination of acetaldehyde, oxidation of 1,1,2-trichloroethylene in the presence of a catalyst ($FeCl_3$, $AlCl_3$, $TiCl_4$ or $SbCl_3$, and by reaction of CCl_4 with formaldehyde. Chloral can be reduced either at the $-CCl_3$ group or the $-CHO$ group. In the first case the product is acetaldehyde while the second gives $Cl_3C{-}CH_2OH$. Oxidation of chloral gives trichloroacetic acid. Polymerization in the presence of H_2SO_4 leads to metachloral or parachloral, depending on the temperature. It undergoes various condensation reactions with alcohols to yield hemiacetals. With organic acids and other functional groups a multitude of reactions are possible. It is used in medicine as a hypnotic.

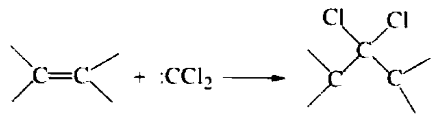
Chlorobiphenyls. These compounds can be synthesized by direct chlorination of biphenyl in the presence of iron or other catalysts. Other means of preparation include reaction of diazotized aminobiphenyl with copper chloride. Treatment of chlorobiphenyls at elevated temperatures (300–400°C) with strong caustic yields hydroxybiphenyls. Various reactions, normal to aromatic systems, will occur—usually on the unsubstituted ring.

Chloroform (trichloromethane). [CAS: 67-66-3]. Although chloroform can be prepared by various means it is almost exclusively produced by the chlorination of methane. It can be oxidized to phosgene, substituted with various halogens, nitrated to chloropicrin (Cl_3CNO_2), hydrolyzed to formic acid $\overset{O}{\overset{\|}{(HCOH)}}$ and carbonylated to dichloroacetic acid. It will react with unsaturated halohydrocarbons in the presence of $AlCl_3$:

$$ClHC{=}CHCl + CHCl_3 \xrightarrow{AlCl_3} Cl{-}\underset{H}{\overset{Cl}{C}}{-}\underset{H}{\overset{Cl}{C}}{-}\underset{H}{\overset{Cl}{C}}\,Cl$$

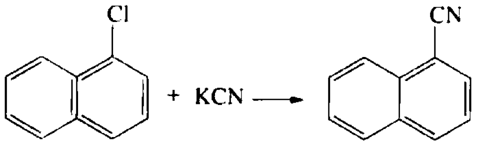
With aromatic aldehyde or ketones base catalyzed additions occur, while it condenses with primary amines to yield isocyanides: $C_2H_5NH_2 + CHCl_3 \xrightarrow{NaOH} C_2H_5N \equiv C$. A special type of addition can occur when chloroform is reacted with an unsaturated molecule in the presence of

potassium alkoxide or sodium hydroxide in a polymer medium. The strong base removes HCl and produces dichlorocarbene ($:CCl_2$) which adds across the double bond:



Commercially, about 60% of chloroform is used in production of fluorocarbon refrigerants and propellants. Cl is replaced by treatment with fluorinated antimony pentachloride. The product, $CHClF_2$ (R-22), is used for home air-conditioning units. It is also used as a feed for production of tetrafluoroethylene, which polymerizes to Teflon. Total demand for chloroform approximates 600 million pounds (136 million kilograms) per year.

Chloronaphthalenes. These compounds can be prepared by direct chlorination of naphthalene in the liquid or vapor phase. They also can be synthesized from naphthylamines via diazotization reactions or from naphthols by treatment with PCl_5. Chloronaphthalenes can be further substituted in normal aromatic reactions e.g., halogenation, nitration and alkylation. The chloro group can be displaced to yield a naphthol, an amine, or a nitrile:

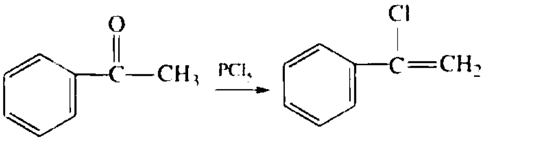


Chlorparaffins. These are produced by the random chlorination of various mixed long-chain paraffins. They are used as secondary plasticizers for polyvinyl chloride, lubricating oil additives, resinous materials for coatings, and in flame-retardants.

A particularly valuable use for chlorparaffins is in preparation of linear, primarily internal olefins as feedstock for long-chain synthetic oxoalcohols. Typically, *n*-paraffins ($C_{11}-C_{14}$) are chlorinated in a fluidized bed at about 300°C. Conversion is maintained low to limit multiple chlorination. After separation of the monochlorinated alkanes by distillation, dehydrochlorination over nickel acetate at 300°C yields the desired internal olefins. Unreacted paraffins are recycled.

Chloroprene (2-chlorobutadiene-1,3). [CAS: 126-99-8]. Chloroprene can be synthesized by addition of HCl to vinyl acetylene $H_2C{=}CH{-}C\equiv CH + HCl \longrightarrow H_2C{=}CH{-}CCl{=}CH_2$, and by dehydrochlorination of dichloro butenes or 2,2,3-trichlorobutane. It undergoes the normal addition reactions across the double bond and readily polymerizes or copolymerizes with other unsaturated compounds. These polymers resemble natural rubber but are superior in some respects, such as oil resistance (neoprene). Almost all the chloroprene produced is used for the manufacture of these polychloroprene rubbers. Chloroprene is a volatile, toxic, flammable liquid and is especially susceptible to oxidation and poly merization.

Chlorostyrene (chlorovinylbenzene). [CAS: 1331-28-8]. The alpha isomer can be prepared by PCl_5 reaction on acetophenone



by heating of acetophenone dichloride, or by hydrolysis of styrene dichloride in aqueous NaOH.

Dichlorobenzenes. [CAS: 95-50-1] [106-46-7] [541-73-1]. Dichlorobenzenes are primarily produced by the chlorination of benzene in the presence of a catalyst ($FeCl_3$ or $AlCl_3$) although there are other possible synthetic routes. The two commercially important isomers are the ortho- and para-dichlorobenzenes. Further chlorination yields 1,2,4-trichlorobenzene. Dichlorobenzenes participate in normal aromatic substitution and alkylation reactions. In the presence of $CuCl_2$, ammonia will react with the dichlorobenzenes to yield chloroanilines. The ortho-dichlorobenzene is used for pesticides, moth control, as a solvent and for dyestuff manufacture. About half of the para is used as a space odorant.

Epichlorohydrin (γ-chloropropylene Oxide). [CAS: 106-89-8]. This compound can be prepared from 1,3-dichloropropanol-2, 2,3-dichloropropanol-1, or allyl chloride. Commercially it is prepared as an intermediate in glycerol synthesis via alkaline hydrolysis of glycerol dichlorohydrin. Both come from allyl chloride. Epichlorohydrin reacts with monohydric alcohols to give ethers by opening the oxide ring. It will react with ethers, aldehydes, ketones, organic acids and amines to give a wide variety of useful syntheses.

Commercially the most important use is production of glycerine. Large volumes are consumed in nonglycerine areas, which largely consist of the various epoxy resins. It has use as a solvent and in the production of epichlorohydrin rubber.

Ethyl Chloride (chloroethane). [CAS: 75-00-3]. This compound can be synthesized by treatment of ethyl alcohol with HCl, cleavage of diethylether with HCl in the presence of a catalyst ($ZnCl_2$), chlorination of ethane or hydrochlorination of ethylene. The latter is the choice of industry. The reaction is carried out at 125°F and 125 psi in the presence of $AlCl_3$, which is dissolved in ethyl chloride. It will undergo all the reactions of a typical alkyl chloride—halogenation, hydrolysis, amination, alkylation—and will form the magnesium Grignard reagent. The compound is used in production of tetraethyllead (TEL) by reaction with sodium-lead alloy:

$$4PbNa + 4C_2H_5Cl \longrightarrow Pb(C_2H_5)_4 + 3Pb + 4NaCl$$

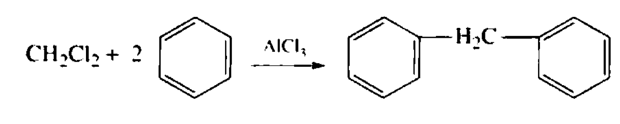
Ethyl cellulose is produced by treating alkali cellulose (cotton linter digested in dilute caustic) with ethyl chloride. Up to three ethyl ether stages can be made, giving various grades. These are used as synthetic gums and thickeners in the lacquer and plastics industries. Ethyl chloride is also used in the Friedel-Crafts alkylation of benzene and other aromatics. Additional uses include solvent, refrigerant, heat-transfer medium, aerosol propellant and anesthetic. Much is used captively by the producers.

Ethylene Dichloride (1,2-dichloroethane). [CAS:107-06-2]. Ethylene dichloride (EDC) is produced by reacting ethylene and chlorine in the presence of ferric chloride, using the liquid product as solvent. It is also produced by oxychlorination—ethylene, hydrogen chloride, and air are reacted at about 250°C with a copper chloride catalyst. This latter is the reaction of choice only when cheap by-product HCl is available. EDC reacts with Cl_2 to give derivatives of ethylene or ethane, depending on conditions and catalysts. It will dehydrochlorinate to give vinyl chloride, which is its principal commercial use. EDC hydrolyzes to ethylene glycol and reacts with aormatic hydrocarbons in the presence of $AlCl_3$ to give polyarylethylene plastics. The largest use is for vinyl chloride; next is its use as a solvent intermediate. Other uses include the manufacture of ethylenediamine and succinic acid, by way of the nitrile. Reaction of EDC with sodium tetrasulfide is used to produce thiokol rubbers.

Methyl Chloride. [CAS: 74-87-3]. This compound is produced by direct chlorination of methane. Since methyl chloride adds chlorine faster than methane, the yield of methyl chloride is increased by using a large excess of methane in the feed, i.e., about ten volumes of methane to one volume of chlorine. The reaction is carried out at about 450°C with very short contact times. Methyl chloride is also commercially produced by reaction of HCl on methanol in the presence of zinc chloride. Methyl chloride is mainly used in the production of silicone resins and rubbers. Silicon is reacted with an excess of methyl chloride at 300°C in the presence of a copper catalyst. The product includes mono-, di-, and trichloromethyl silanes. Hydrolysis of the chloro groups converts them into the corresponding hydroxymethylsilanes. There are then polymerized to silicones. Nearly equal amounts of methyl chloride are used in making these rubbers and the other principal user, production of tetramethyllead. Production of methyl chloride approximates 440 million pounds per year.

Methylene Chloride (dichloromethane). [CAS: 75-09-2]. As with the other members of the methyl series of chlorinated hydrocarbons, methylene chloride can be produced by direct chlorination of methane. The usual procedure involves a modification of the simple methane process. The product from the first chlorination passes through aqueous zinc chloride, contacting methanol at about 100°C. Thus, HCl from chlorination is used to displace the alcohol group, producing additional methyl chloride. This is further chlorinated to methylene chloride. Methylene chloride reacts violently in the presence of alkali or alkaline earth metals and will hydrolyze to formaldehyde in the presence of an aqueous base. Alkylation reactions occur at both functions, thus di-substitutions result. For example,

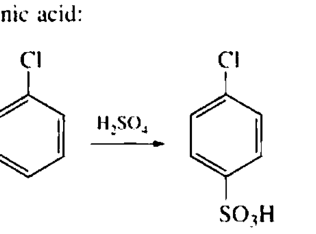
reaction with benzene plus $AlCl_3$ yields diphenyl methane:



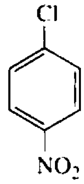
Catalyzed carbonylation (CO) reactions lead to formation of either chloroacetyl chloride or malonyl dichloride.

Methylene chloride is used in refrigeration, aerosol propellants, paint stripping, urethane foam-blowing agents, adhesive, and food extractants. It has low toxicity compared with other chlorinated hydrocarbons and has been shown to be neither mutagenic nor carcinogenic toward humans.

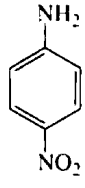
Monochlorobenzene (phenyl chloride). [CAS:108-90-7]. Benzene is chlorinated at 80°C in the presence of $FeCl_3$ catalyst. By using low conversions very little dichlorobenzene is produced. The chlorine on this compound is quite inactive, but hydrolysis can be effected by use of a strong caustic at high temperature and pressure, especially in the presence of a catalyst. This has been an important commercial route to phenol. With concentrated aqueous ammonia heated at high temperatures in the presence of a copper catalyst, aniline or diphenylaniline can be synthesized. Reaction with nitric acid yields chloronitrobenzenes-the para isomer predominates. Treatment with hot sulfuric acid leads to formation of *p*-chlorobenzensulfonic acid:



Monochlorobenzene is used commercially as a solvent and to produce phenol and nitrochlorobenzenes.



p-Nitrochlorobenzene. [CAS:100-00-5]. This compound is made by the nitration of chlorobenzene and is largely used to produce *p*-nitrophenol with smaller production of *p*-nitroaniline:



Various agricultural pesticides, rubber chemicals, phenacetin, and *p*-aminophenol consume about 30% of the total. Most of the production is used captively as an intermediate in the production of other chemicals.

Pentachlorophenol. [CAS: 87-86-5]. This compound can be produced by the chlorination of phenol in the presence of $AlCl_3$, or by hydrolysis of hexachlorobenzene with NaOH in methanol. Pentachlorophenol is used as a wood preservative for poles, crossarms, and pilings and thus competes with creosote.

Vinyl Chloride. [CAS:75-01-4]. This compound is produced by alkaline dehydrochlorination of ethylene dichloride, or by thermal cracking of EDC, or 1,1-dichloroethane. Vinyl chloride is polymerized in various ways to polyvinyl chloride (PVC). It is also copolymerized with various other monomers to make a variety of useful resins. The copolymers with about 3 to 20% vinyl acetate are the most important. Demand for vinyl chloride is high, approximating 8 billion pounds (3.6 billion kilograms) per year.

CHLORINATION (Process). See **Chlorinated Organics**.

CHLORINATION (Water). A principal means for disinfecting municipal water supplies as well as public swimming pools, and some municipal and industrial wastes is by liquid- or gas-phase chlorination. Liquid chlorine is packaged in several types of containers to accommodate a wide range of uses, which may vary from a few hundred pounds during a season (in the case of a swimming pool) to many thousands of tons per year for water supplies. Liquid chlorine is obtainable in pressurized 100- and 150-pound (~45- and 68-kilogram) cylinders, 1-ton (0.9-metric-ton) containers, and for large users, is shipped by railroad tank cars, tank barges, and tank trailers. Large users, of course, must provide local storage means.

Chlorine cylinders are equipped with a single valve. Gas is delivered when the tank is in an upright position; liquid when the cylinder is in an inverted position. However, liquid withdrawal from cylinders is not usually practiced. In the case of ton containers, two valves are provided, permitting easy withdrawal of either gaseous or liquid chlorine. Bulk shipments almost always are unloaded in the liquid phase.

In the case of gaseous withdrawal, the vaporization of the liquid chlorine lowers the temperature surrounding the valve and hence withdrawal rates are limited, ranging up to a maximum of about 1.75 pounds (0.8 kilogram) per hour for a 150-pound (~68-kilogram) cylinder; 15 pounds (6.8 kilograms) per hour for a ton container. Sometimes, cylinders are manifolded to increase the capacity of the system. In the case of liquid withdrawal, the rate ranges up to 400 pounds (181 kilograms) per hour for ton containers; up to 7,000 pounds (3175 kilograms) per hour for a tank car where discharge is from one valve. Usually the liquid is forced out of the container or tank by its own vapor pressure. However, air pressure up to 200 psi (13.6 atmospheres) may be superimposed to increase withdrawal rates.

In municipal water and wastewater treatment installations, the chlorine usually is introduced into the main water system by way of a concentrated water solution of chlorine. Chlorine is metered under a vacuum created by the ejector. The chlorine is dissolved in water in the ejector, and then discharged into the water system as a high-strength solution. Frequently, the chlorine feeding is done automatically in proportion to the flow of water being chlorinated.

In the control of chlorine disinfectant systems, the effective use of the chlorine for its intended purpose is assumed if the treated water considerably downstream from the chlorinator contains a residual of chlorine. Depending upon use, full-contact time may be assumed after ten minutes, or the interval may be extended to several hours. The systems also are usually carefully monitored by bacteriological testing. Normally a dose of 1 to 2 milligrams of chlorine per liter is adequate to destroy all bacteria and leave an effective residual. Residuals of 0.1 to 0.2 milligrams per liter are usually maintained in the effluent streams from water-treatment plants as a factor of safety for consumers.

Surface waters require in most instances more extensive treatment, including chlorination, than do groundwaters. By the time some river water reaches some consuming communities it will have received large inputs of organics. Because of its great oxidizing power, chlorine is highly reactive and can combine in a variety of ways with both inorganic and organic pollutants. Thus, there is concern over the possible formation of carcinogens or otherwise harmful compounds in waters

that are heavily chlorinated, particularly waters that have been recycled a number of times along a waterway. Major halogenated compounds found in water supplies suspected of posing health hazards to humans include: (1) chloro-esters, such as *bis*-(2-chloroethyl)ether and *bis*-(2-chloroisopropyl)ether; (2) halobenzenes, such as chlorobenzenes, bromobenzenes, and chloro-bromo benzenes; and (3) haloforms, such as chloroform, bromodichloromethane, dibromochloromethane, and bromoform. More information on this topic can be found in "Chlorine in the Marine Environment," by J.C. Goldman, *Oceanus*, **22**, 2, 36–43 (1979).

CHLORINE. [CAS: 7782-50-5]. Chemical element, symbol Cl, at. no. 17, at. wt. 35.435, periodic table group 17 (halogens), mp −101°C, bp −34.6°C, density (chlorine gas) 3.209 grams/liter (0°C and 1 atmosphere pressure). Chlorine gas is approximately 2.5 times heavier than air at standard conditions. Chlorine in the gaseous phase is diatomic (mol. wt. 70.906), pale greenish yellow of marked odor, irritating to the eyes and throat, poisonous. At 10°C and one atmosphere pressure 9.8 grams of Cl_2 will dissolve in one liter of water; at 30°C and one atmosphere pressure 5.6 grams will dissolve. Critical pressure is 1118.4 psia (7.7 mPa), critical temperature 144°C. CAS Registry No. 7782-50-5. Other important physical characteristics of chlorine are given under **Chemical Elements**.

Chlorine was discovered by Scheele in 1774 and confirmed as an element by Davy in 1810. It is a high-tonnage industrial chemical with many uses.

Naturally occurring isotopes 35, 37. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^5$. Ionic radius Cl^{7+} 0.26 Å, Cl^- 1.81 Å. Covalent radius 1.050 Å. First ionization potential 13.01 eV; second, 23.70 eV; third, 39.69 eV; fourth, 53.16 eV; fifth, 67.4 eV. Oxidation potential $ClO_3^- + H_2O \longrightarrow ClO_4^- + 2H^+ + 2e^-$, −1.00 V; $HClO_2 + H_2O \longrightarrow ClO_3^- + 3H^+ + 2e^-$, −1.23 V; $\frac{1}{2}Cl_2 + 4H_2O \longrightarrow ClO_4^- + 8H^+ + 7e^-$, −1.34 V; $Cl^- \longrightarrow \frac{1}{2}Cl_2 + e^-$, −1.3583 V; $Cl^- + 3H_2O \longrightarrow ClO_3^- + 6H^+ + 6e^-$, −1.45 V; $\frac{1}{2}Cl_2 + 3H_2O \longrightarrow ClO_3^- + 6H^+ + 5e^-$, −1.47 V; $Cl^- + H_2O \longrightarrow HClO + H^+ + 2e^-$, −1.49 V; $Cl^- + 2H_2O \longrightarrow HClO_2 + 3H^+ + 4e^-$, −1.56 V; $\frac{1}{2}Cl_2 + H_2O \longrightarrow HClO + H^+ + e^-$, −1.63 V; $\frac{1}{2}Cl_2 + 2H_2O \longrightarrow HClO_2 + 3H^+ + 3e^-$, −1.67 V; $ClO_3^- + 2OH^- \longrightarrow ClO_4^- + H_2O + 2e^-$, −0.17 V; $ClO_2^- + 2OH^- \longrightarrow ClO_3^- + H_2O + 2e^-$, −0.35 V; $ClO^- + 2OH^- \longrightarrow ClO_2^- + H_2O + 2e^-$, −0.59 V; $Cl^- + 6OH^- \longrightarrow ClO_3^- + 3H_2O + 6e^-$, −0.62 V; $Cl^- + 4OH^- \longrightarrow ClO_2^- + 2H_2O + 4e^-$, −0.76 V; $Cl^- + 2OH^- \longrightarrow ClO^- + H_2O + 2e^-$, −0.94 V; $ClO_2^- \longrightarrow ClO_2 + e^-$, −1.15 V.

Production

Most of the chlorine produced in the world is manufactured by electrolysis of sodium chloride brine. Two processes are in common use: the mercury cell process and the diaphragm cell process. Since 1969 when international concern about the effect of mercury in the environment became widespread, some mercury cell plants have been shut down. Most expansion of chlorine production has been in diaphragm cell plants. Indeed, all mercury cell plants in Japan must now be converted to diaphragm cell plants. However, it should be noted that existing mercury cell plants operate well within strict standards as to mercury discharge both into the air and into waterways. They produce chlorine (and caustic soda) of the most exacting quality suitable for all uses including food preparation. There is no reason to believe that mercury cell technology is obsolescent in this country or, generally speaking, worldwide.

Technology. In production of chlorine by the diaphragm cell process, salt is dissolved in water and stored as a saturated solution. Chemicals are added to adjust the pH and to precipitate impurities from both the water and the salt. Recycled salt solution is added. The precipitated impurities are removed by settling and by filtration. The purified, saturated brine is then fed to the cell, which typically is a rectangular box. It uses vertical anodes (ruthenium dioxide with perhaps other rare metal oxides deposited on an expanded titanium support). The cathode is perforated metal, which supports the asbestos diaphragm. This is vacuum deposited in a separate operation. The diaphragm serves to separate the anolyte (the feed brine) from the catholyte (brine containing caustic soda). Chlorine is evolved at the anode. It is collected under vacuum, washed with water to cool it, dried with concentrated sulfuric acid, and further scrubbed, if necessary. It is then compressed and sent to process as a gas or liquefied and sent to storage for transfer to shipping containers and, ultimately, shipment to consumers.

A cell of this type is called a monopolar cell. In a cell bank, several cells have their negative electrodes and their positive electrodes connected by means of external bus bars. Some companies use a bipolar cell in which the electrodes are internally connected. This results in a configuration like a plate and frame filter press.

The latest development in cell technology is the so-called membrane cell. This uses a cation exchange membrane in place of an asbestos diaphragm. It permits the passage of sodium ions into the catholyte but effectively excludes chloride ions. Thus the concept permits the production of high-purity, high-concentration sodium hydroxide directly. The chlorine side of the cell is identical to existing technology. Research in membrane cells is proceeding at a rapid rate. Some companies are known to be operating this process commercially, but as of 1981 not all problems have been solved.

In the mercury cell process chlorine is liberated from a brine solution at the anodes which are, today, typically metal anodes (Dimensionally Stable Anodes or DSA). Collection and processing of the chlorine is similar to the techniques employed when diaphragm cells are used. However, the cathode is a flowing bed of mercury. When sodium is released by electrolysis it is immediately amalgamated with the mercury. The mercury amalgam is then decomposed in a separate cell to form sodium hydroxide and the mercury is returned for reuse.

Uses

The principal use of chlorine is in the production of organic compounds. Of these the production of PVC (polyvinylchloride) is probably the single largest consumer although chlorinated solvents as a class account for larger tonnage. See also **Chlorinated Organics**; and **Polyvinyl Chloride (PVC)**.

In many cases chlorine is used as a route to a final product which contains no chlorine. For instance propylene oxide has traditionally been manufactured by the chlorohydrin process. Modern technology permits abandoning this route in favor of direct oxidation, thus eliminating a need for chlorine.

Large quantities of chlorine are used in bleaching. Pulp bleaching for paper manufacture consumes about 13% of all chlorine produced in the United States. Since none of the chlorine used for this purpose winds up in the finished product, it must all be discharged as chlorides or chlorinated organics or be reprocessed. At the present time there is no proven, wholly satisfactory technique for removing chlorine compounds from pulp mill bleach plant wastes. It is doubtful that existing mills will be converted to a bleaching technique that does not require chlorine, but future mills may be designed to minimize the use of chlorine.

Substantial quantities of chlorine go into household bleaches. It is used also in laundry and other commercial bleaches. It is the active element in most swimming pool sanitizers.

Large quantities of chlorine are used for treating municipal and industrial water supplies and this use will probably continue. However, some concern has been felt that traces of organic compounds in all water supplies react with the chlorine to form chlorinated organics, which are suspected of being carcinogenic. Further the usefulness of chlorination of municipal wastes has been questioned in some quarters in the light of the fact that such treatment adds chlorinated organics to the waterways. See also **Chlorination (Water)**.

Safety and Handling

Although chlorine is a hazardous substance, it can be handled safely. All persons who handle chlorine should be thoroughly trained in its properties, in correct use of safety equipment, and in the operation of all other equipment including containers. The Chlorine Institute, 342 Madison Ave., New York, NY 10017, publishes the *Chlorine Manual* (available from the Institute at nominal cost) which provides useful information on these matters. In addition the Chlorine Institute has designed emergency kits capable of capping off certain types of leaks which can occur in chlorine containers.

There have been several recent studies of the physiologic effects of chlorine. These have considered chlorine both as an occupational exposure and as an environmental pollutant (see references). The National Institute of Occupational Safety and Health study recommended an 0.5 ppm concentration of chlorine in air for any 15-minute sampling period as the maximum permissible ceiling value. This contrasts with the generally accepted value of 1 ppm TLV (time weighted average for an eight hour exposure).

Chlorine is primarily a respiratory irritant. When the concentration in the air is sufficient, chlorine irritates the mucous membranes, the respiratory system, and the skin. It causes irritation of the eyes, coughing, and labored breathing. It may cause vomiting. In extreme cases, the difficulty of

breathing may increase to the point where death can occur from suffocation. Liquid chlorine in contact with the eyes or skin will cause local irritation or severe burns.

Persons who have been overcome by chlorine should be removed to an uncontaminated area, their contaminated clothing should be removed, and they should be kept warm. Medical help should be provided. If breathing appears to have ceased artificial respiration should begin immediately. If breathing is labored, the administration of oxygen may be helpful.

Chlorine Chemistry

Chlorine exhibits in common with the other halogen elements a marked readiness to form singly charged negative ions, as would be expected from the fact that these atoms need only one electron to acquire an inert gas configuration. Thus, chlorine behaves in its normal chemical reactions as an electron acceptor. While there are many compounds in which chlorine has a positive valence, there are no simple compounds of positively charged chlorine (contrast the I^+ of iodine). The positively charged chlorine forms part of a radical, as in combination with oxygen. The electron affinity of chlorine (4.02 eV) is the greatest of all the halogens, and is greater than that of oxygen.

Chlorine reacts readily with hydrogen to form hydrogen chloride, with metals and many non-metals to give chlorides, with metal oxides to give chlorides or oxychlorides, and with many salts of metals to give chlorides. These include the iodides and bromides, whose halogen is displaced by chlorine.

Four isolatable oxides of chlorine are known, Cl_2O, ClO_2, Cl_2O_6 ($\rightleftharpoons 2ClO_3$), and Cl_2O_7. Chlorine(I) oxide, Cl_2O, obtained by passing Cl_2 over mercury(II) oxide and sand, is a gas, bp 2°C, somewhat soluble in H_2O to form hypochlorous acid. The Cl–O–Cl bond angle is 111° and the Cl–O distance 1.71 A. Cl_2O is an active oxidizing agent. Chlorine(II) oxide, ClO, is produced by reaction of Cl_2O with atomic chlorine, or as an intermediate product in the decomposition of the Cl_2O. The ClO then decomposes into chlorine and oxygen. In view of this instability the properties of the compound are not established. Chlorine(IV) oxide, ClO_2, is produced by treatment of sodium chlorate, $NaClO_3$, with mixed HCl, oxalic acid or other mild reducing agent, and H_2SO_4 (and H_2O). Cl(IV) oxide is a greenish yellow gas, having an odd electron in its molecule and is consequently paramagnetic. Electron diffraction studies indicate its structure to be

:Cl: :Ö
:Ö:

with the odd electron in an antibonding orbital. The O–Cl–O bond angle is 116.5° and C–O distance 1.49 Å. It is readily hydrolyzed, but is stable when dry. The mechanism of its hydrolysis is complex, yielding all four of the oxychloric acids, and it is widely used as a heavy-duty oxidizing agent. It reacts with metal hydroxides to give the mixture of chlorate and chlorite, with metal peroxides to give chlorite and oxygen and with metals to give chlorite alone. ClO_2 is photosensitive, decomposing when illuminated at about 8°C, to give some Cl_2O_6, bp 3.5°C. Chlorine hexoxide, Cl_2O_6, has a molecular weight corresponding to the formula $ClO_3{-}ClO_3$. Its vapor pressure in the liquid state is 0.31 mm at 0°C against values of 23.7 for Cl_2O_7, 490 for ClO_2 and 699 mm for Cl_2O. This is consistent with a bi-trigonal-pyramidal structure in which the two pyramids have three oxygen atoms at their base corners, and are joined by the two chlorine atoms at the apices. In contrast, the additional oxygen atom of Cl_2O_7 would separate the two chlorine atoms, preventing close packed structure. Chlorine heptoxide, Cl_2O_7, the anhydride of perchloric acid, is obtained by heating the latter with phosphorus pentoxide, and consists of two chlorine atoms, each bonded to three oxygen atoms, and jointly bonded to the seventh. All of the oxides of chlorine are thermodynamically unstable with respect to decomposition into the elements.

Hypochlorous acid, [CAS: 7790-92-3], HClO, is formed by hydrolysis of chlorine(I) oxide. It is present in aqueous solutions of chlorine because of the equilibrium

$$Cl_2 + 2\ H_2O \rightleftharpoons HClO + H_3O^+ + Cl^-$$

and can be freed by the addition of any substance that combines with the Cl^-, such as mercury(II) oxide, or with the H^+, such as calcium carbonate or other weak bases which do not react with HClO. HClO is a weak acid ($K = 3 \times 10^{-8}$ at 25°C). It reacts with hydrochloric acid to give chlorine and H_2O. On warming or irradiation it undergoes this reaction as well as two other decompositions, i.e., to oxygen, H^+ and Cl^-, and to ClO_3^- and H^+. The presence of oxygen favors the last reaction. HClO and its salts are strong oxidizing agents, oxidizing iodine and bromine to iodates and bromates. Covalent hypochlorites are known, such as the alkyl esters, ROCl. In common with other esters of oxidizing acids, these are unstable if R is a primary or secondary alkyl group. However, *t*-butyl hypochlorite is quite stable. Reduction of chlorine dioxide, ClO_2, with hydrogen peroxide, yields oxygen and chlorous acid, $HClO_2$, which exists only in solution. It is stronger than hypochlorous acid ($K = 1.01 \times 10^{-2}$ at 23°C). It is also a strong oxidizing agent and its sodium salt is widely used for this purpose, generally as a source of ClO_2.

Chloric acid, [CAS: 7790-93-4], $HClO_3{\bullet}7H_2O$, is readily prepared by passing chlorine into hot caustic solutions, since these conditions favor the formation of chlorate. Chloric acid is a more active oxidizing agent than HClO, reacting explosively with organic matter. Its alkali salts undergo on heating two modes of decomposition, one (catalyzed, e.g., by manganese dioxide) into the chloride and oxygen, and the other (uncatalyzed) into the chloride and perchlorate.

Perchloric acid, [CAS: 7601-90-3], $HClO_4$, is obtained in anhydrous form from perchlorates by H_2SO_4 distillation, or from ammonium perchlorate by aqua regia distillation. Perchlorates are also obtained by electrolysis of chlorides or chlorates. Perchloric acid is explosive unless properly handled; it is of course a powerful oxidizing agent, but has a higher activation energy than the lower acids.

The chlorides range in character from ionic to covalent compounds, many of them having bonds of intermediate character. There are also a number of interhalogen compounds containing chlorine. Those of iodine and bromine are discussed under those entries. With fluorine, chlorine forms ClF, chlorine monofluoride, which is also obtained (along with ClF_3), when mixtures of the elements are subjected to spark discharge. It may also be obtained by heating a mixture of chlorine and chlorine trifluoride. It is a reactive gas, bp −100.8°C, and with its bond having 20–30% ionic character. Chlorine trifluoride, ClF_3, is also obtained from the elements or from chlorine monofluoride and fluorine, by varying the conditions. It is a gas, bp of liquid 11.3°C, and is a more powerful fluorinating agent than the monofluoride. Present views on its structure suggest a trigonal bi-pyramid having chlorine in the center, a fluorine atom at each apex and the third fluorine and two nonbonding pairs of electrons in the three equatorial positions, giving a T-shaped molecule. ClF_3 reacts with all elements except the noble gases, nitrogen, chromium, and certain noble metals, although some metals (e.g., copper) require elevated temperature. It does not react with oxides or salts as readily as fluorine, but nevertheless ignites such materials as asbestos.

Chlorine Products Used in Food Industry

Chlorine compounds are used effectively to sanitize food-processing equipment and food containers, for washing and conveying raw food products, and for cooling heat-sterilized cans of foods. The use of chlorinated-water sprays at selected locations in a plant reduces or prevents accumulation of microorganisms and off-odors. For sanitizing equipment, solutions of 100–200 micrograms of hypochlorite per milliliter usually are held in or circulated through equipment for at least two minutes. In addition to hypochlorite, chlorinated trisodium phosphates and chloramine compounds have antimicrobial properties. The effectiveness of chlorine-type sanitizers is dependent upon pH, temperature, exposure time, types of organisms, presence of organic matter, and concentration of compound used. Biocidal activity of free-available chlorine compounds is greater if the presence of organic matter is minimized. Further information is given in the Foregoing (1983) reference.

CHLORINITY. A measure of the chloride content of seawater. Originally, chlorinity was defined as the weight of chlorine in grams per kilogram of seawater after the bromides and iodides had been replaced by chlorides. To make the definition independent of atomic weights, chlorinity is now defined as 0.3285233 times the weight of silver equivalent to all the halides.

CHLORITE. Chlorite is a ubiquitous mineral usually a product of secondary origin from the alteration of silicates containing aluminum, ferrous iron, and magnesium. Pyroxenes, amphiboles, biotite garnet, and idocrase within rocks that have undergone metamorphism are common source minerals for chlorite. Distinct crystals are extremely rare; more often found as foliated masses or fine scaly aggregates. Color includes various shades of green. Hardness of 2–2.5, and specific gravity of 2.6–2.9, with vitreous to pearly luster. Individual folia characterized by flexible, not elastic property. A general formula is $(Mg, Fe^{2+}, Fe^{3+}, Mn)_6 AlSi_3O_{10}(OH)_8$.

CHLORITOID. A mineral that occurs as tabular crystals, probably triclinic, foliated masses or scattered scales and plates of a greenish-gray to greenish-black color. It is characteristic of the less intensely altered metamorphic rocks such as phyllites and quartzites. Chemically it is a hydrous iron-aluminum silicate, $Fe_2Al_4Si_2O_{10}(OH)_4$. Ottrelite contains some manganese as well. Chloritoid was originally noted as from the Ural Mountains and named for its greenish color from the Greek word meaning green. Ottrelite was named from Ottrez in Luxemburg.

CHLOROFLUOROCARBONS (CFC). A family of compounds of chlorine, fluorine, and carbon, entirely of industrial origin. CFCs include refrigerants, propellants for spray cans (this usage is banned in the U.S., although some other countries permit it) and for blowing plastic-foam insulation, styrofoam packaging, and solvents for cleaning electronic circuit boards. The compounds' lifetimes vary over a wide range, exceeding 100 years in some cases.

CFCs' ability to destroy stratospheric ozone through catalytic cycles is contributing to the depletion of ozone worldwide. Because CFCs are such stable molecules, they do not react easily with other chemicals in the lower atmosphere. One of the few forces that can break up CFC molecules is ultraviolet radiation, however the ozone layer protects the CFCs from ultraviolet radiation in the lower atmosphere. CFC molecules are then able to migrate intact into the stratosphere, where the molecules are bombarded by ultraviolet rays, causing the CFCs to break up and release their chlorine atoms. The released chlorine atoms participate in ozone destruction. A single atom of chlorine is able to destroy ozone molecules over and over again.

International attention to CFCs resulted in a meeting of diplomats from around the world in Montreal in 1987. They forged a treaty that called for drastic reductions in the production of CFCs. In 1990, diplomats met in London and voted to strengthen the Montreal Protocol significantly by calling for a complete elimination of CFCs by the year 2000.

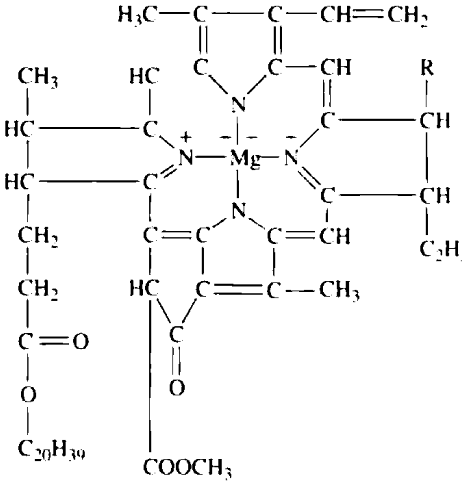
CHLOROPHYLLS. A group of closely related green pigments occurring in leaves, bacteria, and organisms capable of photosynthesis. The major chlorophylls in land plants are designated *a* and *b*. Chlorophyll *c* occurs in certain marine organisms. Because of the overwhelming percentage of the total photosynthesis which is performed by marine organisms, it is possible that chlorophyll *c* is equivalent in importance to chlorophyll *b*. Chlorophyll *a* is several times as abundant as chlorophyll *b*. See also **Photosynthesis**.

The canonical form for chlorophyll *a* is R = CH_3 when substituted in the following formula. For chlorophyll *b*, R = CHO. These structures have been established by a long series of degradation studies mainly by R. Willstätter, Hans Fischer and their collaborators and by synthetic studies by Fischer.



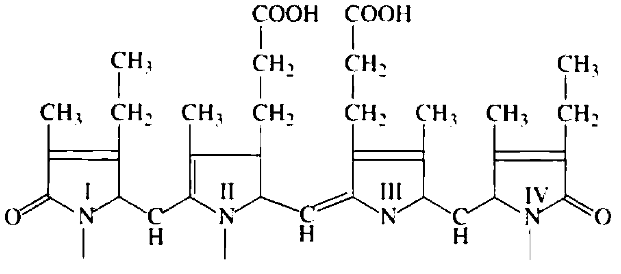
The biological significance of the chlorophylls stems from their role in photosynthesis, the process by which plants fix the sun's energy in the form of organic matter. This process corresponds to the reversal of the combustion of hydrogen. The oxygen liberated is set free in the air. Under special conditions, some organisms are also capable of liberating the hydrogen, but usually this is used for chemical reductions in the plant. Atmospheric carbon dioxide is fixed enzymatically and is thus used as the source of the carbon in the synthetic process, but is not reduced directly. The path of the carbon from carbon dioxide in photosynthesis has been elucidated largely by the studies of Calvin and his collaborators. See references.

While it is known that most of the energy fixed in photosynthesis is absorbed originally by the chlorophylls, the exact reactions which they undergo to initiate the process of reduction are not fully understood. The photosynthetic sequence requires a high degree of organization within the plant cells where it occurs, and destruction of the organization of the chloroplasts by processes like grinding is sufficient to bring photosynthesis to a stop, even when the chlorophyll and the soluble enzymes participating in the process are still presumably intact.

Chlorophyll derivatives with the phytyl group intact are oil soluble and form a series of green dyes used in the coloring of oils and waxes. The chlorophyll soaps, resulting from combined saponification and cleavage of the isocyclic ring, form "water soluble" dyes useful in the coloring of soaps and similar products. Both the medical and cosmetic literature are replete with claims of therapeutic or physiological activity of "chlorophyll." The substances utilized in this work range from partially purified chloroplasts to mixtures of materials that have undergone deep-seated chemical alteration. Some of the types of activity claimed can be shown to be due to incidental impurities. The field for investigation of the action of pure chemical individuals produced by the action of various reagents on chlorophyll or its derivatives is largely unexplored. It is known, however, that neither chlorophyll nor hemoglobin in the diet is utilized by the body in the formation of the physiologically active pyrrole pigments. These are derived, instead, from such simple building blocks as glycine and acetate ion. Only the iron in dietary blood pigment can be utilized by the body.

The work of Granick has shown that, in the physiological processes of plants, chlorophyll is formed from protoporphyrin, which can be obtained in the laboratory by the removal of iron from hemin. The pathways to heme and to chlorophyll diverge at protoporphyrin. To form heme, an organism introduces iron into protoporphyrin. To form chlorophyll from protoporphyrin, an oxidation, a reduction, a ring closure and esterifications are performed and the magnesium is introduced. The end product of the enzymatic synthetic chain is presumably protochlorophyll, the magnesium derivative of the porphyrin corresponding in structure to chlorophyll. The addition of the two hydrogens necessary to convert protochlorophyll to chlorophyll is accomplished under the influence of light.

Phytochrome is a blue-green protein that occurs in minute quantities in plant tissues. Phytochrome pigment is a photoreceptor for photomorphogenetic and photoperiodic responses in plants, and is found in many higher plants. It has been detected both in monocotyledonous plants, such as oats, barley, maize (corn), and at least one aquatic plant. It also occurs in dicotyledonous plants, such as sunflower, beans, peas, parsnip, soybean, lettuce, and radish. It is present in the aerial parts of plants (leaves, stems, buds, and inflorescences), such as in cauliflower. Phytochrome also occurs in some roots and in bryophytes, such as red algae and green algae. The structure of phytochrome is shown below.



Historically, lettuce seeds and cocklebur were the first two plants in which phytochrome was detected. Before isolation, the existence of phytochrome as a specific pigment was implied by physiological work with red and far-red light. The effect of red light (640–670 nm), which promotes germination in lettuce seeds, is reversible by far-red (710–740 nm). Thus, far-red radiation nullifies the promoting effect of the red light. It had been noted as early as 1935 that red light stimulated germination of lettuce seeds and that light of somewhat longer wavelengths inhibited germination. This knowledge was not elaborated further until 1952, when more exacting laboratory experiments were conducted.

CHOLEIC ACIDS. See **Bile**.

CHOLESTEROL. [CAS: 57-88-5]. Also known as cholesterin or 5-cholesten-3-betaol, cholesterol is the most common animal sterol, a monohydric secondary alcohol of the cyclopentenophenanthrene (4-ring fused) system containing one double bond. It occurs in part as the free sterol and in part esterified with higher fatty acids as a lipid in the human blood system. The primary precursor in biosynthesis appears to be acetic acid or sodium acetate. Cholesterol itself in the animal system is the precursor of bile acids, steroid hormones, and provitamin D_3. Cholesterol is a white, or faintly yellow, almost odorless substance and may take the form of pearly granules or crystals. The substance is affected by light; mp 148.5°C; bp 360°C, but tends to decompose at lower temperatures. Specific gravity 1.067 (20/4°C); insoluble in water; slightly soluble in alcohol; soluble in fat solvents, vegetable oils, and in aqueous solutions of bile salts. Cholesterol occurs in egg yolk, liver, kidneys, saturated fats and oils. In addition to its importance in medicine and biology in general, cholesterol is used as an emulsifying agent in cosmetic and pharmaceutical products. It is the source of estradiol.

Research over the years has shown that cholesterol is carried in the bloodstream in complexes with other lipids and proteins. Based upon their density, there are four classes of lipoproteins; the chylomicrons; the VLDLs (very low density); the LDLs (low density); and the HDLs (high density). It is estimated that about 80% of the total blood cholesterol is carried by the LDLs. Most of the remainder is carried by the HDLs. Large quantities of triglycerides, but very little cholesterol, are carried by the chylomicrons and VLDLs.

As early as 1951, researchers at Cornell University Medical College observed that in males with coronary heart disease, the HDL concentrations were low. There were several confirmations of this during the 1950s and 1960s. However, for many years, the principal criteria in connection with heart attack and stroke with relation to cholesterol was considered to be total cholesterol and LDL levels, with little attention given to the HDLs. It was not until 1975 researchers at the Royal Infirmary, Edinburgh, Scotland, reported an inverse correlation between blood concentration of HDLs and total body cholesterol. Miller hypothesized that HDLs may lessen body cholesterol by facilitating its excretion. Epidemiological studies were made shortly thereafter on Japanese-Hawaiian males, Israeli males, and black sharecroppers in Georgia. These studies showed that risk of heart attack increases as blood HDL level decreases. The average value for HDL levels in human males is 45 milligrams per deciliter (55 milligrams for females). The generally higher level of HDLs in females may partially account for their lower heart attack rates. For both sexes, it has been estimated that a 5 milligram drop in the aforementioned HDL levels may increase the risk of heart attack by about 25%.

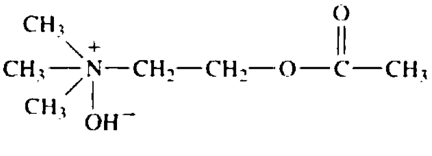
CHOLESTERIC LIQUID CRYSTALS. See **Liquid Crystals**.

CHOLIC ACID. See **Bile**.

CHOLINE AND CHOLINESTERASE. An enzyme (acetylcholinesterase) is specific for the hydrolysis of acetylcholine to acetic acid and choline in the animal body. It is found in the brain, nerve cells and red blood cells and is important in the mechanism of nerve action. Acetylcholine was first synthesized in 1867. It consists of a combination of choline and acetic acid in an ester linkage. The component parts of the acetylcholine molecule are both normal constituents of the animal body. Acetylcholine has the structure:



Acetylcholine assumed no importance to biologists until 1899 when Hunt identified the presence of choline in extracts of the adrenal glands and suggested that some derivative of choline was capable of causing a fall in blood pressure. This stimulated interest in studying the physiological effects of various choline derivatives and, in 1906, Hunt and Taveau found that acetylcholine was 100,000 times more effective than choline in causing a fall in blood pressure. Shortly thereafter, acetylcholine was identified in extracts of ergot, a fungus that grows on rye and other cereal grains. The first real proof of the role of acetylcholine in transmitting the effects of nerve stimulation did not come until 1921. The acetylcholine-cholinesterase system has served as the basis for the development of a number of drugs needed to alter the activity of the autonomic nervous system in certain disease states. Inhibitors of cholinesterase are used in insecticides. Parathion and malathion are examples of organic phosphate cholinesterase inhibitors that are effective for this purpose. Cholinesterase inhibitors are capable of producing poisoning and death in humans and domestic animals by the same mechanism.

Choline is an essential metabolic substance for building and maintaining cell structure. Choline is usually described along with B complex vitamins, although it is essentially a structural component of tissue rather than a metabolic catalyst. Choline is a part of the structure of phospholipids and acetylcholine.

Choline participates in normal fat metabolism and interrelates with methionine in a biochemical manipulation referred to as transmethylation. Choline, when in adequate quantity, can replace the essential amino acid methionine when the latter is in limited quantity; or the reverse may occur, that is, methionine can be dismantled to replace choline. Choline deficiencies result in numerous degradative physiologic changes in livestock. The usual dietary supplements are choline bitartrate and choline chloride.

Human Disease Implications

In Alzheimer's disease, neurochemical studies of cerebral cortex have shown specific reduction in choline acetyltransferase (CAT), the enzyme required for synthesis of the neurotransmitter acetylcholine (ACh). The degree of reduction of ACh correlates with the severity of dementia. This finding may reflect loss of the neurons in the substantia innominata of the basal forebrain that form the cholinergic projection to the hippocampus and cerebral cortex. Degeneration of the terminals of these neurons may initiate the formation of amyloid plaques.

In Huntington's disease, there is a progressive degenerative disease of the basal ganglia that is inherited as an autosomal dominant trait. In terms of the pathologic findings of this disease, there is a marked atrophy of the corpus striatum and depletion of interneurons in the striatum. The major neurochemical abnormalities in the basal ganglia are reduction of GABA (gamma-aminobutyric acid) and its synthesizing enzyme, glutamic acid decarboxylase; reduction of CAT; and reduction of postsynaptic receptors for these neurotransmitters.

CHONDRODITE. Chondrodite, a magnesium fluosilicate mineral $Mg_5(SiO_4)_2(F,OH)_2$, crystallizing in the monoclinic system is a product of metasomatic origin in metamorphosed dolomitic limestones. Crystals are uncommon, usually occurring as discrete grains within the limestone, of light yellow to red color. Vitreous luster, translucent, with hardness of 6–6.5, and specific gravity of 3.1–3.2. This mineral is the most prominent member of minerals falling within the chondrodite group. These are norbergite, chondrodite, humite and clinohumite. Individual members of this group require optical evaluation for positive identification.

Noteworthy world occurrences include Mt. Somma, Italy; Pargas, Finland; Kafveltorp, Sweden; and in the United States at Brewster, and Warwick and Orange Counties, in New York.

CHROMATIN. This term was given by Flemming to denote that substance in cell nuclei which, in the usual treatment with nuclear dyes, takes up the color. In nondividing nuclei, chromatin is distributed throughout the entire nucleus (euchromatin), but in nuclei undergoing cell division, chromatin is confined to the chromosomes (heterochromatin). In Flemming's time, the chemistry of the nucleus was entirely unknown. Even in view of recent knowledge, it is not fully understood as to what particular substance(s) have the special affinity for the dyes. In isolation of chromatin from pea embryos by differential centrifugation and purified by sucrose gradient centrifugation, the composition of chromatin was found to be deoxyribonucleic acid (DNA), 31%; ribonucleic acid (RNA), 17.5%; histone protein, 33%; and the remainder, nonhistone protein.

CHROMATOGRAPHY. An instrumental procedure based on physical absorption principles for separating various components from a mixture of chemical substances. In its broad interpretation, chromatography is a combination of separation, identification, and quantitative measurements. As of the late 1980s, chromatography is a giant among the numerous techniques for chemical analysis; high-performance liquid chromatography (HPLC) and gas chromatography are two of the leaders in the field of separation science. Modern chromatography plays three major roles in science and industry, separately or in combination. (1) As a means for identifying and quantifying the ingredients of a mixture of chemical substances—*as used in the laboratory* for quality control, for example, detecting impurities in chemicals, pharmaceuticals, foodstuffs, etc.; assisting researchers: in the study of biochemistry; measuring and identifying unsafe materials in the environment; and as an aid in forensic science, among scores of other specific applications. (2) As a means for *separating materials* where separation (not analysis per se) is the principal target. In this manner, specific chemicals, not easily obtainable in other ways, can be isolated and then, in turn, used to participate in the synthesis of other chemicals. Simply stated, chromatographic separations yield raw materials, notably for research in organic syntheses. (3) As an important, widely acclaimed process—stream chemical composition controller. For such industrial applications, a chromatograph is a complex transducer which not only puts out a signal that identifies the types and amounts of a given substance, but also first separates the target substances from a stream that may contain numerous other substances, some of which may be closely related physically (close boiling points, specific gravities, etc.) or chemically. The transducer output can be used for off-line quality control, or on-line so that the chromatograph becomes part of the total control loop.

In laboratory chemical analysis, where only minute samples may be available, only milligrams of material or less are required for some forms of chromatography. Chromatography is widely used in pollution control technology.

Beginnings of Chromatography

In 1906, a Russian botanist, Mikhail Tswett, first used the chromatographic principle to separate plant pigments. Tswett filled a vertical glass tube with an adsorbent. As a sample of the pigments was washed through the tube with a solvent, a series of colored *adsorption bands* was produced, in essence forming a colorgraphic display. Thus, the apt term, *chromatography*, but no longer appropriate because frequently materials separated are colorless and the adsorption spectra are presented by way of electronic instrumentation.

Thin-Layer Chromatography (TLC). This format represented the first widespread employment of chromatography as an analytical tool. Surprisingly, even though decades old, the method (refined and improved) still persists and can be found in some pharmaceutical laboratories for drug testing, by medical laboratories, and in the chemical industry. TLC is a simple, low-cost technique. TLC, of course, has been replaced for a host of applications by the more sophisticated chromatographic apparatus available today that offers numerous advantages, disallowing cost, such as the conservation of laboratory workers' time, better performance, and speed. See Fig. 1. Highly engineered, sophisticated chromatographic apparatus did not become easily available until the 1950s and since that time has continually expanded apace. All of the advantages of computer and display technology have been applied to chromatography today.

Fundamentals of Chromatography

In chromatography, the *carrier* or *moving phase* may be a gas, liquid, or supercritical fluid. The separation is effected by distributing the mixture

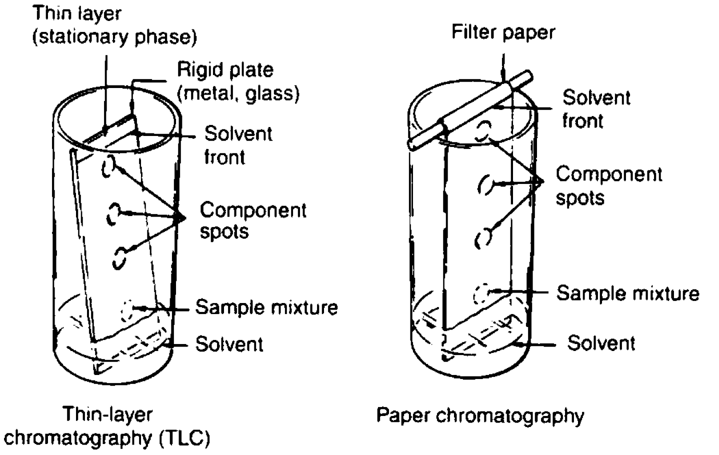

Fig. 1. Thin-layer chromatography (TLC), shown at left, and paper chromatography, shown at right, are similar in apparatus and technique. The sorbent bed is in the form of a thin layer or thin sheet of paper of a finely divided sorbent material. In TLC, the sorbent material is deposited on a supporting metal, glass, or plastic plate. The sample is spotted near one end of the bed, which is then brought in contact with a source of solvent. As the solvent moves through the bed by capillary action, the sample components are washed through the bed at different rates and are separated into spots of pure compound, which can be recovered after the solvent is allowed to evaporate. Spots can be detected visually if the substances are colored, or with ultraviolet light if they are fluorescent. Components can be reacted to give colored or fluorescent derivatives by spraying with reagents. Conventional quantitative determinations can be made after recovery of the substance of interest with solvent, or roughly estimated by comparison with spots produced with known quantities and concentrations. Recording densitometers may be used for quantitative measurements *in situ*. The paper may be drawn automatically past a slit in front of a photocell, and the transmitted or reflected light recorded. Radioactive compounds are detected by contact exposure with x-ray film, which after development can be measured with a densitometer. Quantitative measurements *in situ* can be made with apparatus similar to a densitometer in which a radiation detector is used in place of the photocell

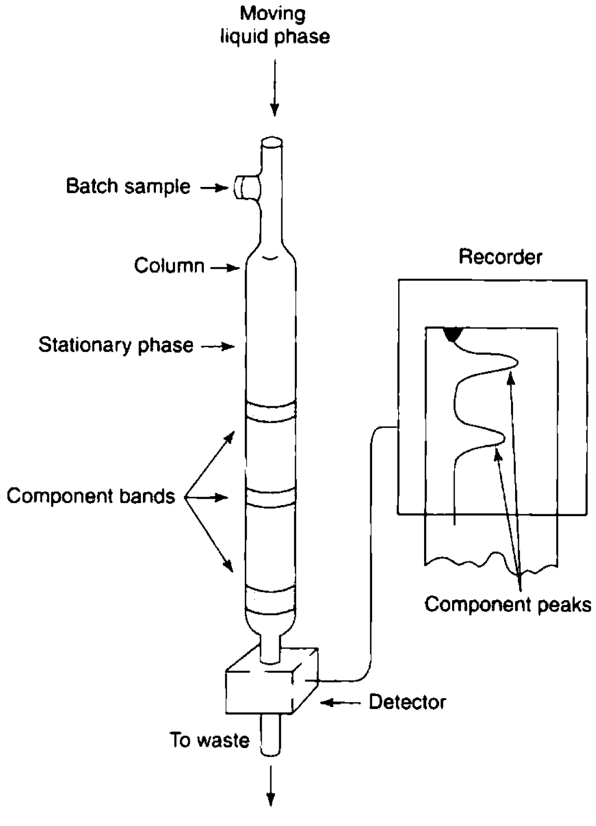

Fig. 2. Schematic of liquid-column chromatograph

between the fixed, or stationary, phase in a column and the carrier. The stationary phase may be a solid or a liquid-coated solid packed into the column, or it may be attached to the walls of a capillary. Liquid samples that can be vaporized can be separated with a gas carrier. High-boiling liquids and unstable compounds can be separated with a liquid carrier. Some materials can be handled better in a supercritical fluid and may separate faster. This latter approach, however, requires much more skill, is expensive, and thus, at present, is limited. A liquid-column is shown in Fig. 2.

Components of the sample are retained in the column for different lengths of time due to adsorption-desorption, solution-dissolution, chemical affinity, size exclusion, and other mechanisms of varying nature. Various components are continually washed from one part of the stationary phase and recaptured by another by the moving phase. Different components elute in groups from the column with respect to time from injection. Dispersion in the system causes the bands of components to emerge with a Gaussian distribution or a distorted peak-shaped curve. A simplified diagram of the process is shown in Fig. 3. It becomes immediately obvious that chromatography not only is an analytical method, but also a separation method for substances that are difficult to separate by more conventional means.

Flow injection techniques are utilized to prepare samples, not only for chromatography, but also for numerous other analytical sensors that use thermal conductivity, flame ionization, and spectrometric principles. As important as these detectors may be, they must not overshadow the critical need to obtain a reliable sample. Flow injection analysis (FIA) is a technique for introducing a discrete sample into a flowing carrier, passing it through a conditioning "operator" system, measuring the concentration of one or more components in the modified sample, and displaying the results. Many different types of operators may be used, but component separation generally is associated with column chromatography. Flow injection is a procedure that was originally developed to automate wet lab test methods, but now has become a universal sample-preparation technique.

Advancements in Chromatography

When it first appeared as an industrial tool, the chromatograph was a single box with all of the components packaged together. Then it was considered

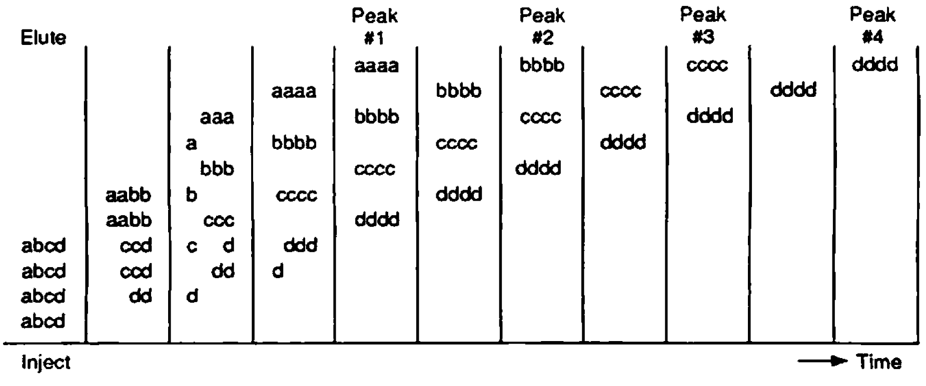

Fig. 3. Chromatographic separation process showing movement through column with time

an analyzer unto itself and required a separate sample conditioning system. Process engineers concerned with analysis began to develop techniques to modify the laboratory practice of using a single column. Multiple columns connected by switching valves were applied to backflush, foreflush, and cut components from the normal sequential elution scheme.

Some years later, laboratory chemists started to apply such techniques to specific industrial and process applications. Remote discrete sampling was developed in 1978. This allowed one to inject the small quantity of sample into a capillary hundreds of feet (tens of meters) from the "analyzer" and transport it to the column as a packet. The transfer line was viewed as a long oven and no longer constrained to a single box. Components of the original box now could be expanded into three-dimensional space by using several boxes with connecting capillaries. The programmer, which controls the system operation, became a main feature of the system.

In more recent years the capillary column, which now plays a major role in process applications, appeared. These columns produce significantly higher resolution of components and, in many cases, are faster and easier to use. Outer-surface-clad fused silica columns have been developed which are less fragile than those made of laboratory glass. Inert inner-surface metal capillary columns with cross-linked and chemically bound stationary phases also are available. The practice of technicians making their own columns has vanished into antiquity. Because there are numerous column types, details cannot be provided here. However, there are several buyers' guides available for the asking. The literature also is rich in terms of such factors as specific column selection, sample introduction techniques, analysis detectors, and overall performance qualities of a chromatographic system.

Control of chromatographic system operation has progressed from electromechanical and electro-optical devices to fully digital electronic components, which also incorporated computational capability. Microprocessors, personal computers, mini- and mainframe computers, as well as programmable logic controllers can be effectively integrated into chromatographic systems. However, for simple operations one still may use cam and digital timers.

A major improvement came with digital electronics, which allows high-resolution timing (0.1 second) and exact repeatability. Precise timing of sequential events is essential to multidimensional sample preparation utilizing column separation operators and switching valves.

Electronics for controlling instrument-operating parameters, such as temperature and pressure, have contributed to more stable operation. This produces better repeatability of the system for multiple cycles leading to higher precision of component isolation. Advantage of improved measurement devices can be realized once the sample preparation function is resolved. Computer hardware and software provide expanded capability for signal processing and data manipulation. Stable and precise sample preparation and measurement systems allow accurate analytical information provided that adequate maintenance and calibration practices are applied.

The wide range of measurement devices currently available makes almost any process chemical analysis possible. Column chromatographic techniques make interference-free determinations a reality.

Gas Chromatography

Almost any organic or inorganic compound that can be vaporized can be separated and analyzed with a gas chromatograph. As shown in Fig. 4, the minimum requirements for a system include: (1) a column that contains the substrate or stationary phase; (2) a supply of inert carrier gas (moving phase), which is continually passed through the columns; (3) a means for maintaining pressure and flow constant; (4) a means of admitting or injecting the sample into the carrier gas stream; (5) a detector which senses the sample components as they elute; and (6) a recorder. The carrier gas may be any gas that does not react with the sample or adversely affect the detector. Helium, hydrogen, nitrogen, and argon are most commonly used.

Microprocessor-Based Automation. Automatic systems now are used to carry out functions previously performed manually by the operator. These systems may take many forms: (1) integral to and dedicated to a single chromatograph and (2) as a separate unit which controls one or several chromatographs. The latter are also available for upgrading older manually operated chromatographs to provide automated data reduction and output.

Systems are equipped with read-only memory (ROM) for the operating system and random-access memory (RAM) for storage of user-specific

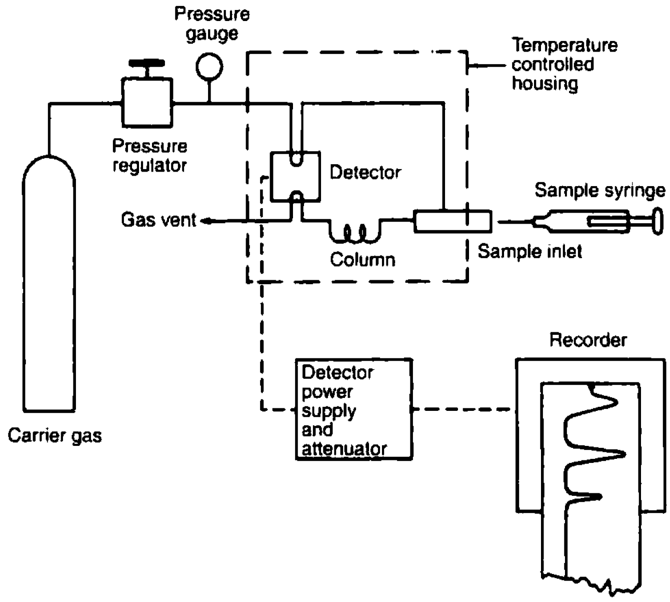

Fig. 4. Minimum requirements for a gas chromatographic system include: (1) a column which contains the substrate or stationary phase, (2) a supply of inert carrier gas (moving phase) which is continually passed through the columns, (3) a means for maintaining pressure and flow constant, (4) a means of admitting or injecting the sample into the carrier gas stream, (5) a detector which senses the sample components as they elute, and (6) a display (recorder). The carrier gas may be any gas that does not react with the sample or adversely affect the detector. Helium, hydrogen, nitrogen, and argon are often used

methods, operating instructions, and analytical data acquisition and manipulation.

Depending on user requirements, one or more of the following functions can be provided:

1. Individual temperature control and indication of column, ovens, detectors, and sample inlets
2. Dynamic control of programmed temperature profiles, starting and ending temperatures, rate of temperature increase with one or more time-controlled segments of isothermal temperature, and cooling-down cycle.
3. Automatic integration of peak areas or peak height measurements, with a choice of several calibration methods for calibration of results.
4. Raw data storage with post-run calculation and manipulation of data for optimizing variables and methods development.
5. Integral printer-plotter for hard copy of chromatograms and analytical results.
6. Keyboard for input of analytical parameters and operator-selected variables.
7. Video terminal for display of chromatograms and analytical results.
8. Cassette or floppy disk extended memory for storage of files, methods, and user-specific applications programs.
9. High-level language for user programming of special calculations such as physical properties and comparison with alarm levels.
10. Serial communications via RS-232 ports with a central computer or other peripheral devices.
11. Timed output control signals to peripheral and ancillary devices such as sample valves, column switching valves, and other external functions which are part of the automated procedure.
12. On-board diagnostics to aid in troubleshooting and isolating and identifying failures.

Chromatograph Data Reduction—Qualitative Analysis. For a given substrate, under given conditions, each compound has a characteristic retention time, which can be used for tentative identification. However, two or more compounds may have the same elution time on a particular column. In such cases the compound may be rerun on a different column with other characteristics to reduce ambiguity. Extensive compilations of individual compound retention times on different substrates are available

for reference. Positive identification can be made only by collecting the compound or transferring it as it elutes directly into another apparatus for analysis by other means, such as infrared or ultraviolet spectroscopy, mass spectrometry, or nuclear magnetic resonance. Commercially available apparatus is available which combines in a single unit both a gas chromatograph and an infrared, ultraviolet, or mass spectrometer for routine separation and identification. The ancillary system may also be microprocessor-based, with an extensive memory for storing libraries of known infrared spectra or fragmentation patterns (in the case of mass spectrometers). Such systems allow microprocessor-controlled comparison and identification of detected compounds.

Quantitative Analysis. This is based on the proportionality of detector response to the amount of component in the elution band. The most widely used measure of detector response is the area under the chromatogram peak. However, the peak height (amplitude of the detector signal at peak maxima) also may be used. Early methods for measuring the peak area included direct measurement on the chart with a planimeter, calculating from the height and width of the peak, and using a ball-and-disk integrator attached directly to the recorder. Electronic integrators have also been used to sense the detector signal directly, or after it is amplified, and to provide a digital printout of the peak area and time of peak maxima.

These methods of quantitation have been largely replaced by micro processor-based data systems. The detector signal is directly coupled to a high-speed analog-to-digital converter which samples it at predetermined rates as high as 40 Hz. The digitized values are stored in memory for subsequent manipulation. Slope sensing algorithms find the beginning and end of peaks, peak maxima, and valley points between incompletely resolved peaks and can differentiate between peaks and the baseline (absence of peaks) to correct the digitized signal for baseline drift. Tangent skimming algorithms can locate and digitize small "rider" peaks on tailing edges of larger peaks.

The microprocessor sums the digitized values for a given peak to obtain the peak area. Results are then calculated by various methods:

1. *Area Percentage, Normalized.* In this method, the area of each peak is determined as a percentage of the total of the areas of all peaks. Results must add up to 100 percent to indicate that all components have been detected.
2. *Concentration by Relative Response Factors, Normalized.* This is similar to area percentage, but each area is corrected by a relative response factor characteristic of a given compound.
3. *Internal Standard.* The results are calculated relative to a standard added to the sample in a known amount. Results are independent of sample size. The internal standard must be a compound not normally present in the sample and well separated from other components in the sample.
4. *Standard Addition.* The sample is analyzed with and without the addition of a known amount of a compound that is also in the sample (spiking). The concentration is calculated from the observed increase in area.
5. *External Standard.* The area of each component is compared to the area of a separately run standard with a known concentration of each component.

Process Gas Chromatography

This is a system for continuous, repetitive, and fully automatic on-line analysis of process streams; it is similar to the laboratory chromatograph in all essential elements of basic technique but different in design and appearance. Factors affecting design include the need (1) to comply with the National Electrical Code for operation in hazardous atmospheres, (2) to automate the procedure, and (3) for ready adaptability to closed-loop process control and communication with process control systems and computers. The demand for maximum reliability and minimum maintenance has emphasized simplicity of hardware and methodology. Emphasis is placed on analyzing for a few rather than a number of components and on minimizing analysis time. These design targets have resulted in the extensive use of multicolumn techniques for rapid separation of selected components, with large portions of the sample being discarded. As shown in Fig. 5 the major components of a microprocessor-based process gas chromatograph system are (1) the analyzer, (2) the data processor, (3) the sample conditioner system, (4) one or more recorders,

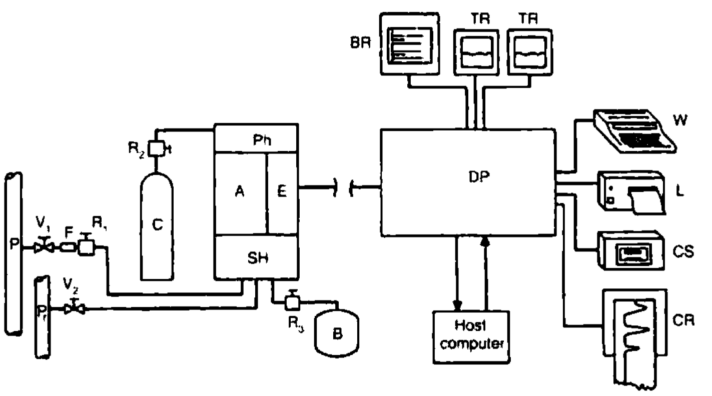

Fig. 5. Basic elements of process gas chromatograph. The vapor sample is continuously withdrawn at a high rate from process line *P*, circulated through sample conditioner *SH*, and returned to lower pressure point *P*, through shutoff valves V_1 and V_2. Particulate matter is removed by filter F_1 and the pressure reduced to a constant low level be regulator R_1. The sample conditioner contains flow control and other conditioning components and a valve for switching to synthetic calibration blend *B* through pressure regulator R_3. A sample slipstream is circulated to the sample valve in analyzer *A*, which also contains columns, detectors, and a temperature-control system. Carrier gas *C* is controlled by regulator R_2 and pneumatics control section *P*. A microprocessor in electronics module *E* stores an analytical program in RAM and controls analyzer functions and data acquisition and reduction. Analytical results are transmitted over a serial link to data processor *DP*, which converts results to an analog signal for presentation to bar graph recorder *BR* and as many as 30 to 40 trend recorders *TR*. Real-time constructed chromatogram is presented for maintenance on recorder *CR*. Serial outputs (RS-232) flow to writer or panel-mounted line printer *L* for data logging and to cassette recorder *CS* for storing applications programs. Results and alarm messages flow to host computer via serial link. An applications program is entered via data processor and downloaded to an analyzer RAM for execution in the analyzer. The processor controls several analyzers

and (5) analog and serial outputs to peripheral devices or process control systems and computers.

Analyzer. This equipment usually is located close to the sampling point, enclosed in a shelter for weather protection. An analyzer is typically designed to comply with NEC Class I, Groups B, C, and D, Division I, requirements for operation in hazardous areas by combination of explosion-proof enclosures, air purging, and intrinsically safe electric circuits. Sections of the analyzer include a controlled temperature compartment (heated air bath) for the columns, sample and column switching valves, and a detector. A pneumatics section for pressure or flow controllers for the carrier gas and other auxiliary gases (such as hydrogen and combustion air for an FID), as well as service air for the heater, electronics purge, and valve actuation. The electronics compartment contains a microprocessor with a central processing unit (CPU) and RAM and ROM for program control, data acquisition and reduction, output, and all communications functions. The RAM is battery-backed to prevent loss of applications programs due to power failure.

In its most usual form, the microprocessor performs these functions:

1. Controls all sequenced analyzer functions, such as sample injection and valve switching, by means of the applications program stored in RAM.
2. Samples and digitizes the detector signal at up to 40 Hz; performs peak area integration or peak height measurement with baseline correction and deconvolution of incompletely resolved peaks.
3. Identifies components by comparing elution times with values stored in memory.
4. Calculates the composition with a choice of several calibration and calculation methods stored in ROM.
5. Controls the sequencing of sample conditioner in multistream systems.
6. Performs automatic calibrations by analyzing calibration standards at user-selected intervals and automatically updating calibration factors.

7. Performs auxiliary calculations such as determining average molecular weight, specific gravity, heating (thermal units) value, or other properties based on the calculated sample composition.
8. Monitors electromechanical sensors in the analyzer and sample conditioner system to detect abnormal conditions: oven temperature out of limits, carrier gas flow failure, sample flow failure, etc.
9. Performs software diagnostics on the detector signal and analytical results to detect abnormal conditions: change in elution time, total peak area out of limits, excessive baseline noise or drift.
10. Communicates with data processor over a serial link to transmit analytical data and calculations and receives new or modified applications programs. A digitized form of the detector signal may also be transmitted for remote reconstruction of a real-time chromatogram.

In addition, the analyzer can accept analog signals from other field-mounted analyzers or sensors such as flowmeters and pressure transducers. The signal can be scaled, digitized, and incorporated into special calculations to determine mass flow, therms per day, reactor yields, and so on.

In alternative forms of these systems, the applications program is stored in the processor: the analyzer microprocessor digitizes only the detector signal and transmits the digitized values to the data processor. Applications program event commands are received in real time from the data processor and converted at the analyzer to electrical and pneumatic signals for sample valve actuation, column switching, sample conditioner control, and so on.

Data Processor. This unit commonly is located near or in the control room in a nonhazardous environment, and as much as 2000 to 3000 feet (610 to 914 meters) from the analyzers. The data processor also has its own microprocessor with a CPU and a complement of ROM and RAM in which the operating system and user-specific applications programs are stored. Communication with the analyzers is by a serial link. In its most usual form, the processor is a special-purpose microprocessor and can control up to six or eight analyzers. In other forms the processor may be a microprocessor-based minicomputer and control as many as 32 analyzers.

The processor has several main functions:

1. Input of applications programs by means of a special-purpose keyboard, with an alphanumeric display and interactive dialogue. Prompting of the operator and screening of the input data ensures the input of all necessary parameters and prevents conflicting data inputs. The program is down-loaded into the analyzer memory and can be recalled for editing and modifications. In some versions, input may be accomplished through an ancillary video terminal with a keyboard and menu-driven operator communications.
2. Receives data from the analyzers and distributes them to the various output devices in analog or digital form as required.
3. Monitors the status of the analyzers and displays alarms and transmits them to peripherals.
4. Provides manual control of all analyzer functions during setup and maintenance and acts as a diagnostic center for troubleshooting and corrective maintenance. A real-time chromatogram is available.

Except for the initial setup and maintenance of the analyzer, all operations, including programming, manual operation, and calibration, take place at the processor location.

In some versions the applications program for all analyzers may be stored in the processor memory instead of the analyzer. Event commands are sent to the analyzer in real time over the serial link and converted to analog commands by the analyzer. Digitized data are received from each analyzer, with all data acquisition and reduction accomplished in the processor.

In yet other versions the processor is part of the analyzer and may be dedicated to, and integral to, a single analyzer at the analyzer location with all analyzer and processor functions described performed locally.

The simplest form of record is a bar graph. The record consists of a series of bars, one for each component, of height proportional to the component concentration. The output for each component is scaled to give a full-scale reading equivalent to a convenient concentration value. Each component may have a different full-scale range. A large number of components in one or many streams may be recorded on the same instrument. Different streams may be identified by the height of a flat-top bar preceding the series of bars for that stream.

Trend outputs consist of a continuous electrical signal [0 to 10 volts or 4 to 20 milli (mA)] from the processor. As many as 30 to 40 such outputs may be available from a single processor. Each output represents the concentration of a particular component in one of the sample streams on a given analyzer scaled to some convenient range. Component identity and scale factors for each output channel are user-assigned from the processor keyboard.

The output value is held constant at the last value until a new value is determined in a subsequent analysis, causing a stepwise change in the record as the signal is updated at the end of each analytical cycle. A separate recorder pen is required for each trend output recorded. Trend outputs may also be used to input analytical data to a process control system. A separate two-wire 4- to 20-mA output line is typically required for each component input.

A real-time chromatogram for any selected analyzer may be obtained at the data processor for setup and maintenance. The chromatogram is received in digital form at a rate of 10 or more data points per second and reconstructed into analog form and scaled at the processor.

Serial output ports (RS-232) are usually provided for serial transmission of data—usually in ASCII code as previously shown in Fig. 5.

Valves. Electrically or pneumatically operated valves are used for the injection of liquid or gas samples and column switching. Rotary, spool-and-O-ring, diaphragm, and sliding-plate valves with from 4 to 12 ports are used. Vaporizing liquid sampling valves mounted through the wall of the analyzer transfer the liquid sample from the cold exterior zone to the heated vaporizing zone within the oven. The sample valve meters a fixed volume of liquid or gas into the column with a repeatability of ±0.25 percent. The sample size may vary from approximately 0.1 mL to 50 mL (with an external sample loop).

Liquid-Column Chromatography

This method is particularly useful for the separation and analysis of high-molecular-weight compounds beyond the range of gas chromatography. It is generally classified according to the stationary phase or to the nature of its interaction with sample components.

1. Liquid-liquid partition chromatography, where the sample components are partitioned between a moving liquid phase and a stationary liquid phase deposited on an inert solid. The two solvent phases must be immiscible. The stationary phase may be a large molecule chemically bonded to the surface of a solid (bonded liquid phase) to prevent loss by solubility in the moving phase. This method can also be subdivided into normal-phase systems, in which the moving phase is less polar than the stationary phase, and reverse-phase systems, in which it is more polar.
2. Liquid-solid or absorption chromatography, in which the sample components are absorbed on the surface of an adsorbent such as silica gel.
3. Ion exchange, in which ionic sample components interact with functional groups on a permeable ionic resin.
4. Exclusion or gel permeation, in which compounds are separated by molecular size into a range of pore sizes in a polymeric gel. This method is useful for measuring the molecular-weight distribution of polymers.

Isocratic elution uses a solvent of constant composition throughout the analysis. Gradient elution is a modification of the technique, in which the solvent is a mixture of two solvents that differ in solvent strength. The composition or ratio of the two is changed during the analysis in accordance with a predetermined program. The change may be continuous, linear or nonlinear, stepwise, or a combination.

Apparatus Required. The need for more efficient columns and faster separations has led to the development of stationary phase packings with particles as small as 2 mm, operating at pressures as high as 10,000 psig (69 MPa), and with solvent flow rates as low as 1 mL/min or less. This has in turn led to the development of detectors with internal volumes of only a few microliters and special fittings and connectors with minimum dead volume to prevent band spreading and loss of resolution. These improvements in apparatus and technique have resulted in an ability to

achieve complex separations with speeds comparable to those of gas chromatography.

The solvent is moved through the system by constant-flow or constant-pressure pumps which are driven mechanically (screw-driven syringe or reciprocating) or by gas pressure with pneumatic amplifiers. For gradient elution two pumps may be synchronized and programmed to provide a controlled, reproducible composition change.

Samples may be introduced by syringe directly into the column through a septum or by means of valves with a fixed volume that has been prefilled with the sample. Valves may be of a rotary, sliding plug, or diaphragm design and of stainless steel and fluoroplastic construction for inertness. Auto samplers are used for unattended injection of samples loaded into vials and sequentially rotated into the injection mechanism.

CHROMITE. An important mineral in the chromite series of multiple oxides. The dominant compound is $FeCr_2O_4$, but most chromite also contains magnesium (Mg) and aluminum (Al). Crystallizes in the isometric system. Hardness, 5.5; specific gravity, 4.5–4.8; color, black. Associated with peridotite and serpentine (metamorphized peridotite). Commercial amounts occur as placer deposits in serpentine areas. In the United States chromite has been mined in Maryland, Pennsylvania, California, Montana, Oregon, Wyoming and North Carolina. Important deposits occur in Quebec, Canada. Valuable deposits occur in Asia Minor, Zimbabwe, New Caledonia, Cuba, India, and the Philippines; also in New South Wales, and in the Ural Mountains associated with platinum.

CHROMIUM. [CAS: 7440-47-3]. Chemical element, symbol Cr, at. no. 24, at. wt. 51.996, periodic table group 6, mp 1837–1877°C, bp 2672°C, density 7.2 g/cm^3. Elemental chromium has a body-centered cubic crystal structure. The metal is silver-white with a slight gray-blue tinge, very hard (9.0 on the Mohs scale), capable of taking a brilliant polish, not appreciably ductile or malleable. The element is not affected by air or H_2O at ordinary temperatures, but when heated above 200°C, chromic oxide Cr_2O_3 is formed. There are four stable isotopes: ^{50}Cr, and ^{52}Cr through ^{54}Cr. Four radioactive isotopes have been identified, all with comparatively short half-lives ^{48}Cr, ^{49}Cr, ^{51}Cr, and ^{55}Cr. The element was first identified by Vauquelin in 1797.

Ionization potential 6.76 eV; second, 16.6 eV. Oxidation potentials $Cr \longrightarrow Cr^{3+} + 3e^-$, 0.71 V; $Cr^{2+} \longrightarrow Cr^{3+} + e^-$, 0.41 V; $2Cr^{3+} + 7H_2O \longrightarrow Cr_2O_7^{2-} + 14H^+ + 6e^-$, 1.33 V; $Cr + 3OH^- \longrightarrow Cr(OH)_3 + 3e^-$, 1.3 V; $Cr + 4OH^- \longrightarrow CrO_2^- + 2H_2O + 3e^-$, 1.2 V; $Cr(OH)_3 + 5OH^- \longrightarrow CrO_4^{2-} + 4H_2O + 3e^-$, 0.12 V.

Other important physical properties of chromium are given under **Chemical Elements**.

Chromium occurs chiefly as chromite (ferrous chromite), $Fe(CrO_2)_2$, in Zimbabwe, the Republic of South Africa, the former U.S.S.R., New Caledonia, India, Philippine Islands, Japan, Turkey, Greece, Cuba, and California. (1) Heating chromite in the electric furnace with carbon yields ferrochrome for alloys, and (2) when chromite is heated with sodium carbonate and nitrate, sodium chromate is formed, which is then extracted with H_2O. This is the substance from which chromium compounds are obtained. See also **Chromite**.

Chromium is used extensively for (1) decorative and wear-resistant electroplating, (2) many important alloys, and (3) the manufacture of numerous chemicals and refractory materials.

Alloys

In constructional steels, chromium imparts hardness by improving hardenability and promoting the formation of carbides. These steels have exceptional wear resistance and are relatively stable at elevated temperatures. In stainless and heat-resisting steels, chromium improves corrosion and heat resistance. As shown in Table 1, stainless steels may be grouped into three principal classes (1) austenitic, (2) martensitic, and (3) ferritic stainless steels. The fundamentals of stainless steels are further described under **Iron Metals, Alloys, and Steels**. Stainless steels, as a group of major ferrous alloys, are characterized by their high degree of resistance to chemical attack. They possess a property commonly referred to as passivity, a property eminently displayed by elemental chromium. This property is manifested in steels when the chromium content exceeds about 11%. A very marked improvement in corrosion and heat resistance is achieved when chromium is added to this or a greater extent to low-carbon steels. The addition of nickel, along with chromium, enhances these properties even more. Although a steel that contains 12% chromium will stain, it will not undergo progressive rusting in normal atmospheres. When the chromium content is increased to 18%, staining will not occur in normal atmospheres, but may occur to a limited extent in particularly bad industrial environments. However, the addition of 8% nickel, along with the 18% chromium, will make the steel stain-resistant in all but the most rigorous industrial atmospheres. Additional resistance to corrosion and heat resistance may be obtained by the presence of molybdenum and other elements in smaller quantities.

An example of the effect of chromium content on the corrosion resistance of steel is demonstrated as follows:

A low-carbon steel placed in boiling 65% HNO_3 for one month:

TABLE 1. REPRESENTATIVE STAINLESS STEELS

Type	Composition and characteristics
	Austenitic Stainless Steels
302	Basic alloy of the group: Cr, 17-19%; Ni, 6-8%
302B	Silicon (2-3%) added to increase scaling resistance
303	Sulfur (0.02-0.05%) added to improve machinability
303Se	Selenium (0.15%) added to improve machinability
304L	Extra low carbon for improved weldability
304	Lower carbon content to improve weldability and inhibit carbide formation: Cr, 18-20%; Ni, 10-12%
305	Nickel increased to lower work-hardening: Cr, 17-19%; Ni, 10-13%
308	Chromium and nickel increased to increase corrosion and scaling resistance: Cr, 19-21%; Ni, 10-12%
309S	Lower carbon content (0.08% max) for improved weldability
314	Silicon added for increased scaling resistance at high temperatures: Cr, 23-26%; Ni, 19-22%; Si, 2% max
316	Molybdenum added to improve resistance to pitting corrosion and strength at high temperatures: Cr, 16-18%; Ni, 10-14%; Mo, 2-3%
316L	Extra-low carbon content for improved weldability
317	Additional molybdenum to further improve resistance to pitting corrosion: Cr, 18-20%; Ni, 11-15%; Mo, 3-4%
321	Titanium added to prevent chromium carbide precipitation: Cr, 17-19% Ni, 9-12%; C, 0.08% max: Ti, 5×C content
347	Columbium (niobium) or tantalum added to prevent chromium carbide precipitation
	Martensitic Stainless Steels
410	Basic alloy of the group: Cr, 11.5-13.5%; Ni, 0.5% max
405	Aluminum added to prevent weld hardening
414	Nickel (2%) added to improve corrosion resistance
416	Sulfur added to improve machinability
416 Se	Selenium added to improve machinability
420	Carbon increased for higher hardness: Cr, 12-14%; Ni, 0.5% max; C, over 0.15%
431	Chromium increased to further improve corrosion resistance: Cr, 15-17%; Ni, 1.25-2.50%
440A	Carbon slightly decreased to improve toughness: Cr, 10-18%; Ni, 0.5% max; C, 0.6-0.75%
440B	Carbon decreased slightly to improve toughness even more
440C	Carbon increased to increase hardness; chromium increased to make up loss in corrosion resistance: Cr, 16-18%; Ni, 0.5% max; C, 0.95-1.2%
	Ferritic Stainless Steels
430	Basic alloy of the group: Cr, 14-18%; Ni, 0.5% max
430FSe	Selenium added to improve machinability
442	Chromium increased to improve resistance to scaling and corrosion: Cr, 23-27%; Ni, 0.5% max

4.5% chromium	corrosion rate, 12.9 in.
8.0% chromium	0.14
12.0% chromium	0.01
18.0% chromium	0.003
25.0% chromium	0.0006

The corrosion resistance of iron-chromium alloys was known in England and France in the early 1800s, but passivity was not clearly recognized and reasonably understood until 1910 as the result of studies by Borchers and Monnartz in Germany. Commercial stainless steels were introduced shortly thereafter in Germany, France, England, and a bit later in the United States. Worldwide production of stainless steels now is measured in terms of millions of tons annually.

Research programs worldwide are seeking to improve the performance of 8 to 14% chromium ferritic steels for high-temperature applications up to 650°C (1200°F), particularly with applications in advanced power plants as targets. Such alloys are needed for future coal-fired power plants as well as for fast breeder and nuclear fission reactors. In addition to traditional uses of high-temperature steels as found in steam and gas turbine and boiler tube uses, the new alloys will be intended for use as fuel cladding, wrapper and steam generator tubing for fast breeder reactors, and first-wall materials for fusion reactors as currently conceived.

In addition to ferrous alloys, chromium also is added to copper, vanadium, zirconium, and other metals to form several hundred chromium-bearing alloys. Nickel-chromium-iron alloys have high electrical resistance and are used widely as electrical heating elements. *Nichrome* and *Chromel* are examples.

Chromium Plating

Although the tonnage of chromium used for electroplating is far below its consumption for alloys, plating represents a major market for the element. In terms of special protective coatings, chromium is behind only copper, lead, and zinc in consumption. Generally, chromium plating is used for two purposes: (1) wear-resistance and (2) decorative effect, taking on polish and a much brighter surface than the other electroplated metals. The "bright work" of automotive hardware, plumbing fixtures, and electrical appliances are examples. Normally, chromium is plated over nickel where the nickel is about 100×thicker than the chromium. In decorative plating, the thickness of the chromium plate ranges only from 0.00001 to 0.00002 inch (0.00025 to 0.00051 millimeter). Hexavalent chromium also forms protective chromate coatings over aluminum, cadmium, copper, magnesium, and zinc. These chromate conversion coatings are used on hot-dipped or electrogalvanized parts, on zinc die castings, and extensively on aluminum parts for aircraft.

In 1979, scientists at the General Motors Research Laboratories (Warren, Michigan) announced some interesting findings concerning chromium plating. The conventional process uses a bath containing Cr^{6+} ions. During plating, the Cr^{6+} ions reduce to Cr^{3+} and then to metallic Cr. Investigators wondered for years why the process will not succeed if one commences with Cr^{3+} ions, thus avoiding the double step. The GM scientists found that starting with Cr^{3+} fails because it immediately forms a stable complex with water molecules from which Cr cannot be deposited. Commencing with Cr^{6+} succeeds because during reduction a chemical film forms around the cathode (part being plated). Since Cr^{3+} is bound in that film, it does not react with water, but, instead, plates out as chromium metal. See Fig. 1.

As reported in 1983 by Dr. James Hoare, Research Fellow (General Motors Research Laboratories), the electrolyte for plating is a chromic acid solution which contains various chromate ions: chromate, dichromate, and trichromate. From a series of steady-state polarization experiments, Dr. Hoare concluded that trichromate is the ion important in chromium deposition. Sulfuric acid has been recognized as essential to chromium plating and has been assumed by some to be a catalyst for the process. In this strongly acidic solution, sulfate should be mostly present as the bisulfate ion (HSO_4^-). Dr. Hoare found, contrary to expectation, that the addition of sulfuric acid to the plating bath decreased the conductivity of the solution.

Combining these findings with the results of prior investigations, Dr. Hoare concluded that the electroactive species was a trichromate-bisulfate complex. See Fig. 2. From equilibrium considerations, he theorized that the maximum concentration of this species occurred at a 100-to-1 chromic acid/sulfuric acid ratio. The observation that the maximum rate of chromium deposition also occurred at this ratio supports the conclusion that this trichromate-bisulfate complex is the electroactive species. During the plating process, the complex diffuses from the bulk solution toward the cathode. See Fig. 3. Electron transport takes place by quantum mechanical tunneling through the potential energy barrier of the Helmholtz double layer, and the unprotected chromium in the complex (Cr atom on the left

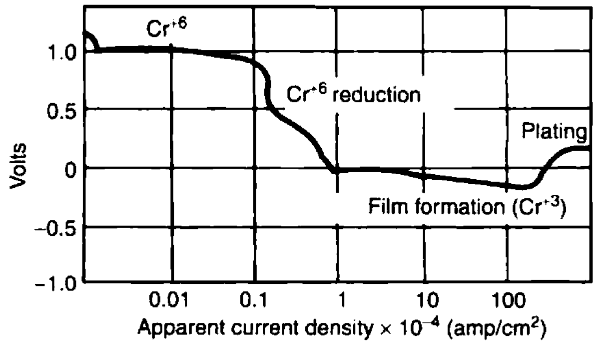

Fig. 1. Typical polarization curve made during investigation of chromium plating process. (*General Motors Research Laboratories*)

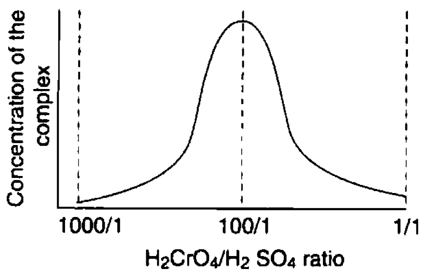

Fig. 2. The electroactive complex and a theoretical plot of its concentration as a function of chromic acid to sulfuric acid ratio. (*General Motors Research Laboratories*)

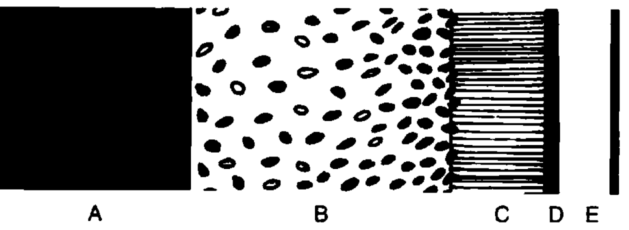

Fig. 3. The electroactive complex diffuses from the bulk electrolyte solution (A) through the diffusion layer (B) to the Helmholtz double layer (C) to be discharged as metallic chromium (D) on the cathode surface (E). (*After General Motors color sketch*)

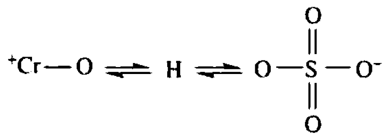
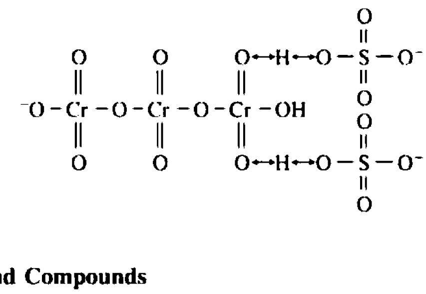
in Fig. 1) loses electrons by successive steps, going from Cr^{+6} to Cr^{+2}. Decomposition of the resulting chromodichromate complex takes place by acid hydrolysis to form a chromous-oxybisulfate complex:



The positive end of this complex is adsorbed onto the cathode surface. Electrons are transferred from the cathode to the adsorbed chromium ion, forming metallic chromium and regenerating the HSO_4^- ion. Thus, Dr. Hoare's mechanism explains how sulfuric acid, in the form of the bisulfate ion, participates in the plating process. (Information regarding Cr plating furnished by General Motors Research Laboratories and gratefully acknowledged.)



Chemistry and Compounds

Chromium metal is soluble in dilute HCl or H_2SO_4 and made passive by dilute or concentrated HNO_3 or concentrated H_2SO_4.

In keeping with the $3d^54s^1$ electron configuration of the atom, chromium forms compounds in which it is in the stable 6+ state. The compounds of 2+ and 3+ chromium are also quite numerous. The compounds with chromium oxidation numbers of 4+ and 5+ are unstable except under extremely alkaline conditions. The one known chromium 1+ complex is also unstable.

As is evident from the oxidation potential for Cr^{2+} to Cr^{3+}, the Cr^{2+} ion in aqueous solution is an extremely strong reducing agent, readily reacting with atmospheric oxygen. It is therefore stable in aqueous solution only in a complex or a slightly ionized salt. It may be obtained by reducing hexavalent or trivalent chromium in acid solution with one of the active metals, such as zinc. The four halogens form halides of divalent chromium, CrX_2, which dissolve in water with the evolution of heat, although the fluoride is less soluble than the other halides. The ammoniacal solution of chromium(II) sulfate, $CrSO_4$, is particularly reactive with gases, not only with oxygen like the other Cr^{2+} compounds, but also acetylene. Chromium(II) acetate is only slightly soluble in H_2O.

The Cr^{3+} ion readily forms complexes; it exists in aqueous solution as $Cr(H_2O)_6^{3+}$, and forms other complexes with anions, such as $Cr(H_2O)_5Cl^{2+}$, $Cr(H_2O)_4Cl_2^+$, etc. Thus chromium(III) halides may be crystallized in a number of forms differing in color and other properties due to variation in the bonding. Compounds of the trichloride have been reported with the following arrangements: $Cr(H_2O)_6Cl_3$, $[Cr(H_2O)_5Cl]Cl_2 \cdot H_2O$, and $[Cr(H_2O)_4Cl_2]Cl{\bullet}2\ H_2O$. Trivalent chromium also forms double salts, notably the chromium alums, hydrated double salts of Cr(III) sulfate and the alkali metal (or thallium or ammonium) sulfates.

The three oxides of chromium, CrO, Cr_2O_3, and CrO_3, are of interest in exhibiting the transition in properties from basicity to acidity and from electrovalence to covalence, with increasing oxygen content, and the consequent increase in charge upon the Cr atom. Thus Cr_2O_3, the middle oxide, is amphiprotic, dissolving either in strong alkali hydroxide solutions or in acids.

One of the most stable of the compounds of Cr(IV) is the tetrafluoride, CrF_4, brown solid, steel-blue vapor at 150°C, prepared by direct reaction of the elements; even this compound readily undergoes hydrolysis. Chromium tetrachloride, $CrCl_4$, may be prepared as a gas by reaction of Cl_2 and $CrCl_3$ at elevated temperature, but decomposes at room temperature. Chromium(V) occurs in CrF_5, fire-red, volatile, and in the hypochromates, M_3CrO_4, green, which may be prepared by fusion of alkali chromate and alkali hydroxide at high temperature.

CrO_3 is the anhydride of chromic and dichromic acids, H_2CrO_4 and $H_2Cr_2O_7$, which have not been isolated, but whose anions are found in many salts. pK_{A1} and $pK_{A2} = 0.745$ and 6.49, and −1.4 and 1.64 respectively. They are strong oxidants in acid solution, and are readily obtained in basic solution by oxidation of Cr(III) compounds. The oxyhalogen compounds of chromium are chiefly the CrO_2X_2 (chromyl) compounds, which are acid halides of chromic acid. Chromyl chloride, CrO_2Cl_2, deep red, liquid, is prepared by heating sodium dichromate and sodium chloride with H_2SO_4, while chromyl fluoride undergoes polymerization to a white solid. Chlorochromates, e.g., $KCrO_3Cl$, and fluorochromates, e.g., $KCrO_3F$, are also known, but are hydrolyzed in water.

Chromates and Dichromates

Sodium chromate, Na_2CrO_4, potassium chromate, K_2CrO_4, ammonium chromate, $(NH_4)_2CrO_4$, calcium chromate, $CaCrO_4$, are yellow soluble solids; barium chromate, $BaCrO_4$, pale yellow, strontium chromate, $SrCrO_4$, pale yellow, lead chromate, $PbCrO_4$, yellow (used as a pigment, "chrome yellow"), zinc chromate, $ZnCrO_4$, yellow, used as a pigment, mercurous chromate, Hg_2CrO_4, yellow to red to brown, silver chromate, Ag_2CrO_4, reddish-brown, are insoluble solids. Sodium dichromate, $Na_2Cr_2O_7$, potassium dichromate, $K_2Cr_2O_7$, readily crystallized, ammonium dichromate, $(NH_4)_2Cr_2O_7$ (forming nitrogen gas and green chromic oxide solid upon heating) are red soluble solids, of important application as oxidizing agents, e.g., sulfurous acid causes reduction to chromic; silver dichromate, $Ag_2Cr_2O_7$, red insoluble solid, changing to silver chromate, Ag_2CrO_4 upon boiling with H_2O. Solutions of chromate in the presence of acid are changed to the corresponding dichromate.

A number of peroxychromates are known, including the deep-blue, organic soluble reaction product of H_2O_2 and acid $Cr_2O_7^{2-}$ solutions, which is H_4CrO_7, i.e., $CrO_3 \cdot 2H_2O_2$.

Trivalent chromium forms many complexes. The large number is due in part to the many possible arrangements in which the same elements may be present as part of a complex anion or as the cation, as was indicated for the chloride complexes of the hydrated Cr^{3+} ion. The ligands may also be present in various proportions. As in the case with Co^{3+}, Cr^{3+} forms complexes with ammonia in the various color series, e.g., a violeo-chloride, $[Cr(NH_3)_4Cl_2]Cl$, a purpureo chloride, $[Cr(NH_3)_5Cl]\ Cl_2$ and a luteo chloride, $[Cr(NH_3)_6]Cl_3$. In addition to NH_3 many amines, especially ethylenediamine and its derivatives, form stable complexes with Cr^{3+}. In the oxalato complexes, the tripositive chromium ion coordinates with oxalate groups to form such anions as $[Cr(C_2O_4)_3]^{3-}$ and $[Cr(C_2O_4)_2(H_2O)_2]^-$. There are many cyano, thiocyano, nitrato, fluoro, bromo, iodo, azido, acetylido and nitro complexes.

Organometallic Compounds

These include a large number of cyclopentadienyl compounds. In addition to dicyclopentadienyl chromium itself, $(C_5H_5)_2Cr$, there are many derivatives of it with additional radicals or molecules such as $(C_5H_5)_2CrBr$, $(C_5H_5)_2CrNH_3$, $C_5H_5Cr(NO)_2CH_2Cl$, $H(C_5H_5)Cr(CO)_3$ and $C_5H_5(CO)_3CrCr(CO)_3C_5H_5$. The compounds of Cr with other hydrocarbon radicals are fewer ($Cr(C_6H_6)_2$ is known), such as $(C_6H_5)_5CrOH \cdot H_2O$ and $(C_6H_5)_3Cr \cdot 3$ THF (THF =Tetrahydrofuran).

Besides $Cr(C_6H_6)_2$, chromium hexacarbonyl, $Cr(CO)_6$, white, solid, bp (extrap.) 145.7°C, represents chromium in the zero oxidation state. This is a nonpolar compound, insoluble in H_2O, freely soluble in organic solvents. The zero-valent compound $K_6Cr(CN)_6$ has also been made by the reaction of $K_3Cr(CN)_6$ and potassium metal in liquid NH_3.

Cermets

The term *cermet* derives from the combination of ceramic and metal. Cermets are produced by powder metallurgy techniques and represent the bonding of two or more metals. They are particularly useful at high temperatures (850–1250°C). Chromium is used in several cermet combinations, including chromium-bonded aluminum oxide, metal-bonded chromium carbide, and metal-bonded chromium boride.

Biological Aspects

The first indication for a biological role of chromium in metabolism was derived from the enzymatic studies in 1939. The succinate-cytochrome dehydrogenase system, an important enzyme system for the production of energy, requires certain inorganic cofactors. Of various elements tested, chromium produced the greatest increase of enzyme activity. A significant stimulation of the activity of phosphoglucomutase by chromium was described by Strickland in 1949. This system which has an important function in the early steps of carbohydrate metabolism requires magnesium and one other metal for optimal activity. Chromium was outstanding as a "second metal" because it produced the highest enzyme activation and supported a measured amount of activity even when given alone.

Chromium also stimulates fatty acid and cholesterol synthesis from acetate in liver. That chromium is an essential cofactor for the action of insulin on the rat lens was shown by Farkas in 1964. In the absence of the element, no significant insulin effect on glucose utilization of lens can be demonstrated. Chromium supplementation to the donor animals results in a significant response of lens tissue to the hormone. Numerous other findings indicate that chromium may play several vital roles in biological systems.

Chromium levels in biological matter have been studied extensively. In contrast to findings with other metals, chromium concentrations in the United States population are highest at the time of birth, with a pronounced decline during the lifetime, whereas they appear to remain high in some other countries, such as Thailand and the Philippines. These findings suggest the possibility of a relative chromium deficiency in the United States. The relationship of this to disturbances of carbohydrate metabolism in humans, while under study, remains to be established.

Not all of the various chemical forms of chromium are effective in improving sugar metabolism, and the exact nature of the compound or compounds involved in activating insulin is not established. Some of the chromium in plants may not be present in nutritionally effective forms. It has not been established that chromium is essential to plants, but high concentrations of the metal are toxic. Most agricultural crops, especially their seeds, contain only low levels of chromium.

Chromium Use in Strain Gage

Strain measurements at high temperatures are required in developing designs for turbine engines and hypersonic aerospace vehicles. Operating temperature may exceed 1000°C (1830°F). Reliable strain gages for this range have not been available. Maximum operating temperature of traditional gages is 400°C (750°F). Thus, engineers were required to research a number of metal combinations that would perform reliably at such high temperatures. The ideal strain gage must change its electrical resistance only in response to strain and be unaffected by temperature changes.

Researchers at NASA (National Aeronautics and Space Administration, Cleveland, Ohio) tested a large number of alloys, such as iron-chromium-aluminum, platinum-tungsten, platinum-palladium-molybdenum, and palladium-chromium. The search was narrowed to the palladium (Pd)-chromium (Cr) combination. Ultimately, the combination of Pd-13% Cr (wt) was selected as optimal. A platinum wire that is wound around the periphery of the gage grid provides the required temperature compensation.

CHROMIZING. Production of a high chromium content surface layer on iron and steel by heating at high temperatures in a solid packing material containing chromium powder, or in an atmosphere containing chromium chloride. The surface layer is formed by diffusion of chromium into the iron in the same manner as carbon diffuses into iron in carburizing; however, the process is much slower and requires higher temperatures than carburizing. A similar result can be obtained by high-temperature diffusion of electrodeposited chromium. Chromized coatings have corrosion resistance and elevated temperature oxidation resistance similar to the high chromium types of stainless steels.

CHROMOGENIC COUPLERS. Couplers are used in secondary color development. See also **Dyes**. The term "coupler" is applied to a large number of organic compounds that combine with a limited number of chromogenic developers to produce dye images with a wide range of color and intensity. Couplers are dye intermediates but differ from chromogenic developing agents in that they do not as a rule have the ability to develop a silver image.

Couplers may be hydroxy or amine derivatives of aromatic compounds, such as benzene, naphthalene or anthracene. Phenol, napthol, aniline, cresol, paraaminophenol and dimethylparaphenylenediamine are examples. With these compounds coupling takes place with the hydrogen atom which is in the ortho or para position to the hydroxy or amino group on the coupler.

Compounds having active methylene, $=CH_2$ groups, with strong polar groups for other valences as the cyano $-CN$, the carbonyl $=CO$, the aceto CH_3CO-, the acid ester $-COOC_2H_5$, and the phenyl, $-C_6H_5$ groups will couple. Acetoacetic ester and paranitrophenylacetonitrile are illustrations.

The methylene group may be part of a ring structure as in coumarine and indoxyl, or may be part of a heterocyclic ring attached to a phenyl group as in 1-phenyl-3-methyl-5-pyrazolone.

Compounds having an N in the ring will couple if there is a methyl $-CH_3$ group, attached to the ring in the alpha position to the nitrogen. Two illustrations for this type are picoline and 2-methylthiazole.

Because secondary color development has been particularly successful in the development of color materials, and because of the ease by which it is possible to control color by this method, the field of couplers has expanded rapidly.

CHROMOPHORE. Certain groups of atoms in an organic compound cause characteristic absorption of radiation irrespective of the nature of the rest of the compound. Such groups are called chromophores or color carriers.

CHROMOPHORIC ELECTRONS. Electrons in the double bonds of the chromophore groups. Such electrons are not bound as tightly as those of single bonds and can thus be transferred into higher energy levels with less expenditure of energy. Their electronic spectra appear at frequencies in the visible or near ultraviolet region of the spectrum.

CHROMOPLASTS. See **Plastids**.

CHRYSOBERYL. The mineral chrysoberyl, an aluminate of beryllium corresponds to the formula $BeAl_2O_4$, crystallizes in the orthorhombic system with both contact and penetration twins common, often repeated resulting in rosetted structures. Hardness, 8.5; specific gravity, 3.75; luster vitreous; color various shades of green sometimes yellow. A variety which is red by transmitted light is known as alexandrite. Streak colorless; transparent to translucent, occasionally opalescent. Chrysoberyl also is known as *cymophane* and *golden beryl*.

Chrysoberyl occurs in granitic rocks, pegmatites and mica schists; often is found in alluvial deposits. The Ural Mountains yield alexandrite. Other localities for chrysoberyl are Czechoslovakia; Ceylon; Rhodesia; Brazil; and Madagascar, where it occurs of gem quality in the pegmatites of that island. In the United States it is found in Maine, Connecticut, and New York. The word chrysoberyl is derived from the Greek words meaning golden and beryl. Cymophane has its derivation also from the Greek words meaning wave and appearance, in reference to the opalescence exhibited at times.

CHRYSOCOLLA. This mineral, a hydrous silicate of copper probably corresponding to the formula $Cu_2H_2Si_2O_5(OH)_4$, is perhaps a mineral gel, for it usually appears as an amorphous mass, in veins, or as incrustations. Common occurrence as massive cryptocrystalline character, possibly orthorhombic; extremely rare as small acicular crystals.

Chrysocolla is generally some shade of blue or green but if impure may be brown or black. It has a characteristic conchoidal fracture; hardness, 2–4; sp gr, 2.24; vitreous to dull luster; translucent to opaque.

Chrysocolla is a secondary mineral and associated commonly with other copper minerals of similar origin. It is one of the less important ores of copper and has a minor use as a gemstone. Among the localities for excellent specimens may be mentioned Cornwall and Cumberland, England; Congo; Chile; Lebanon and Berks Counties, Pennsylvania; the Clifton-Morenci Globe and Bisbee districts in Arizona; Dona Ana County, New Mexico, and the Tintic district, Utah.

The word chrysocolla is derived from the Greek words meaning gold and glue, formerly the name for gold solder.

CHRYSOTILE. A delicately fibrous variety of serpentine which separates easily into silky, flexible fibers of greenish or yellowish color, with formula $Mg_3Si_2O_5(OH)_4$. It crystallizes in the monoclinic system; hardness, 2.5; sp gr, 2.55. Its name is derived from the Greek words meaning gold and fibrous. Most of the common asbestos of commerce is chrysotile. It is mined in Thetford, Province of Quebec, and in the Republic of South Africa. See also **Asbestos**; and **Serpentine**.

CINNABAR. The mineral cinnabar, mercuric sulfide (HgS) occurs in small and often highly modified hexagonal crystals, usually of rhombohedral or tabular habit. It is found chiefly in crystalline crusts, granular or simply massive. The overture of cinnabar is subconchoidal; hardness, 2–2.5; specific gravity, 8–8.2; luster, adamantine tending toward metallic, sometimes dull. This mineral has a characteristic cochineal-red color which, however, may be brownish at times, occasionally dull lead gray. The streak is scarlet; it is transparent to opaque.

Cinnabar occurs in veins or may be in masses in shales, slates, limestones and similar rocks due to the impregnation by mineral-bearing solutions or as replacements. The former U.S.S.R., former Czechoslovakia, Bohemia, Bavaria, Italy and Spain have furnished excellent specimens. The most important of the world's mercury deposits is at Almaden in Spain. Italy, Peru, Surinam, China and Mexico have commercially valuable occurrences of cinnabar. In the United States this mineral is found in California (most important deposit), Nevada, Utah, Texas and Oregon. Cinnabar is the chief ore of mercury. Its name is supposed to be of Hindu origin.

CIS-COMPOUND. See **Isomerism**.

CITRIC ACID. [CAS: 77-92-9]. $C_3H_4(OH)(COOH)_3$, formula weight 192.12, white crystalline solid, mp 153°C, decomposes at higher temperatures, sp gr 1.542. Citric acid is soluble in H_2O or alcohol and slightly soluble in ether. The compound is a tribasic acid, forming mono-, di-, and tri- series of salts and esters. Citric acid may be obtained: (1) from some natural products, e.g., the free acid in the juice of citrus and acidic fruits, often in conjunction with malic or tartaric acid; the juice of unripe lemons (approximately 6% citric acid) is a commercial source; (2) by fermentation of glucose (blackstrap molasses is a major source); and (3) by synthesis.

Citric acid and sodium citrate have found use as additives in effervescent beverages and medicinal salts, although excessive quantities are considered toxic. Citric acid can be used as an effective antioxidant. Because the acid is not readily soluble in fats, it is added to formulations that improve solubility, such as propylene glycol and butylated hydroxy anisol, and this can be used as a stabilizer for tallow, fats, and greases. Citric acid also is used for adjusting pH in certain electroplating baths. It finds a number of miscellaneous uses in etching, textile dyeing and printing operations.

Citrates (like tartrates) in solution change silver of ammonio-silver nitrate into metallic silver. Calcium citrate, due to its solubility characteristics, is of importance in the separation and recovery of citric acid. Calcium citrate plus dilute H_2SO_4 yields citric acid plus calcium sulfate, and the latter may be separated by filtration. Citric acid may be obtained by evaporation of the filtrate.

In most living organisms, the citric acid cycle constitutes the final common pathway in the degradation of foodstuffs and cell constituents to carbon dioxide and water. This cycle is described in the entry on **Carbohydrates**.

Derivatives

Salts. The trisodium citrate salt is made by dissolving citric acid in water at a concentration of 50% w/w or higher. A 50% solution of sodium hydroxide is carefully added to pH 8.0–8.5. The reaction is exothermic and cooling is necessary to prevent boiling. The tripotassium salt of citric acid is made in a similar manner using potassium hydroxide. The product crystallizes as the monohydrate. Ammonium salts of citric acid are made by adding either aqueous or anhydrous ammonia to citric acid dissolved in water. They are usually used in the liquid form rather than isolated as a dry product.

Esters. The significant esters of citric acid are trimethyl citrate, triethyl citrate, tributyl citrate, and acetylated triethyl- and tributyl citrate. Many other esters are available but have not been used on a commercial scale. Citric acid esters are made under azeotropic conditions with a solvent, a catalyst, and the appropriate alcohol.

Catalysts used are usually acids such as sulfuric acid, p-toluenesulfonic acid, sulfonic acid ion-exchange resins, and others. The water from the reaction of the citric acid and the alcohol is continuously removed as the azeotrope until no more water is formed. At this point, the reaction is usually complete and the solvent and any excess alcohol is distilled off under mild vacuum. The catalyst is neutralized using carbonate or sodium hydroxide, leaving a crude product. If a pure product is desired, the ester can be distilled under high vacuum.

Citric acid esters are used as plasticizers in plastics such as poly(vinyl chloride), poly(vinylidene chloride), poly(vinyl acetate), poly(vinyl butyral), polypropylene, chlorinated rubber, ethylcellulose, and cellulose nitrate. Most citrate esters are nontoxic and are acceptable by the FDA for use in food-contact packaging and for flavor in certain foods. As a plasticizer, citrate esters provide good heat and light stability and excellent flexibility at low temperatures.

CITRIC ACID CYCLE. See **Carbohydrates**.

CITRINE. The mineral citrine is a yellow variety of quartz sometimes used as a gem. It is often marketed under the name topaz and may mislead the unwary. Brazil and Madagascar have furnished material of excellent quality. See also **Quartz**.

CLARIFYING AGENTS. Chemical substances used in connection with the purification of various solutions and liquors that occur during the processing of raw materials to final end-products. These agents operate in connection with mechanical equipment to bring about the removal of suspended particles that represent product impurities. Allowing such particles to settle by gravity alone would require very long periods. Clarification is part of the total process of sedimentation, which may be defined as the removal of solid particles from a liquid stream by gravitational force. The operation is effected by slowing the velocity of a feed stream in a large-volume tank so that gravitation settling can occur. Sedimentation is divided into two functions: (1) thickening, where the primary purpose is to increase the concentration of suspended solids of the feed stream, i.e., to remove liquids (this is largely a mechanical operation,

assisted sometimes by clarifying agents); (2) clarification, where the purpose is to remove fine-sized particles and produce a clear effluent, i.e., to remove solids. Some equipment does both and the dividing line between thickening and clarification is not always sharp. See also **Classifying (Process)**. A clarifying agent to assist in this operation must possess certain properties for acting on the suspended particles—chemical precipitation, attractive via ionic forces, absorption qualities (large surface areas plus weak forces).

In the sugar refining industry, for example, various soluble nonsugar compounds are present in sugar juices as the result of rupturing plant cells (either from pressing sugar cane stalks or by extraction of the sliced root of sugar beets). Lime is commonly used to precipitate impurities, followed by carbonation of the solution with carbon dioxide to remove residual lime as calcium carbonate. Where filtration is used, various filter aids, such as fuller's earth, may be used. Filtering-type centrifuges also may be used. Phosphates, frequently in the form of orthophosphoric acid, may be used to precipitate the calcium. Some authorities suggest the use of polyphosphates, such as superphosphate and pyrophosphate, along with lime in the clarification operation. Phosphates assist in regulating the pH for optimal precipitation of calcium.

Tannin is used as a clarifying agent in wine making. Polyvinylpyrrolidone (PVP) has been used as a clarifying agent in the food industry. Ion exchange processes are also used in various processes, along with or in lieu of conventional clarification. For example, in ion exchange, the demineralization of sugar solutions can be effected; iron can be removed from wine by substitution with hydrogen ions.

Generally, wherever practical and economical, food processors prefer to accomplish clarification without the aid of chemicals—because all or but a trace of these chemicals must be removed so that they do not reappear in the final food product.

CLASSIFYING (Process). An operation or series of operations designed to separate a mixture of substances of various sizes and specific gravities into two or more categories, the cuts or divisions being made both with reference to size and to specific gravity (density). These operations find wide application in mining, metallurgical, water and sewage treatment, as well as use in other fields, such as the chemical industry.

Flotation. This is a means of separating a relatively small particle from a liquid medium. The particle may have a specific gravity greater than, less than, or the same as the liquid from which it is floated. There are two fundamental requirements: (1) a gas bubble and particle must come in contract with each other; and (2) the particle should have an *affinity* for attaching itself to the bubble.

To achieve the first objective, various methods of bubble production and particle agitation have been used. Since the invention of flotation by Haynes in 1860, two basic methods have emerged:

(a) *Dissolved gas-impeller agitation*, wherein gas under pressure is sparged into the bottom of a vessel in which an impeller mixes the rising bubbles with the agitated particles.
(b) *Self-induced gas-impeller agitation*, wherein the impeller is so positioned in the liquid that it inspirates ambient gas into the liquid as bubbles. These bubbles are brought into contact with the agitated particle at the impeller's most dynamic zone. This method (see Fig. 1) has become the most accepted method.

The second requirement has been served by the development of a number of chemical reagents, which fall into five basic categories: (1) collection; (2) conditioning; (3) levitation; (4) frothing; and (5) depressant.

Frothers are chemicals whose molecules contain both a polar and a nonpolar group. The purpose of a froth is to carry mineral-laden bubbles for a period of time until the froth can be removed from the flotation machine for recovery of its mineral content. Typical frothing chemicals are alcohols, cresylic acids, eucalyptus oils, camphor oils, and pine oils, all of which are slightly soluble in water. Soluble frothers in common use include alkyl ethers and phenyl ethers of propylene and polypropylene glycols.

Collectors are chemical reagents that selectively coat the particles to be floated with a water-repellant surface that will adhere to air bubbles. Collectors generally are classified as cationic, anionic, or nonionic. Examples of collectors include the xanthates, dithiophosphates, thiocarbonilides, and thionocarbonates, all of which are anionic collectors

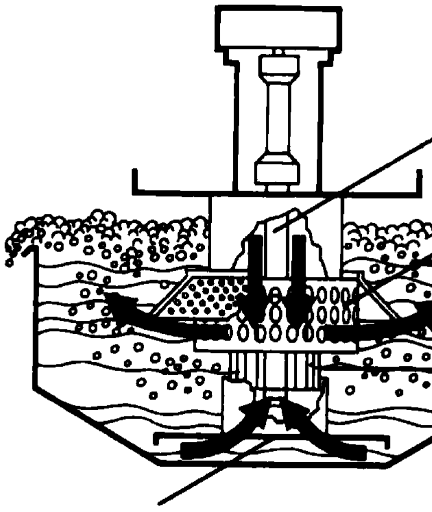

Fig. 1. Flotation cell. Upper portion of rotor draws air down the standpipe for thorough mixing with pulp. Lower portion of rotor draws pulp upward through rotor. Disperser breaks air into minute bubbles. Larger flotation units include false bottom to aid pulp flow

for sulfides, a major need in ore processing. Fatty acids and soaps are anionic collectors and serve for nonsulfides. Amine salts are cationic collectors for nonsulfides.

Depressants are mainly inorganic salts, which compete with the collector for position on the sulfide surface. This permits the separation of one sulfide mineral from another. In one case, for example, in an alkaline solution, the addition of sodium cyanide prevents flotation of sphalerite and pyrite by xanthates, but not of galena, thus producing a higher grade of galena concentrates. The cyanide solution does not permanently affect the floatability of sphalerite as it can be floated by adding cupric sulfate and xanthate.

Activators are chemical reagents, which alter the surface of a sulfide so that it can absorb a collector and float. Cupric sulfate is the most widely used activator. For example, xanthate as a collector will not readily float sphalerite, but the addition of cupric sulfate to the pulp changes the surface of the sphalerite particles to copper sulfide. Xanthate then will readily float the activated sphalerite as it behaves similarly to copper sulfide.

Although flotation was developed as a separation process for mineral processing and applies to the sulfides of copper, lead, zinc, iron, molybdenum, cobalt, nickel, and arsenic and to nonsulfides, such as phosphates, sodium chloride, potassium chloride, iron oxides, limestone, feldspar, fluorite, chromite, tungstates, silica, coal, and rhodochrosite, flotation also applies to nonmineral separations. Flotation is used in the water disposal field, particularly in connection with petroleum waste water cleanup.

Dense-media Separation. This operation is useful for the separation of solid particles of different densities. A liquid suspension of finely divided high-gravity solids is prepared. Ores of different densities, when exposed to such a suspension will tend to separate by rising or settling in the liquid suspension. Numerous types of solids have been used to obtain a high-gravity medium, but the magnetic solids (ferro-silicon and magnetite) are most frequently used. These solids, alone or in combination, can provide a suitable dense medium over a gravity range of 1.25 to 3.40. Dense-media separation is applicable to any ore in which the valuable component has an appreciable gravity difference from the gangue components. In coarse-ore heavy-media separation plants, the limiting bottom size of dense-medium feed is 10 mesh and the upper size limit is 12 inches (0.3 meter). The magnetic particles of the dense medium subsequently are removed by a magnetic separator.

Jigging. In this operation, a pulsating stream of liquid flows through a bed of materials of different specific gravities, causing the heavy material to work down to the bottom of the bed and the lighter material to rise to the top. This is a very old operation used for concentrating heavy mineral

from the lighter gangue. Construction costs are low, but power and water consumption are high. The process is used for the concentration of coal.

Tabling. In this concentration process, a separation between two or more minerals is effected by flowing a pulp across a riffled plane surface inclined slightly from the horizontal, differentially shaken in the direction of the long axis, and washed with an even flow of water at right angles to the direction of motion. A separation between two or more minerals depends mainly on the difference in specific gravity between the effective gravity (sp gr of mineral minus sp gr of water) of the valuable and the waste material. Tables treat metallic ores effectively in size ranges from 6 to 150 mesh, but can be used to treat lighter materials, such as coal of a considerably larger size. Dry tables also are used. The shaking motion is similar except that the direction of motion is inclined upward from the horizontal and, instead of water acting as the medium of distribution, a blast of air is driven through a perforated deck. Tables also are used for selective flocculation or agglomeration of grains of one mineral in an aggregate by the addition of an agglomerating agent.

Sedimentation. This is a general term for an operation wherein suspended solids are removed from a liquid by gravitational settling. The two major forms of sedimentation equipment are (1) thickeners, and (2) clarifiers. The term *decanting* also is sometimes used to designate sedimentation.

Thickeners. The primary objective of thickening is to increase the concentration of the feedstream. The mechanical continuous thickener, equipped with sludge-raking arms, is the most common type. Usually the operation is performed in cylindrical tanks. The sludge collection system and the removal system are designed to move the settled material continuously across the tank floor to a discharge point. Feed enters through a central feed well designed to distribute around the periphery. Thickened sludge, raked toward the center by a slowing revolving mechanism, enters a central collecting trough or cone and is discharged through a spigot or removed by a sludge pump. See Figs. 2 and 3.

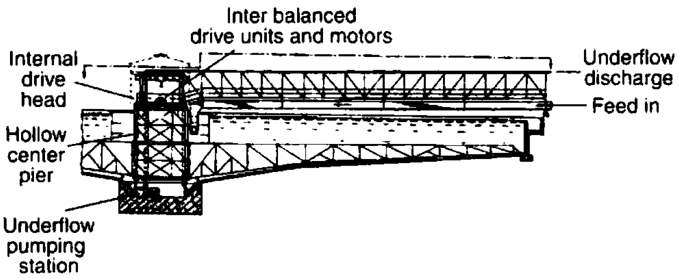

Fig. 2. Caisson-type thickener

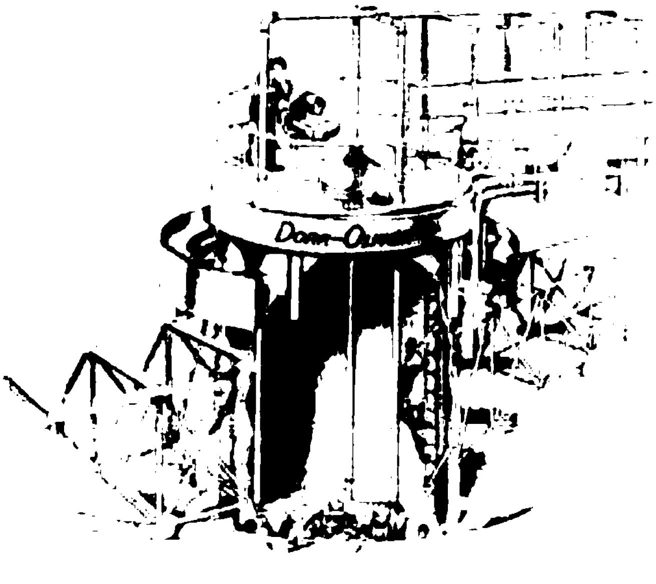

Fig. 3. Center-pier type thickener, showing pumps and access

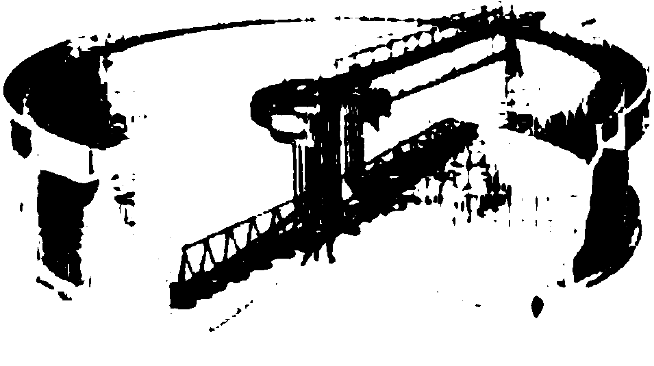

Fig. 4. Activated sludge final clarifier

Clarifiers. The primary objective of clarifying is to free solids from a relatively dilute stream. These units operate on the basis of gravity sedimentation and utilize a raking mechanism, as in a thickener. Frequently, clarifiers are operated in conjunction with flocculation equipment, which employs chemical coagulants, such as alum, iron salts, lime, polyelectrolytes, activated silica sol, and other chemical reagents. Clarification essentially expedites the natural gravity settling process. An activated sludge final clarifier is shown in Fig. 4.

CLATHRATE. See **Compound (Chemical)**.

CLAUDE PROCESS. See **Ammonia**.

CLAYS. The terms *clay* or *clays* commonly refer to either rocks that are consolidated or unconsolidated sediments, or a group of minerals having unique properties. Traditionally, clays (rocks) are distinctive in at least two properties that render them technologically useful: plasticity and composition. Clays are predominantly composed of hydrous phyllosilicates, referred to as clay minerals. These are hydrous silicates of Al, Mg, K, and Fe, and other less abundant elements. Clay minerals are extremely fine crystals or particles, often colloidal in size and usually plate-like in shape. The nonclay mineral portion of clays (rocks) may consist of other minerals, portions of rocks, and organic compounds.

The very fine particles yield very large specific surface areas that are physically sorptive and chemically surface reactive. Many clay mineral crystals carry an excess negative electric charge owing to internal substitution by lower valent cations, and thereby increase internal reactivity in chemical combination and ion exchange. Clays, which may have served as substrates selectively absorbing and catalyzing amino acids in the origin of life, apparently catalyze petroleum formation in rocks. See also **Petroleum**.

A clay deposit usually contains nonclay-like minerals as impurities and these impurities may actually be essential in determining the unique and specially desired properties of the clay. Both crystalline and amorphous minerals and compounds may be present in a clay deposit.

A broad definition of clays includes the following properties: *(1)* Crystalline hydrated silicates of aluminum, iron, and magnesium comprise the majority of clay minerals; however, amorphous hydrated aluminum compounds are also included. Distinctions among clay minerals are made by chemical and structural parameters. The chemical variations range from kaolinite, which is relatively uniform in chemical composition, to smectite minerals, which vary widely in chemical composition, base exchange properties, and expanding crystal lattice. Clay minerals are excellent examples of mixed layering, both random and regular, in layer-structure silicates. These mixed-layer clays are among the most ubiquitous of the various clay minerals. The structural differences among clay minerals are related to the arrangement of tetrahedral (T) and octahedral (O) layers, and the manner in which electrostatic charge imbalances, created by chemical substitution, are neutralized. Figure 1 shows several examples. *(2)* The possible content of hydrated alumina and iron. *(3)* The extreme fineness of individual clay particles, which may be of colloidal size in at least one dimension. *(4)* The property of thixotropy in various degrees of complexity. *(5)* The possible content of quartz, SiO_2, sand and silt, feldspars, mica, chlorite, opal, volcanic dust, fossil fragments, high density so-called heavy

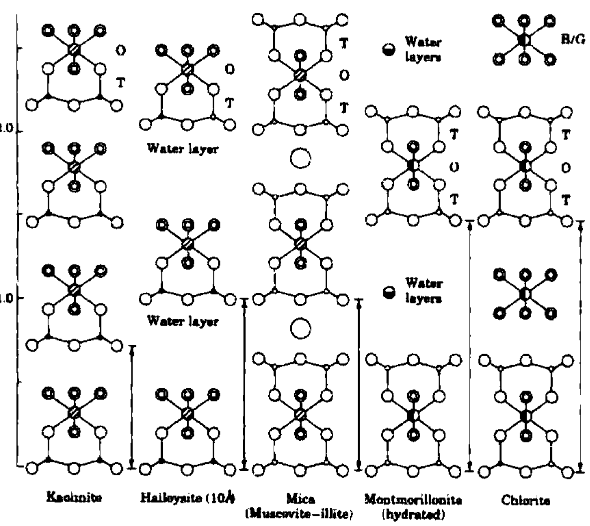

Fig. 1. Diagrammatic representation of the succession of layers in some layer lattice silicates (12) where O is oxygen; ◎, hydroxyl; •, silicon; Si–Al; ⊘, aluminum; ◐, Al–Mg; O, potassium; ⊖, Na–Ca. Sample layers are designated as O, octahedral; T, tetrahedral; and B/G, brucite- or gibbsitelike. The distance depicted by arrows between repeating layers in nm are 0.72, kaolinite; 1.01, halloysite (10 Å); 1.00, mica; ca 1.5, montmorillonite; and 1.41, chlorite

minerals, sulfates, sulfides, carbonate minerals, zeolites, and many other rock and mineral particles ranging upward in size from colloids to pebbles.

Geology and Occurrence

Clays may originate through several processes: *(1)* hydrolysis and hydration of a silicate, i.e., alkali silicate + water → hydrated aluminosilicate clay + alkali hydroxide; *(2)* solution of a limestone or other soluble rock containing relatively insoluble clay impurities that are left behind; *(3)* slaking and weathering of shales (clay-rich sedimentary rocks); *(4)* replacement of a preexisting host rock by invading guest clay where the constituents are carried in part or wholly by solution; *(5)* deposition of clay in cavities or veins from solution; *(6)* bacterial and other organic activity, including the extraction of metal cations as nutrients by plants; *(7)* action of acid clays, humus, and inorganic acids on primary silicates; *(8)* alteration of parent material or diagenetic processes following sedimentation in marine and freshwater environments; and *(9)* resilication of high alumina minerals.

Clays or shales that may be utilized in the manufacture of bricks, tiles, and other heavy clay products exist in every state in the United States. Glacial clays, as unassorted glacial till or secondarily deposited melt water are abundant in the United States north of the Missouri and Ohio Rivers. Fire clays are those that resist fusion at a relatively high temperature, usually around 1600°C. Missouri, Pennsylvania, Ohio, Kentucky, Georgia, Colorado, New Jersey, Texas, Arkansas, Illinois, and Maryland are large producers of fire clays. Adobe, a calcareous, sandy to silty clay used extensively for making sundried brick, is available in the more arid southwestern states. Slip clay for glazing pottery is produced near Albany, New York.

Bentonite, widely distributed geographically and geologically, also varies widely in properties.

Each continent has clays of almost every type; however, certain deposits are outstanding.

The commercial value of a clay deposit depends on market trends, competitive materials, transportation facilities, new machinery and processes, and labor and fuel costs. Naturally exposed outcrops, geological area and structure maps, aerial photographs, hand and power auger drills, core drills, earth resistivity, and shallow seismic methods are used in exploration for clays. Clays are mined primarily by open-pit operation, including hydraulic extraction; however, underground mining is also practiced.

Mineralogy

The development of apparatus and techniques, such as x-ray diffraction, contributed greatly to research on clay minerals. Crystalline clay minerals are identified and classified primarily on the basis of crystal structure and the amount and locations of charge (deficit or excess) with respect to the basic lattice. Amorphous (to x-ray) clay minerals are poorly organized analogues of crystalline counterparts.

The structural variations among the clay minerals can be understood by considering various physical combinations of tetrahedral and octahedral sheets and the electrostatic effect chemical substitution has on the structural units. The tetrahedral sheets are composed primarily of Si^{4+} and oxygen, but minor amounts of Al^{3+} or Fe^{3+} may substitute for Si^{4+}. The substitution of M^{3+} for Si^{4+} leaves the tetrahedral sheet negatively charged. The cations of the octahedral sheet are composed primarily of Al^{3+}, Fe^{3+}, Mg^{2+}, and Fe^{2+}, but all other transition elements, except Sc, may be included. The anions of the octahedral sheet are O^{2-}, OH^-, and F^-. The smallest unit of the octahedral sheet contains three octahedral having an ideal net charge of negative six, i.e., three O^{2-}. If the negative charge is balanced by two trivalent cations, the layer is referred to as a dioctahedral layer; if balanced by three bivalent cations, the layer is referred to as a trioctahedral layer. Substitution of bivalent cations for trivalent cations, univalent cations (Li^+) for bivalent cations or unfilled octahedral sites, leaves the octahedral layer a net negative charge. The tetrahedral apical oxygen is shared with the octahedral layer to join the two types of layers.

The least complicated clay minerals are the 1:1 clay minerals composed of one tetrahedral (T) layer and one octahedral (O) layer.

Clay minerals that are composed of two tetrahedral layers and one octahedral layer are referred to as 2:1 clay minerals or TOT minerals.

The multitude of variation in clay minerals is caused by substitution in the octahedral and tetrahedral layers, resulting in charge deficits. The manner in which the charge deficit is balanced leads to many of the useful and unique properties of clay minerals.

Crystalline and Paracrystalline Groups

Kaolins. The kaolin minerals include kaolinite, dickite, and nacrite which all have composition $Al_2O_3 \cdot 2\ SiO_2 \cdot 2\ H_2O$; halloysite (7 Å), $Al_2O_3 \cdot 2\ SiO_2 \cdot 2\ H_2O$; and halloysite (10 Å), $Al_2O_3 \cdot 2\ SiO_2 \cdot 4\ H_2O$. The structural formulas for kaolinite and halloysite (10 Å), which are shown in Figure 1, are $Al_4Si_4O_{10}(OH)_8$ and $Al_4Si_4O_{10}(OH)_8 \cdot 4\ H_2O$, respectively. The so-called fire clay mineral is a *b*-axis disordered kaolinite; halloysite (7 Å) and halloysite (10 Å) are disordered along both the *a*- and *b*-axes. Indeed, most variations in the kaolin group originate as structural polymorphs, related to variations in layer stacks.

Halloysite, a mineral in the kaolin family, has a chemical composition similar to, but physical properties that differ greatly from, kaolinite. Halloysite differs from kaolinite in tetrahedral Al content, layer stacking sequence, and configuration of the six-fold rings. Four basic morphologies of halloysite are recognized: tubular (long and short), spheroidal, platy, and prismatic.

Kaolin most commonly originates by the alteration of feldspar or other aluminum silicates via an intermediate solution phase, usually by surface weathering or by rising warm (hydrothermal) waters.

Large deposits of relatively pure kaolinite have developed from parent, feldspar-rich pegmatites, whereas others are secondarily deposited in sedimentary beds after transportation.

The textures of kaolin (rock) include varieties similar to examples observed in igneous and metamorphic as well as sedimentary rocks. Kaolin grains and crystals may be straight or curved, sheaves, flakes, face-to-face or edge-to-edge floccules, interlocking crystals, tubes, scrolls, fibers, or spheres.

Serpentines. Substituting 3 Mg^{2+} for the 2 Al^{3+} in the kaolin structure results in the serpentine minerals, $Mg_3Si_2O_5(OH)_4$. In serpentines all three possible octahedral cation sites are filled. Most serpentine minerals are tubular to fibrous in structure presumably because of misfit between Mg octahedral and tetrahedral layers.

Talc and Pyrophyllite. Talc and pyrophyllite are 2:1 layer clay minerals having no substitution in either the tetrahedral or octahedral layer. These are electrostatically neutral particles ($x = 0$) and may be considered ideal 2:1 layer hydrous phyllosilicates. Talc and pyrophyllite are found in metamorphic rocks that are rich in Mg and Al, respectively.

Smectites (Montmorillonites). Smectites are the 2:1 clay minerals that carry a lattice charge and characteristically expand when solvated with water and alcohols, notably ethylene glycol and glycerol.

Smectites are structurally similar to pyrophyllite or talc, but differ by substitutions mainly in the octahedral layers.

The minerals of the smectite group have been formed by surface weathering, low temperature hydrothermal processes, alteration of volcanic

dust in stratified beds, action of circulating water of uncertain source among fractures and in veins, and laboratory synthesis.

Illite. Illite is a general term for the clay mineral constituents of argillaceous sediments that strongly resemble mica minerals. Other names that have been used for illite include bravaisite, degraded mica, hydromica, hydromuscovite, hydrous illite, hydrous mica, K-mica, micaceous clay, and sericite. Illite and the mica minerals have a 2:1 sheet structure similar to the smectite minerals except that the maximum charge deficit in mica is typically in the tetrahedral layers and contains potassium held tenaciously in the interlayer space, which contributes to a 1.0-nm basal spacing.

The formula of illite can be expressed as $2K_2O \cdot 3MO \cdot 8R_2O_3 \cdot 24SiO_2 \cdot 12H_2O$, and the crystal structure by the formula $K_y[Al_{4-x}(Fe, Mg)_x](Si_{(8-y)+x}Al_y)O_{20}(OH)_4$ where y refers to the K^+ ions that satisfy the excess charges resulting when about 15% of the Si^{4+} positions are replaced by Al^{3+}.

Illite was defined as the most abundant clay mineral in Paleozoic shale and is widespread in many other sedimentary rocks; it is common in soils, slates, certain alteration products of igneous rocks, and recent sediments. Its origin has been attributed to alteration of silicate minerals by weathering and hydrothermal solutions, reconstitution, wetting and drying of soil clays, and diagenesis involving other three-layer minerals and potassium during geologic time and pressure under deep burial. Illitization of smectite via illite–smectite mixed-layer intermediates is a very common and an important reaction in the formation of shales during burial diagenesis.

Glauconite. Glauconite is a green, dioctahedral, micaceous clay rich in ferric iron and potassium. The generally accepted formula for glauconite is $(Na, K)_{0.78}(Fe^{3+}_{1.01}Al_{0.45}\,Mg_{0.39}Fe^{2+})_{2.05}(Si_{3.65}Al_{0.35})O_{10}(OH)_2$. Glauconite has many characteristics common to illite, but much glauconite contains random mixed expanding layers, and can be referred to as interstratified glauconite–smectite minerals. In addition, glauconite found in Late Cenozoic rocks tends to have less crystallographic order than older glauconite; therefore, the modifiers ordered (well crystalline) and disordered (poorly crystalline) are commonly used.

Glauconite occurs abundantly in sand-size or bigger pellets, or in pellets within fossils, notably foraminifera, giving it an organic connotation.

Celadonite is an iron-rich dioctahedral micaceous mineral that is similar to glauconite. Celadonite has a composition of: $(Na, K)_{0.83}(Fe^{3+}_{0.72}Al_{0.49}\,Mg_{0.63}Fe_{2+0.20})_{2.05}(Si_{3.81}Al_{0.19})O_{10}(OH)_2$ (39) and, like glauconite, has well crystalline, poorly crystalline, and interstratified varieties.

Chlorite and Vermiculite. Chlorite is a 1.4-nm (14 Å) clay mineral that cannot be expanded or collapsed by traditional laboratory procedures. Structurally, the unit layer of chloride is composed of a 2:1 layer combined with a 0.4-nm Mg or Al interlayer or hydroxide sheet.

Palygorskite and Sepiolite. Palygorskite (attapulgite) and sepiolite are clay minerals in which the 2:1 layers are linked together in chain-like or a combination of chain-sheet structures.

Palygorskite and sepiolite are different from other clay minerals in the manner in which the 2:1 layers are joined. Rather than being joined in a continuous manner, the tetrahedral sheets are joined to an adjacent inverted tetrahedral layer, making the octahedral layers noncontinuous and leaving an open channel in the mineral structure.

Palygorskite has an ideal formula that approximates $MgAl_3Si_8O_{20}(OH)_3(OH_2)_4 \cdot x[R^{2+}(H_2O)_4]$; the ideal formula for sepiolite is $Mg_8Si_{12}O_{30}(OH)_4(OH_2)_4 \cdot x[R_{2+}(H_2O)_8]$. The chemical composition of a specific sample may vary widely because there is substitution of Na, Fe, Mn, Al, and Ni in the octahedral sheets of sepiolite, and substitution of Na, Fe, and Mn in palygorskite.

These clays have distinctive uses and properties not shown by platy clay minerals.

Mixed-Layer Minerals. In addition to polymorphism resulting from the disordering and proxying of one element for another, clay minerals exhibit ordered and random intercalation sandwiches with one another.

Mixed-layer clays, particularly illite–smectite, are very common minerals and illustrate the transitional nature of the 2:1 layered silicates. The transition from smectite to illite occurs when smectite, in the presence of potassium from another mineral such as potassium feldspar, or from thermal fluids, is heated and/or buried. With increasing temperature smectite plus potassium is converted to illite.

The physical structure of mixed-layer minerals is open to question. In the traditional view, the MacEwan crystallite is a combination of 1.0-nm (10-Å) nonexpandable units (illite) that forms as an epitaxial growth on 1.7-nm expandable units (smectite) that yield a coherent diffraction pattern. This view is challenged by the fundamental particle hypothesis which is based on the existence of fundamental particles of different thickness.

Amorphous and Miscellaneous Groups

Allophane and Imogolite. Allophane is an amorphous clay that is essentially an amorphous solid solution of silica, alumina, and water. Allophane has been found most abundantly in soils and altered volcanic ash. It usually occurs in spherical form but has also been observed in fibers.

Imogolite is an uncommon paracrystalline clay mineral assigned the formula $1.1SiO_2 \cdot Al_2O_3 \cdot 2.3\text{–}2.8H_2O$. The morphology of imogolite has been reported as thread-shaped and as hollow spheres. Imogolite is generally viewed as an intermediate between allophane and kaolinite. In modern environments both allophane and imogolite are associated with volcanic material in areas of high rainfall.

High Alumina Clay Minerals. Several hydrated alumina minerals should be grouped with the clay minerals because the two types may occur so intimately associated as to be almost inseparable. Diaspore (α-AlO(OH)) and boehmite (γ-AlO(OH)), both $Al_2O_3 \cdot H_2O$(Al_2O_3, 85%; H_2O, 15%) are the chief constituents of diaspore clay, which may contain over 75% Al_2O_3 on the raw basis. Gibbsite, $Al_2O_3 \cdot 3\,H_2O$ (Al_2O_3, 65.4%; H_2O, 34.6%), and cliachite, the so-called amorphous alumina hydrate (much cliachite is probably cryptocrystalline), as well as the monohydrates, occur in bauxite, bauxitic kaolin, and bauxitic clays.

The hydrated alumina minerals usually occur in oolitic structures (small spherical to ellipsoidal bodies the size of BB shot, about 2 mm in diameter) and also in larger and smaller structures. High alumina minerals are found where intense weathering and leaching has dissolved the silica. It is generally believed that a very humid, subtropical climate is required for this (lateritic) stage of weathering.

CLINICAL CHEMISTRY. A subdivision of chemistry that deals with the behavior and composition of all types of body fluids, including the blood, urine, perspiration, glandular secretions, etc. It involves analysis and testing of these for content of numerous metabolic constituents, as well as foreign materials; thus it also includes toxicological factors.

CLINOZOISITE. Clinozoisite, crystallizing in the monoclinic system, is a hydrous calcium aluminum silicate, $Ca_2Al_3Si_3O_{12}(OH)$. Crystals are usually of prismatic habit with striations parallel to the *b*-axis. May occur as granular or columnar masses. Hardness 6.5, sp gr 3.21–3.38, vitreous luster, transparent to translucent. Color gradations from gray through green to pink.

Clinozoisite occurs in crystalline schists, which are products of metamorphism from calcic feldspar-rich dark igneous rocks. Zoisite (orthorhombic) represents its dimorphous counterpart.

CLOUD POINT. (1) The temperature at which a solution becomes cloudy as it is cooled at a specified rate. The cloud point is an important property in the specification of lacquers, oils, and other industrial solutions.

(2) In petroleum technology, the temperature at which a waxy solid material appears as a diesel fuel is cooled. This material is harmful to engine performance. See also **Petroleum**.

COACERVATION. An important equilibrium state of colloidal or macromolecular systems. It may be defined as the partial miscibility of two or more optically isotropic liquids, at least one of which is in the colloidal state. For example, gum arabic shows the phenomenon of coacervation when mixed with gelatin. It also may be defined as the production, by coagulation of a hydrophilic sol, of a liquid phase, which

often appears as viscous drops, instead of forming a continuous liquid phase. See also **Colloid Systems**.

COAGULATION. 1. In its general scientific usage this term has two closely related meanings: (1) The process of complete or partial solidification of a colloidal solution to a gelatinous mass; or of the separation from a liquid system of a gelatinous mass. It involves the separation of the disperse from the continuous phase which fact distinguishes it from "gelation." (2) The result of an alteration of a disperse phase or of a dissolved solid which causes the separation of the system into a liquid phase and an insoluble mass, as the coagulation of egg albumin. See also **Colloid Systems**.

2. In cloud physics, coagulation is generally used synonymously with accretion. Less frequently, it refers to any process by which a cloud's numerous small cloud drops are converted into a smaller number of larger precipitation particles. When so used, the term is employed in analogy to the coagulation of any colloidal state. (See 1 above.)

3. In biological science, the term coagulation has two somewhat more specific meanings: (1) The clotting of blood or lymph. (2) The changes produced in tissue of the application of increased temperatures or by certain chemicals. See also **Anticoagulants**; and **Blood**.

Coagulation value, is the concentration of a coagulant that effects a given amount of coagulation of a colloidal, or other dispersed system.

COAGULATION (Hofmeister Series). A definite order of arrangement of anions and cations according to their powers of coagulation when their salts are added in quantity to lyophilic sols. Thus, the order of cations is $Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+} > Li^{+} > Na^{+} > K^{+} > Rb^{+} > Cs^{+}$. The Hofmeister series is also called the *lyotropic series*, and the effect is called salting-out, a term applied strictly to the effect of electrolytes upon true solutions.

COAL. Containing more than 50% (weight) and 70% (volume) of carbonaceous material, including inherent moisture, coal is a readily combustible rock. Coal was formed from the compaction and induration of variously altered plant remains similar to those found in peat. Coal was formed during earlier geological periods, the process of formation acting slowly over extremely long periods of time. Coal is not a uniform substance, but reflects the conditions of its formation. These include:

1. *Differences in the kinds of plant materials* from which the coal was derived account for different types of coal.
2. *Differences in the degree of metamorphism occurring* during the formation of coal determine the different ranks of coal.
3. *Differences in the range of impurity* in coal account for the *different grades of coal*.

The fermentation of vegetable matter under conditions of no air and abundant moisture where volatiles are retained, resulting in the formation of bitumens, such as peat and coal, is known as *bituminous fermentation*. The metamorphic transformation of bituminous coal into anthracite is known as *anthracitization*. *Coalification* is the alteration or metamorphism of plant material into coal; the biochemical process of diagenesis and the geochemical process of metamorphism in the formation of coal. The peat-to-anthracite theory of coal formation is described as a process in which the progressive ranks of coal are indicative of the degree of coalification and, by inference, of the relative geologic age of the deposit. Peat, as the initial stage of coalification, is of recent geological age. Lignite, as an intermediate stage, is usually Tertiary or Mesozoic, and bituminous coal and anthracite, as the more advanced stages of coalification, are usually Carboniferous.

Status of Coal as a Major Energy Source

In 1991 coal furnished 55% of the total fuel required to generate electricity in the United States. One ton of coal consumed by a power plant generates approximately 2000 kilowatt hours of electricity. Then current consumption of 772 million tons/year for electricity generation was expected to rise to close to 1.3 billion tons by the year 2030. Clean coal technologies will be mandated. Even after installation of considerable environmental correction equipment, coal remains the least expensive of the fossil fuels by a wide margin. The cost to generate a million Btu of energy for petroleum is $2.63; for natural gas, $1.18; and for coal, $0.77. U.S. recoverable coal reserves are approximate at 268 billion tons and, at current rates, would not be exhausted until the year 2230. That provides technology scores of years to further develop and refine renewable energy sources. Refer to **Alphabetical Index** for other energy sources.

The other principal coal-using categories are coke plants, industrial chemical and transportation applications, and residential and commercial uses.

The capital costs of environmental controls for coal-burning electric utility plants rose from 5% of total plant costs in the early 1970s to well over 35% near 1990s. The operating costs of environmental controls have followed a similar pattern. New coal-consuming generating technologies, such as fluidized-bed combustion and gasification-combined cycle, integrate emission controls so that the plant has greater flexibility in meeting emissions standards with a wide variety of coal types and may reduce the total cost of using coal. Nevertheless, such advanced technologies consume large quantities of fuel and produce significant amounts of solid wastes. The pollution problems associated with coal combustion are covered in the article on **Pollution (Air)**, the restoration of strip-mined land is covered in this article.

As reported by the World Energy Council, the United States has about 15% of the world's estimated recoverable coal, more than any other country except China. See Fig. 1. These statistics illustrate why the United States is a major exporter of coal.

Major Types of Coal

The major coals may be defined as follows:

Anthracite Coal. Coal of the highest metamorphic rank, in which the fixed carbon content is between 92 and 98%. It is hard, black, and has a semimetallic luster and semiconchoidal fracture. Anthracite ignites with difficulty and burns with a short, blue flame and without smoke. Anthracite coal is also known as hard coal, stone coal, kilkenny coal, and black coal.

Semianthracite Coal. Coal having a fixed-carbon content of between 86 and 92%. It is between bituminous coal and anthracite coal in metamorphic rank, although its physical properties more closely resemble those of anthracite.

Semibituminous Coal. Coal that ranks between bituminous coal and semianthracite. It is harder and more brittle than bituminous coal, has a high fuel ratio and burns without smoke. Semibituminous coal is also known as metabituminous coal which is defined as containing 89–91.2% carbon, analyzed on a dry, ash-free basis. The term smokeless coal also is used.

Bituminous Coal. Coal that ranks between sub-bituminous coal and semibituminous coal and that contains 15–20% volatile matter. It is dark brown-to-black in color and burns with a smoky flame. Bituminous coal is the most abundant rank of coal and is commonly Carboniferous in age. The most common synonym is soft coal.

Sub-bituminous Coal. A black coal intermediate in rank between lignite and bituminous coals, or in some classifications, the equivalent of black lignite. It is distinguished from lignite by higher carbon content and lower moisture content.

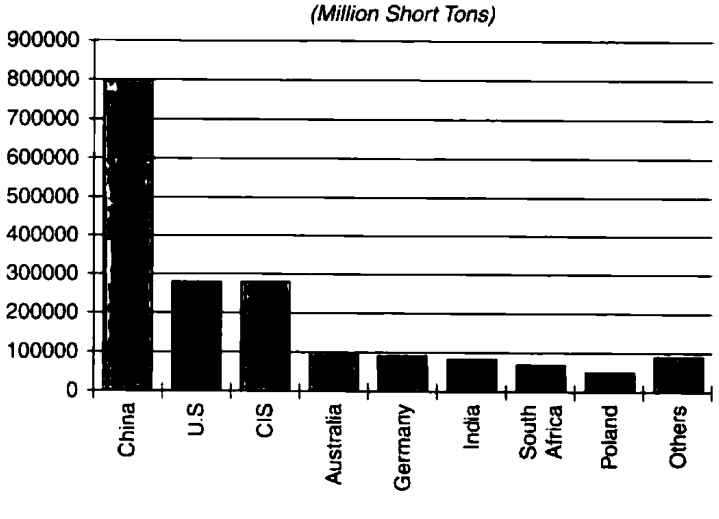

Fig. 1. World recoverable coal reserves (millions of short tons). (*World Energy Council*)

The sub-bituminous coals are further classified in terms of their calorific value:

Sub-bituminous A Coal—A type of sub-bituminous coal having 10,500 or more, but less than 13,000 Btu per pound (5838–7228 Calories/kg).

Sub-bituminous B Coal—A type of sub-bituminous coal having 9,500 or more, but less than 10,500 Btu per pound (5282–5838 Calories/kg).

Sub-bituminous C Coal—A type of sub-bituminous coal having 8,300 or more, but less than 9,500 Btu per pound (4615–5282 Calories/kg).

Lignite Coal. A brownish-black coal that is intermediate in coalification between peat and sub-bituminous coal; consolidated coal with a calorific value less than 8,300 Btu per pound (4615 Calories/kg), on a moist, mineral-matter-free basis. Synonyms include *brown lignite* and *brown coal.* Further classifications of lignite are made on the basis of calorific value:

Lignite A Coal—A lignite that contains 6,300 or more Btu per pound, but less than 8,300 Btu per pound (3503–4615 Calories/kg). Also known as *black lignite.*

Lignite B Coal—A lignite that contains less than 6,300 Btu per pound (3503 Calories/kg). Also known as brown lignite or brown coal.

Peat. This is an unconsolidated deposit of semicarbonized plant remains of a water-saturated environment, such as a bog or fen, and of persistently high moisture content (minimum of 75%). It is considered an early stage or rank in the development of coal. The carbon content is about 60%; oxygen content is about 30%. Structures of the vegetal matter can be seen. When dried, peat burns freely.

Peat Coal. This refers to two materials: (a) a coal transitional between peat and brown coal or lignite; and (b) an artificially carbonized peat that is used as a fuel.

Cannel Coal. A compact, tough *sapropelic coal* that contains spores and that is characterized by a dull-to-waxy luster, conchoidal fracture, and massiveness. It is attrital and high in volatiles. By American standards, it must contain less than 5% anthraxylon. Synonyms include *candle coal, kennel coal, cannel, cannelite, parrot coal,* and *curley cannel.* A sapropelic coal is derived from organic residues (finely divided plant material, spores, algae, etc.) in stagnant or standing bodies of water. Putrefaction is under anaerobic conditions rather than by peatification.

Ranks of Coal

Coals are classified in order to identify end-use and also to provide data useful in specifying and selecting burning and handling equipment and in the design and arrangement of heat-transfer surfaces. One classification of coal is by rank, that is, according to the degree of metamorphism, or progressive alteration, in the natural series from lignite to anthracite. Volatile matter, fixed carbon, inherent or bed moisture (equilibrated moisture at 30°C and 97% humidity), and oxygen are all indicative of rank, but no one item completely defines it. The classification of the American Society for Testing and Materials (ASTM) uses fixed carbon and calorific values, calculated on a mineral-matter-free basis, as the classifying criteria.

In establishing the rank of coals, it is necessary to use information showing an appreciable and systematic variation with age. For the older coals, a good criterion is the "dry, mineral-matter-free fixed carbon or volatile." However, this value is not suitable for designating the rank of the more recent, younger coals. A dependable means of classifying the

TABLE 1. CLASSIFICATION OF COALS BY RANK (ASTM)

		Fixed Carbon Limits, % (Dry, Mineral-Matter-Free Basis)		Volatile Matter Limits, % (Dry, Mineral-Matter-Free Basis)		Calorific Value Limits, Btu/Pound (Moist*, Mineral-Matter-Free Basis)		
Class	Group	Equal or Greater Than	Less Than	Greater Than	Equal or Greater Than	Equal or Greater Than	Less Than	Agglomerating Character
I Anthracite	1. Meta-anthracite	98	—	—	2	—	—	Nonagglomerating
	2. Anthracite	92	98	2	8	—	—	Nonagglomerating
	3. Semianthracite[c]	86	92	8	14	—	—	Nonagglomerating
II Bituminous	1. Low volatile bituminous	78	86	14	22	—	—	
	2. Medium volatile bituminous	69	78	22	31	—	—	
	3. High volatile A bituminous	—	69	31	—	14,000[a]	—	Commonly Agglomerating[b]
	4. High volatile B bituminous	—	—	—	—	13,000[a]	14,000	
	5. High volatile C bituminous	—	—	—	—	11,500	13,000	
						10,500[b]	11,500	Agglomerating
III Subbituminous	1. Subbituminous A	—		—	-	10,500	11,500	
	2. Subbituminous B	—	—	—	—	9,500	10,500	Nonagglomerating
	3. Subbituminous C	—	—	—	—	8,300	9,500	
IV Lignitic	1. Lignite A	—	—	—	—	6,300	8,300	
	2. Lignite B	—	—	—	—	—	6,300	Nonagglomerating

* Moist refers to coal containing its natural inherent moisture, but not including visible water on the surface of the coal.

[a] Coals having 69% or more fixed carbon on the dry, mineral-matter-free basis are classified according to fixed carbob, regardless of calorific value.

[b] It is recognized that there may be nonagglomerating varieties in these groups of the bituminous class, and there are notable exceptions in high-volatile c bituminous group.

[c] If agglomerating, the coal is classified in the low-volatile group of the bituminous class.

The terms, *mineral-matter-free fixed carbon*; and *mineral-matter-free Btu* are defined by the following formulas:

Parr formulas

Dry, Mm - free

$$FC = \frac{FC - 0.15S}{100 - (M + 1.08A + 0.55S)} \times 100, \%$$

Dry, Mm - free VM = 100 × Dry, Mm-free FC, %

Moist, Mm - free

$$Btu = \frac{Btu - 50S}{100 - (1.08A + 0.55S)} \times 100, \text{ per pound}$$

Approximation formulas

$$\text{Dry, Mm - free FC} = \frac{FC}{100 - (M + 1.1A + 0.1S)} \times 100, \%$$

Dry, Mm-free VM = 100 - Dry, Mm-free FC, %

$$\text{Moist, Mm - free Btu} = \frac{Btu - 50S}{100 - (1.1A + 0.1S)} \times 100, \text{ per pound}$$

Symbols Used: Mm = mineral matter; Btu = heating value per pound; FC = fixed carbon,%; VM = volatile matter, %; M = bed moisture,%; A = ash, %; S = sulfur, %, all for coal on a moist basis.

Conversion Factor: 1 Btu/pound = 0.556 Calories/kg.

latter is the "moist, mineral-matter-free Btu" which varies little for the older coals, but appreciably and systematically for younger coals.

Classification of major coals according to rank or age is given in Table 1. The criteria given in the prior paragraph are used in classifying the older and younger coals. Seventeen United States coals are arranged in order of the classification of Table 1 and presented in Table 2.

Classification of coals in Europe and other parts of the world differs somewhat from the American system. European classifications include: (1) the *International Classification of Hard Coals by Type*; and (2) the *International Classification of Brown Coals*. These systems were developed by a Classification Working Party established in 1949 by the Coal Committee of the Economic Commission for Europe. The term "hard coal" is defined as a coal with a clorific value of more than 10,260 Btu per pound (5705 Calories/kg) on the moist, ash-free basis. The term "brown coal" refers to a coal containing less than 10,260 Btu per pound (5705 Calories/kg). In European terminology, the term "type" is equivalent to rank in American coal classification terminology and the term "class" approximates the ASTM rank. Space does not permit a full comparison of the various systems. Reference to various ASTM publications is suggested.

Commercial Sizes of Coal

Anthracite Coal. Standard sizes for anthracite coal are indicated in Table 3. The broken, egg, stove, nut and pea sizes are largely used for hand-fired domestic units and gas producers. Buckwheat and rice are used in mechanical types of firing equipment.

Bituminous Coal. The sizes of bituminous coal are not well standardized, but the following sizings are commonly recognized:

(*Run of Mine*)—Coal that is shipped from the mine without screening. It is used for both domestic heating and commercial steam production.

(*Run of Mine—8-inch*)—This is run-of-mine coal with oversize lumps broken up. (8 inches = 20.3 centimeters.)

(*Lump—5-inch*)—This size will not go through a 5-inch round hole. It is used for hand-firing and domestic purposes. (5 inches = 12.7 centimeters.)

(*Egg—5 by 2-inch*)—This size goes through a 5-inch hole, but is retained on 2-inch round-hole screens. It is used for hand-firing, gas producers, and domestic firing. (5 × 2 inches = 12.7 × 5.1 centimeters.)

(*Nut—2 by $1\frac{1}{4}$-inch*)—This size is used for small industrial stokers, gas producers, and hand-firing. (2 × $1\frac{1}{4}$ inches = 5.1 × 3.2 centimeters.)

(*Stoker Coal—$1\frac{1}{4}$ by $\frac{3}{4}$-inch*)—This size is largely used for small industrial stokers and domestic firing. ($1\frac{1}{4}$ × $\frac{3}{4}$ inches = 3.2 × 1.9 centimeters.)

TABLE 3. ANTHRACITE COAL SIZES

Name Used in the Trade	Diameter of Hole: Will Pass Through, Inches	~Centimeters	Will Not Pass Through, Inches	~Centimeters
Broken	$4\frac{3}{8}$	11.1	$3\frac{1}{4}$ to 3	8.3 to 7.6
Egg	$3\frac{1}{4}$ to 3	8.3 to 7.6	$2\frac{7}{16}$	6.2
Stove	$2\frac{7}{16}$	6.2	$1\frac{5}{8}$	4.1
Nut	$1\frac{5}{8}$	4.1	$\frac{13}{16}$	2.1
Pea	$\frac{13}{16}$	2.1	$\frac{9}{16}$	1.4
Buckwheat	$\frac{9}{16}$	1.4	$\frac{5}{16}$	0.8
Rice	$\frac{5}{16}$	0.8	$\frac{3}{16}$	0.5

(*Slack—$\frac{3}{4}$-inch and under*)—This is used for pulverizers, cyclone furnaces, and industrial stokers. ($\frac{3}{4}$-inch = 1.9 centimeters.)

Geology of Coal

Coal is interspersed as individual beds within other types of sedimentary rock beds, including sandstones, limestones, clays, shales, and mixtures of these materials. The plant material that ultimately became coal deposits was accumulated in upland bogs, coastal or near-coastal swamps, or delta plains. It is envisioned that the conditions were somewhat similar to the conditions existing today in the Okefenokee Swamp in Georgia or the Everglades of Florida. These areas may have varied from a few acres to several hundreds of square miles (hectares/square kilometers). Hence, the variation in the occurrence of coal as we find it today.

For the geological processes (coalification) to convert such plant materials into coal, it was necessary that the original swamps be submerged—by way of rises in sea level or land subsidence. Probably many submersive actions occurred with intermittent deposition of calcareous materials deposited from water containing muds, sands, and slimes. As the result of a series of compactions, with varying depths of burial, heat, and pressure, and length of time, the progress of coalification also varied—from peat to lignite, to sub-bituminous coal, to bituminous coal, possibly to anthracite.

TABLE 2. REPRESENTATIVE UNITED STATES COALS ARRANGED IN ORDER OF ASTM CLASSIFICATION

Coal rank: Class	Group	State	County	Coal analysis, bed moisture basis: M	VM	FC	A	S	Btu	Rank FC	Rank Btu
I	1	Pennsylvania	Schuylkill	4.5	1.7	84.1	9.7	0.77	12,745	99.2	14,280
I	2	Pennsylvania	Lackawanna	2.5	6.2	79.4	11.9	0.60	12,925	94.1	14,880
I	3	Virginia	Montgomery	2.0	10.6	67.2	20.2	0.62	11,925	88.7	15,340
II	1	West Virginia	McDowell	1.0	16.6	77.3	5.1	0.74	14,715	82.8	15,600
II	1	Pennsylvania	Cambria	1.3	17.5	70.9	10.3	1.68	13,800	81.3	15,595
II	2	Pennsylvania	Somerset	1.5	20.8	67.5	10.2	1.68	13,720	77.5	15,485
II	2	Pennsylvania	Indiana	1.5	23.4	64.9	10.2	2.20	13,800	74.5	15,580
II	3	Pennsylvania	Westmoreland	1.5	30.7	56.6	11.2	1.82	13,325	65.8	15,230
II	3	Kentucky	Pike	2.5	36.7	57.5	3.3	0.70	14,480	61.3	15,040
II	3	Ohio	Belmont	3.6	40.0	47.3	9.1	4.00	12,850	55.4	14,380
II	4	Illinois	Williamson	5.8	36.2	46.3	11.7	2.70	11,910	57.3	13,710
II	4	Utah	Emery	5.2	38.2	50.2	6.4	0.90	12,600	57.3	13,560
II	5	Illinois	Vermilion	12.2	38.8	40.0	9.0	3.20	11,340	51.8	12,630
III	1	Montana	Musselshell	14.1	32.2	46.7	7.0	0.43	11,140	59.0	12,075
III	2	Wyoming	Sheridan	25.0	30.5	40.8	3.7	0.30	9,345	57.5	9,745
III	3	Wyoming	Campell	31.0	31.4	32.8	4.8	0.55	8,320	51.5	8,790
IV	1	North Dakota	Mercer	37.0	26.6	32.2	4.2	0.40	7,255	55.2	7,610

Note: Definition of coal rank is given in Table 1.
M = equilibrium moisture, %; VM = volatile matter, %; FC = fixed carbon,%; A = ash, %; S = sulfur, %; Btu = high heating value, Btu per pound; Rank FC = dry, mineral-matter-free fixed carbon,%; Rank Btu = moist, mineral-matter-free Btu per pound.
All calculations are per the Parr formula defined in Table 1.
Conversion Factor: 1 Btu = 0.2520 Calorie.

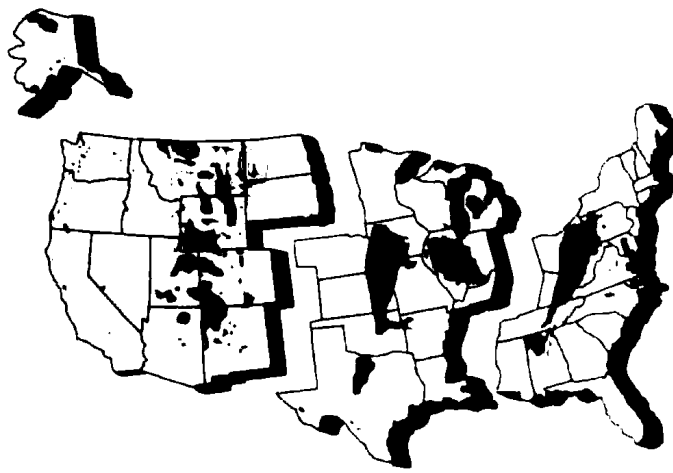

Fig. 2. Main coalfields in the United States. In the United States coal is truly a national resource that is present in 38 states, stretching from the East to West coasts. About half of these coal deposits are located in the western United States, including Alaska; 28% of the deposits are in the interior of the country and 22% occur in Appalachia. The western United States includes a huge deposit called "Wyodak," which currently is the leading source of coal production. The Powder River Basin in Wyoming and southeastern Montana is part of this deposit. This western coal combines with significant low-sulfur reserves in the East to provide an important source of low-sulfur coal for electric power plants. Coal "seams" or deposits in this basin average 70 feet (21.3 meters) in thickness, although some exceed 100 feet (33.6 meters). In the East the most important deposits are in the Appalachian Basin, an area encompassing 72,990 square miles (189,044 square kilometers). The lighter shading shows a large lignite deposit. (*National Coal Association*)

Major coalfields in the United States are shown in Fig. 2.

Coal Formation in the United States. It is postulated that coal formed in the U.S. during three major geological periods.

1. During the Pennsylvanian (Carboniferous) period which dates back approximately 300 million years. Deposits include the predominately bituminous coal beds in the Appalachian Province extending from Pennsylvania (including the anthracite beds in central Pennsylvania) into northeastern Alabama. Also the contiguous Eastern Interior Region of Illinois, southwestern Indiana, and western Kentucky; in the contiguous Western Interior Region of Iowa, Kansas, Missouri, northeastern Oklahoma and northwestern Arkansas; and in the separated central portion of Texas (excluding Texas lignite).
2. During the Cretaceous period which dates back approximately 100 million years. Deposits include the predominately bituminous and sub-bituminous coal beds in the Rocky Mountain Province, extending in large, separated regions from central Montana into northeastern Arizona and northwestern New Mexico.
3. During the Tertiary period which dates back approximately 65 million years. Deposits include the sub-bituminous coal and lignite beds in the Great Plains Province, which includes northeastern Wyoming, eastern Montana, western North Dakota, and northwestern North Dakota.

Coal beds form only a very small percentage of the total thicknesses of the overall sedimentary strata comprising the so-called "Coal Measures" in coal-bearing areas. The thicknesses of individual coal beds within the United States range from a few millimeters (horizon markers) to as much as 100 feet (30 meters) or more. The number of individual coal beds of commercial significance may range from less than 10 feet (3 meters) to over 100 feet (30 meters). The coal, however, is rarely found in full vertical sequence at any one particular spot, but usually is distributed unevenly in single beds or small groups of beds around the margin or within the interior of the generally basin-shaped areas of coal-bearing strata.

Depending on the desired or feasible rate of annual production, the amounts of coal reserves required to support a new mine designed for an economic life of 20 years or more may range from a comparatively few tons to 300 million tons or more. Such amounts are dependent upon the coal-bed thickness and the ease of mining and particularly whether surface or underground mining techniques will be required. Thus, a given mining area may range from as little as one thousand acres to as much as 50 square miles (130 square kilometers).

A variety of detrimental irregularities may accompany or interrupt an otherwise orderly accumulation of plant material either during swamp growth or shortly thereafter. While many coal beds or portions of beds are relatively low in ash content, other beds or portions of beds may contain depositional admixtures of particles of mud or silt which were washed or blown into the swamp during plant growth. Where relatively abundant, these particles serve to increase the ash content of the eventual coal bed and thus to decrease its quality correspondingly. During periods of prolonged swamp flooding, layers of mud or silt may have been deposited on the preexisting plant accumulations. Such deposition then may have been followed by additional plant accumulation. Such layers of impurities between underlying and overlying accumulations of plant materials, eventually hardening into shales or silty shales, are called *partings*. These may range from knife-edge thickness to thicknesses of up to a foot ($\frac{1}{3}$ meter) or more. Such partings within a single coal bed decrease the quality of the coal as mined and impair the mining procedures, particularly when such partings have become pyritized.

Such partings are not always evenly deposited over large portions or the entire extent of a coal-forming swamp, but may become progressively thicker toward the source of the deposited material. The partings may be wedge-shaped, with the overlying plant material occurring increasingly higher above the underlying plant material and sometimes becoming increasingly thinner to the point of disappearance. Deposition of impurities in this manner results in splitting the total thickness of the coal bed into two or more diverging *benches*. This causes mining difficulties and sometimes a bench may be so thin as not to be economically recoverable.

In some coal beds, relatively flat, lenticular masses ranging up to several feet in diameter, composed of pyrite, calcite or siderite, were formed during plant growth. Such materials (concretions) may represent the eventual immediate roof of the coal bed. These concretions impede mining operations and cause a hazard because of their tendency to drop out of the roof unexpectedly during operation of the mine.

From initial deposition and burial under overlying sedimentary materials through succeeding geological periods, coal beds are continually subject to the action of ground water. Thus, some coal beds have developed a system of essentially vertical fractures—thin cracks, often filled with coatings of pyrite, calcite, kaolinite and other minerals deposited from ground water. Impurities from these veins lower the quality of the coal.

During the long periods since formation, many coal beds have been subject to folding and sharp deformation, resulting in specific dislocations or faults. Such shifting may range from a foot or two (less than one meter) to several hundred feet (meters) and even up to thousands of feet (meters) in linear extent. The coal and lignite fields in the Great Plains Province are relatively undisturbed. The coal-bearing strata in the Appalachian Province are relatively flat along their northwestern margin, but increase in intensity of relatively mild but significant folding toward the southeast at right angles to the regional northeast-southwest trend of the component coal fields. The coal beds in the various basins comprising the Rocky Mountain Province range from comparatively gentle slopes of but a few degrees over areas of broad extent to areas of similar extent with prevailing dips of up to 20 or 30°, along with a few areas of limited extent where the coal beds are highly deformed.

Exploration Techniques. The diamond core drill historically has been the most extensively used tool in coal exploration. Cores of coal, properly recovered, enable accurate seam descriptions and measurements; also provide material for chemical analysis. Geologging or electric logging, used for several years in the oil and gas fields, is now gaining acceptance in coal-exploration technology. The system involves hoisting a sensor up the length of a drill hole while electric pulses are transmitted through the hoist cable to a console in a truck or on the surface. Here instruments record the variations in properties of the rock strata as a function of hole depth. The electric curves usually run in coal exploration are resistivity and spontaneous potential. Radiometric or nuclear curves include gamma ray, neutron, and the density or gamma-gamma log.

The impurities in coal beds, present either as distinct partings or disseminated throughout, are composed of clay materials that have a high density and a high natural radioactivity relative to coal. Consequently, the

gamma ray and density curves, invaluable for bed correlation and thickness determination, also can be used as semiquantitative indices of coal quality.

Coal Mining Technology

The manner in which coal is mined depends upon several factors, including depth of the coal bed from the surface and the geological character of the terrain. Generally, coal that is 200 feet (61 meters) or more from the surface is mined *underground*, using "deep mining" techniques. Shallow deposits are extracted by surface *mining* methods. Of the approximately 3500 operating mines in the United States, the number is virtually split between the two methods. The trend in total number of mines, since 1980, has trended downward, while the production per mine has increased to 500,000 tons of coal or more. This trend has resulted from greater mechanization, the use of large-capacity equipment, and access to large blocks of coal from which to form *mining units*, especially in the western states.

Surface Mining. This method of mining permits removal of as much as 90% of the total coal from a given deposit. Very large dragline excavators are used to remove the overburden (rock and soil covering the coal). Other equipment includes power shovels for loading operations, front-end loaders, trucks, and bucketwheel excavators. Land restoration has become an intimate part of the total surface mining operation. Reclamation is required by both federal and state laws.

Since passage of the federal Surface Mining Control and Reclamation Act (1977), the U.S. coal industry has reclaimed in excess of 2.5 million acres (1+ million hectares). This is an area larger than the state of Delaware. Also, more than 100,000 additional acres of abandoned mines, remnants of neglect from prior years, have been reclaimed through funds paid by coal producers into a national land trust. Responsible coal operators are guided by the principle that the right of coal extraction carries with it the responsibility of restoring the land. Reclaimed sites are returned to productive use, depending upon location, to farms, parks, and building sites. Surface mining equipment and methodologies are shown in Figures 3 through 9.

Underground Coal Mining. In general, most underground coal is mined by the room-and-pillar system, which involves excavating a series of "rooms" into the coalbed and leaving "pillars" or columns of coal to help support the mine roof. More than half of the coal taken from underground mines is produced by *continuous mining*, which uses a specialized cutting machine that mechanizes the entire extraction process. This "continuous miner" tears the coal from a seam and automatically removes it from the area by conveyor. See Figures 10 and 11.

Another form of underground mining is known as conventional mining. This process accounts for about 11% of deep-mined coal and consists of a series of operations that involve cutting the coalbed so that it breaks easily when blasted with explosives. The broken coal then is ready to be removed from the mine. Where the geology is favorable, this is the most practical and economical underground mining method.

Shortwall Mining. This method is used in relatively few underground mines. It involves the use of a continuous mining machine and movable

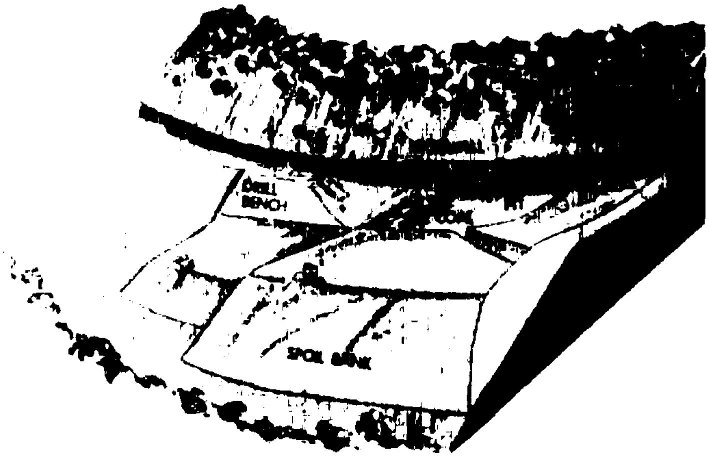

Fig. 3. Early method of contour surface mining. This was the predominant way of mining throughout Appalachia until passage of stringent legislation that ushered in a new integrated mining technique. (*Caterpillar Inc*)

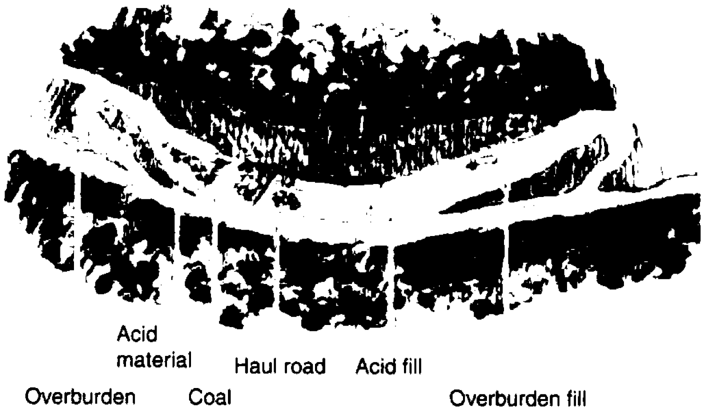

Fig. 4. Haulback method of surface mining. Using either scrapers or off-high way trucks, the major principle of this method is that all spoil except that from the initial cut is moved along the bench rather than being placed on the outslope. (*Caterpillar Inc*)

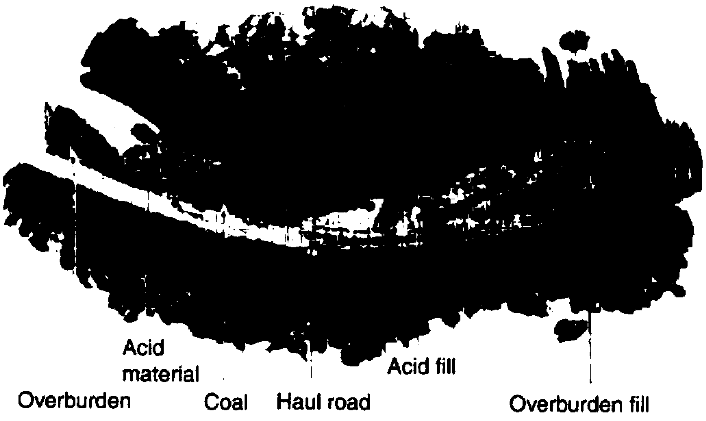

Fig. 5. Truck haulback method of surface mining is used mainly in rocky overburden, which is uneconomical for loading by scrapers. With either truck or scraper haulback operations, nonacid rock or clay overburden is placed over acidic material to facilitate revegetation. (*Caterpillar Inc*)

Fig. 6. Valley fill method of surface mining. In this method the miner generally hauls overburden in trucks and constructs fills over the side at bench height. When scrapers are used, the operator ejects overburden at bench height and tractors doze it over the edge. (*Caterpillar Inc*)

roof supports to shear coal panels 150 to 200 feet (46–61 meters) wide and more than 0.5 mile (0.8 kilometer) long.

Longwall Mining. With favorable geology, an increasing amount of underground coal production is the result of *longwall mining*. This is one of the most important technological advances to impact the coal

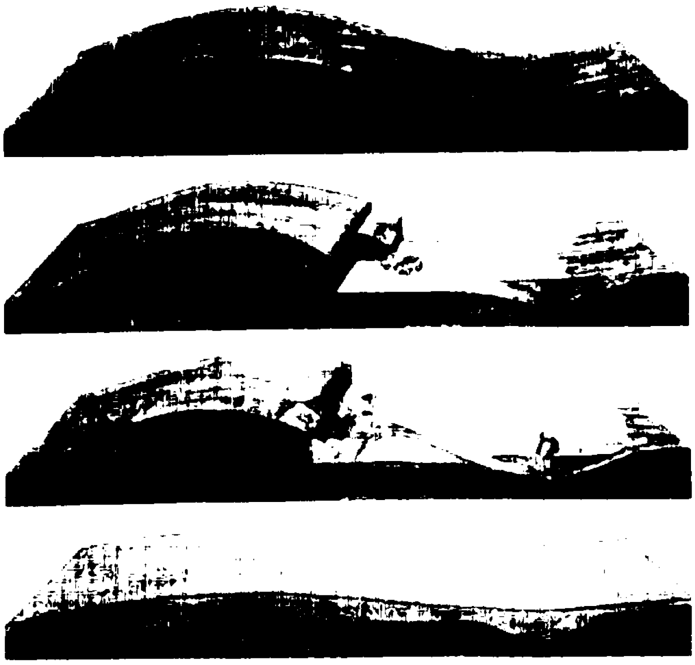

Fig. 7. In mountaintop leveling, a part of the mountain top is moved to fill an adjacent valley and build a near-level fill in the mined area. The reclaimed flat or gently rolling land that results from this type of operation can then be used for a variety of purposes which could increase the value of the land. (*Caterpillar, Inc*)

Fig. 9. An 85-ton capacity off-highway truck for use in hauling overburden in a surface mine. (*Caterpillar, Inc*)

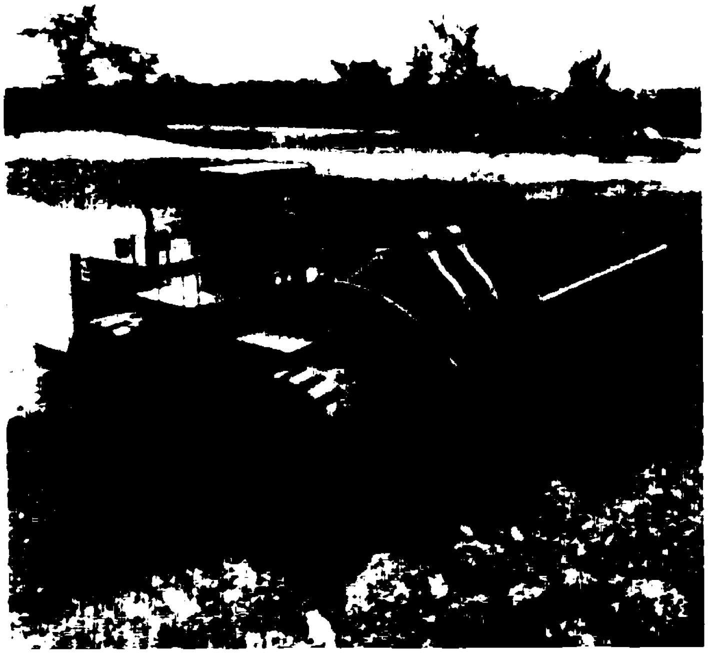

Fig. 8. A 13.5 cubic yard (10.3 cubic meter) wheel loader working a load-and-carry operation in a surface mine. (*Caterpillar Inc*)

Fig. 10. Continuous mining machine used in underground mine. As coal accumulates on the mine floor, the helical screw effect of the cutting head constantly moves the pile toward the center of the head, contributing to fast loading and improved productivity and cleanup. Two powerful motors handle all motions of the machine. Safety provisions are incorporated in the design. (*National Coal Association*)

industry since the introduction of mechanized equipment a half-century ago. This methodology has made a significant contribution toward doubling underground mining productivity over recent decades. The production of coal per shift from longwall is, on average, more than double that of either conventional or continuous mining. Coal recovery rates of 80% are possible under favorable circumstances.

In the longwall system, which originated in Europe, two parallel entries are excavated from the main mine entry directly into the coal seam. The parallel entries, which may be as much as 750 feet (365 meters) apart or more, are then joined together at their far end by a crosscut. The coal face that is formed at the crosscut is called the "longwall."

In a longwall operation, a rotating shear or plow on a mining machine moves back and forth across this long seam, cutting and transporting the coal from the face by a conveyor system that is part of the mining machine. The machine has its own movable electrohydraulic roof supports, or "walking props," that are advanced as the seam is removed. The mined-out areas behind the roof support are allowed to cave. In addition to supporting the roof, these props also help protect the work area, increasing safety. Longwall mining units and the mining cycle are remotely controlled, usually by a miner stationed in one of the entries.

There are about 100 longwall mining installations in U.S. underground mines, most of which are located in Appalachia and the Midwest. The applicability of the methodology to a specific coalbed depends upon several factors, including the thickness and suitability of the seam and the strength of the surrounding strata. See Fig. 12.

Fig. 11. Closeup of cutting edge and helical screw, which cuts and removes coal from the mine seam. (*National Coal Association*)

High-Pressure Mining Techniques. In the early 1990s a joint effort was undertaken by the University of Missouri and the National Aeronautics and Space Administration's Jet Propulsion Laboratory, to develop a prototype of a machine known as RAPIERS (Room and Pillar In-Seam Excavator/Roof Supporter). This machine employed a pair of jet-lances to carve a horizontal slot in the center of the face of the seam. Hydraulic jets then progressively cut vertical slots, using wedge-shaped cutters to move the coal toward the center slot. Mechanical arms transferred the cut pieces of coal onto a conveyor belt. With the use of water, coal dust was kept to a minimum. The machine also could support the tunnel ceiling prior to the installation of support bolting.

Coal Preparation Plants

Raw coal from the mine must be treated (washed, sized, sorted, etc.) prior to shipment to the end user. The amount of refuse discarded may be up to 20% of the raw coal. Power plants and other coal consumers use transport systems, furnaces, heaters, reactors, and the like that demand *uniform* feedstocks. Coal preparation plants are not highly standardized because of differences in the physical and chemical properties of the raw coal from one mine location to the next. See Fig. 13.

Since most coal impurities have specific gravities greater than coal, the density of a coal particle is a direct measure of its purity. The differences in this physical parameter is the basis for mechanical separation of coal from refuse. Both gravity and centrifugal force devices are used and these may employ air or liquids as washing media. There are relatively few instances where air washing will work because of the moisture required to be on the coal to meet mining regulations. The few cases where the raw coal is dry enough for air washing require a complete dust collection system to meet air pollution standards. Thus, few plants utilize air washing. There may be a trend to air washing in the western coal fields because of the scarcity of water.

Washing processes fall into three classes: (1) hydraulic separation; (2) dense medium separation; and (3) centrifugal (cyclone) separation.

Hydraulic separation depends on a process called jigging, which creates a particle stratification from an alternate expansion and compaction of a bed of particles by a pulsating fluid flow. As originally developed, a basket filled with material was moved up and down in a tank filled with water. The more modern Baum jig process utilizes an air impulse concept in which the water is moved by air pressure from an adjacent sealed chamber. There are several refinements of the process, including the McNally Norton standard washer.

More accurate separations are made in dense medium vessels. Coal is slurried in a medium with a specific gravity close to that at which the separation is to be made. The lighter coal tends to float and the refuse to sink. The two fractions then can be mechanically separated. Theoretically, any size particle can be treated by the dense medium process. Practically, the sizes range from about 0.5 millimeter to about 6 inches (15 centimeters). Organic liquids, salt solutions, aerated solids and water suspensions have found use as commercial media. Water suspensions meet most practical requirements and are the least costly. The bulk of coal mechanically cleaned by the dense medium process is separated in suspensions of magnetite in water.

The use of centrifugal force as an aid in coal-refuse separation is a relatively recent addition to the coal-cleaning process. As originally developed, the device employed a dense working medium. The latest units do not employ an artificial gravity suspension and are known as hydrocyclones. Design of the unit allows the formation of a hindered settling bed as the dense particles move down the side wall under the force of gravity. Less dense particles are unable to penetrate this heavy bed and move back into the main hydraulic current and are discharged out the top of the unit.

Tables are also used to wash coal. The reciprocating action of a table stratifies the high-gravity coal particles on the bottom and the low-gravity particles rise to the upper level of the bed. As the low-gravity particles rise, they are moved across riffles that separate the high- and low-gravity material by the water flowing to the low side of the table deck. The refuse is trapped in the riffle troughs and the motion of the deck moves the refuse to discharge off the end.

For separating fine coal particles from refuse particles, flotation is often used. Finely disseminated air bubbles are passed through a coal slurry. The fine coal particles adhere to the air bubbles and rise to the top where they are removed as a concentrate while the heavy refuse particles sink and are removed by the flow of water through the flotation cell. A frothing reagent, such as methylisobutylcarbinol, is added to the feed. See also **Classifying (Process)**.

Water remaining on marketable coal is a contaminant as serious as the undesirable ash. It may cause problems in handling and shipping, increase freight cost, and reduce heating value per unit weight. The difficulty of dewatering increases with increases in the surface area of the material. Several processes are used, depending upon the particle size of the coal. Vibrating-screen type centrifuges may be used. For the removal of very fine material (28-mesh and smaller), a filter process may be required. Both disk-type and drum-type filters are used. Where filters are required, filtration is usually preceded by sedimentation. Chemical flocculants sometimes are used to assist the settling process. A final reduction of moisture content frequently is accomplished by thermal drying. The use of fluidized bed coal dryers is increasing.

Transportation of Coal

Railroads handle approximately 60% of the coal mined in the United States during some part of its journey from mine to point of consumption or shipment overseas. Most American railroads offer four distinct types of service for the transportation of coal: (1) single carload; (2) multiple carload; (3) trainload volume; and (4) unit train. Each type of freight service has its own operating characteristics, which result in a distinct level of operating cost and freight rates. The first two methods are self-evident. Trainload volume is the tendering of a sufficient number of carloads of freight on one day from one origin to one destination to permit the carrier to handle the movement in a special train. The number of carloads required to form a trainload will vary from one railroad to the next. Trainload volume movements are an irregular movement on an irregular schedule. The basic operation requires simplified switching and terminal operations, resulting in economies in rail operation. Trainload volume trains use rail cars assigned to a car pool. The trains are governed by tariff provisions requiring a limited control over the loading and unloading of the railroad equipment and occasionally requiring a minimum annual volume.

A unit train movement is an integral movement of coal moving from a single origin to a single destination on a regularly scheduled train, avoiding all terminals and switching operations. Unit trains utilize specialized loading and unloading facilities and specialized railroad equipment assigned to dedicated service. The unit train movement is governed by tariff provisions requiring both controlled loading and unloading of the railroad equipment and a minimum annual tonnage. The loading of a unit train at the York Canyon Mine (New Mexico) is shown in Fig. 14. When large volumes of coal are to be loaded within a short time, some form of flood-loading is required, permitting the coal to free fall into the cars. The four basic types of flood-loading are: (1) Ground storage with loading tunnel; (2) ground storage with loading bin; (3) silo storage; and (4) silo

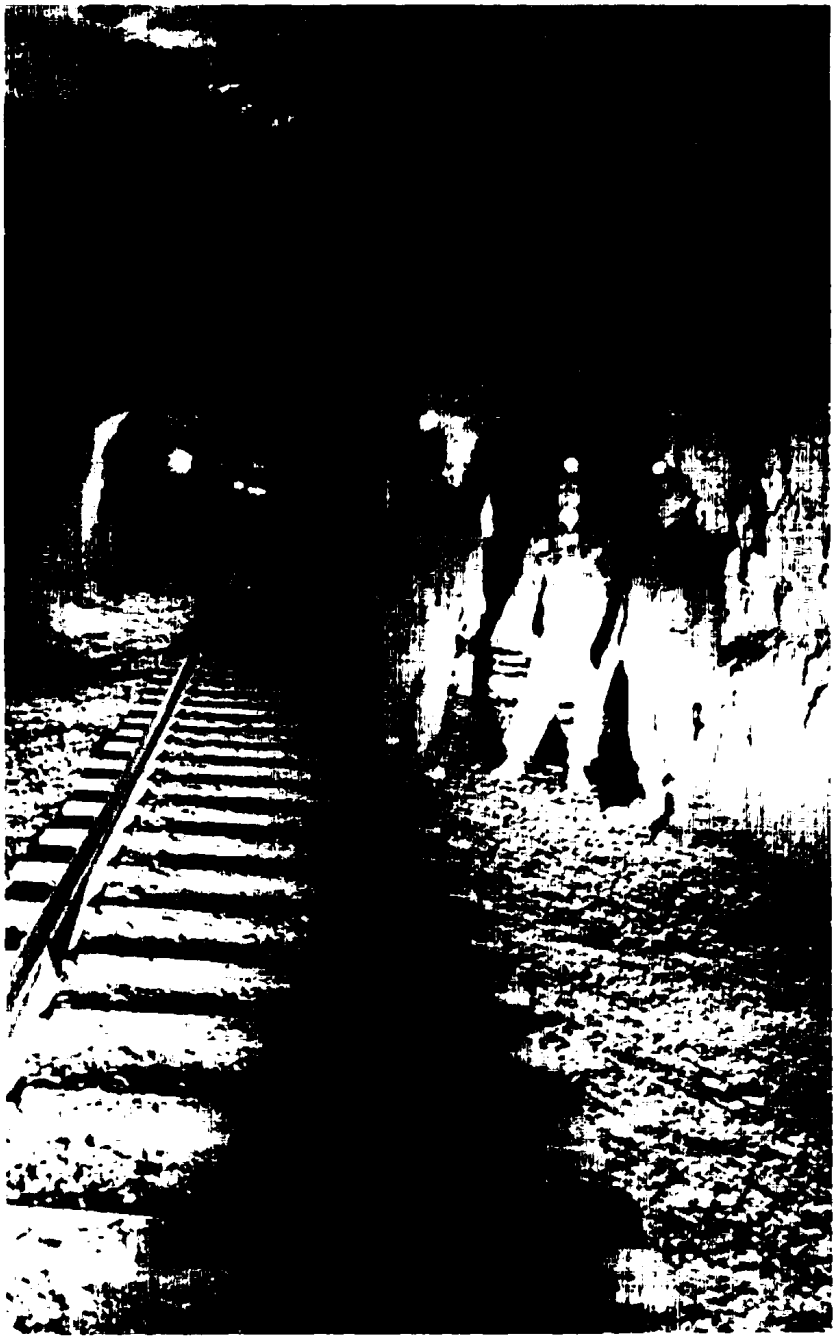

Fig. 12. Example of longwall mining. (*National Coal Association*)

storage with loading bin. The first type is used in the system shown in Fig. 14. A unit train being loaded from a storage silo is shown in Fig. 15.

The unloading of coal cars can be accomplished by several methods. A unit train with conventional hopper cars would be unloaded with the cars being spotted over the storage area. The gates on the cars would be opened by laborers stationed alongside the rail cars. After the first cars over the unloading area were discharged, the train would move forward until the next loaded car is moved into place. This spotting, unloading, and spotting sequence must be repeated perhaps a hundred times until the entire train is unloaded.

A unit train with quick-opening bottom-drop cars would be unloaded by having the gates on the rail cars opened by either a mechanical tripping mechanism or by an electrical device as the cars roll over the pit or trestle. After the cars are unloaded, the gates on the cars would be closed by a similar mechanical or electrical mechanism. Motion unloading systems, although costly, represent many advantages. Proceeding across the pit area at 4 to 5 miles (6.4 to 8 kilometers) per hour, a 100-car, 10,000-ton (9000-metric ton) unit train can be unloaded in 15 minutes. Considering startup time, the total unloading time may approximate one hour. The same 100-car unit train, in an efficient two-car rotary dump facility, will require from 4 to 5 hours to unload the train. If a single-car rotary dump facility were used, the unloading time will range from 8 to 12 hours. A motion unloading facility is illustrated in Fig. 16.

After coal arrives at its destination for consumption—say an electric power generating plant—considerable handling remains prior to the coal-fired boilers. See Figs. 17 and 18.

Barge and Truck Transport of Coal. Approximately 28% of U.S. coal is transported by barges over inland waterways. Trucks account for approximately 13% and used mainly for deliveries of 100 miles (161 kilometers) or less. Because of weight limitations, trucks are not used for long hauls.

Coal Slurry Pipelines. The first patent covering the pumping of coal and water dates back to 1891. In 1914, the first commercial transport of coal in water was carried out in England, when a short 8-inch (20-centimeter) pipeline was used to carry coal from river barges to a power plant. Thereafter, several proposals were submitted for the long distance transport of coal from mine to market in the eastern United States, but failed to materialize for several reasons, not the least of which were technical problems. Intensive research into slurry transport was continued and, by 1957, technology and engineering had advanced to the point where the

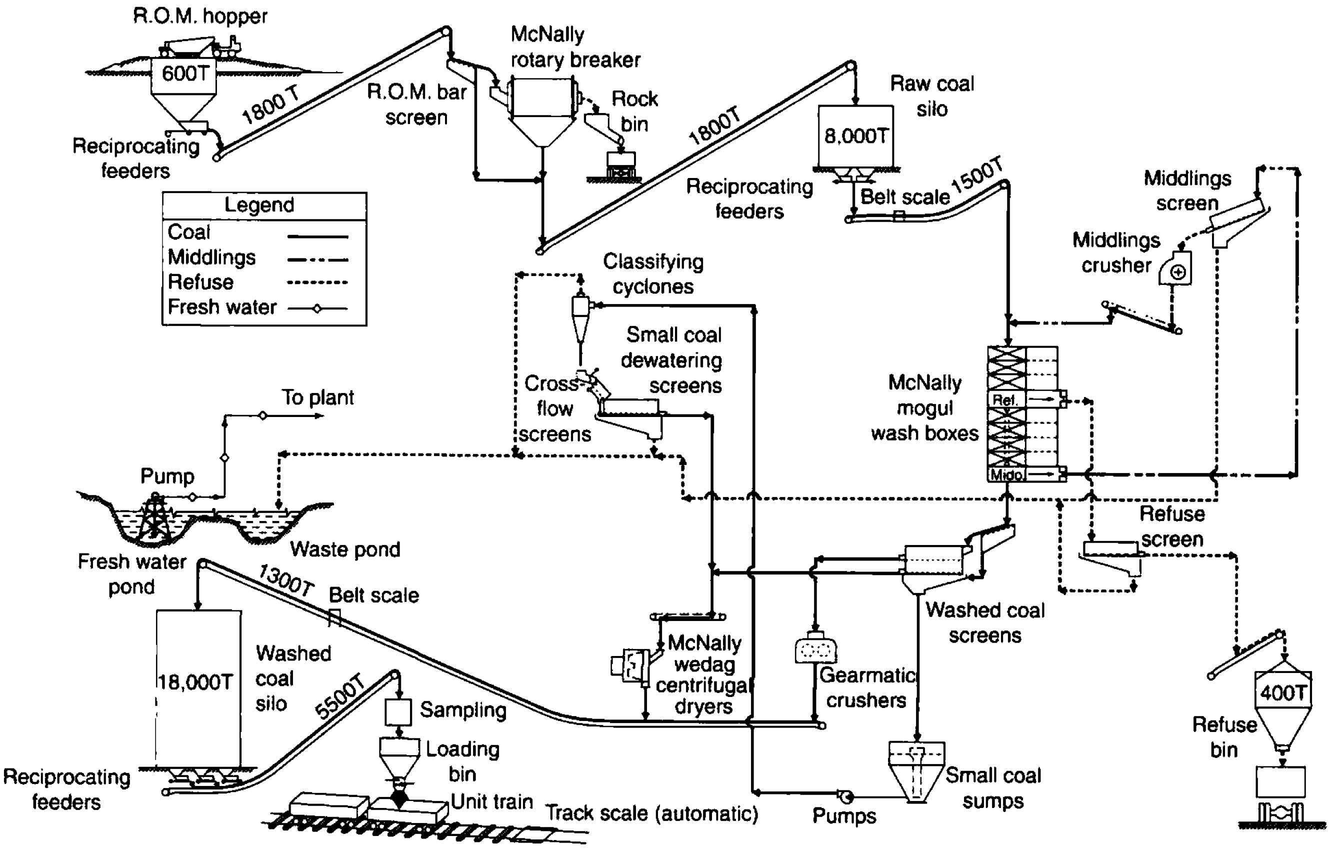

Fig. 13. Coal preparation plant. (*McNally Pittsburgh Mfg. Corp*)

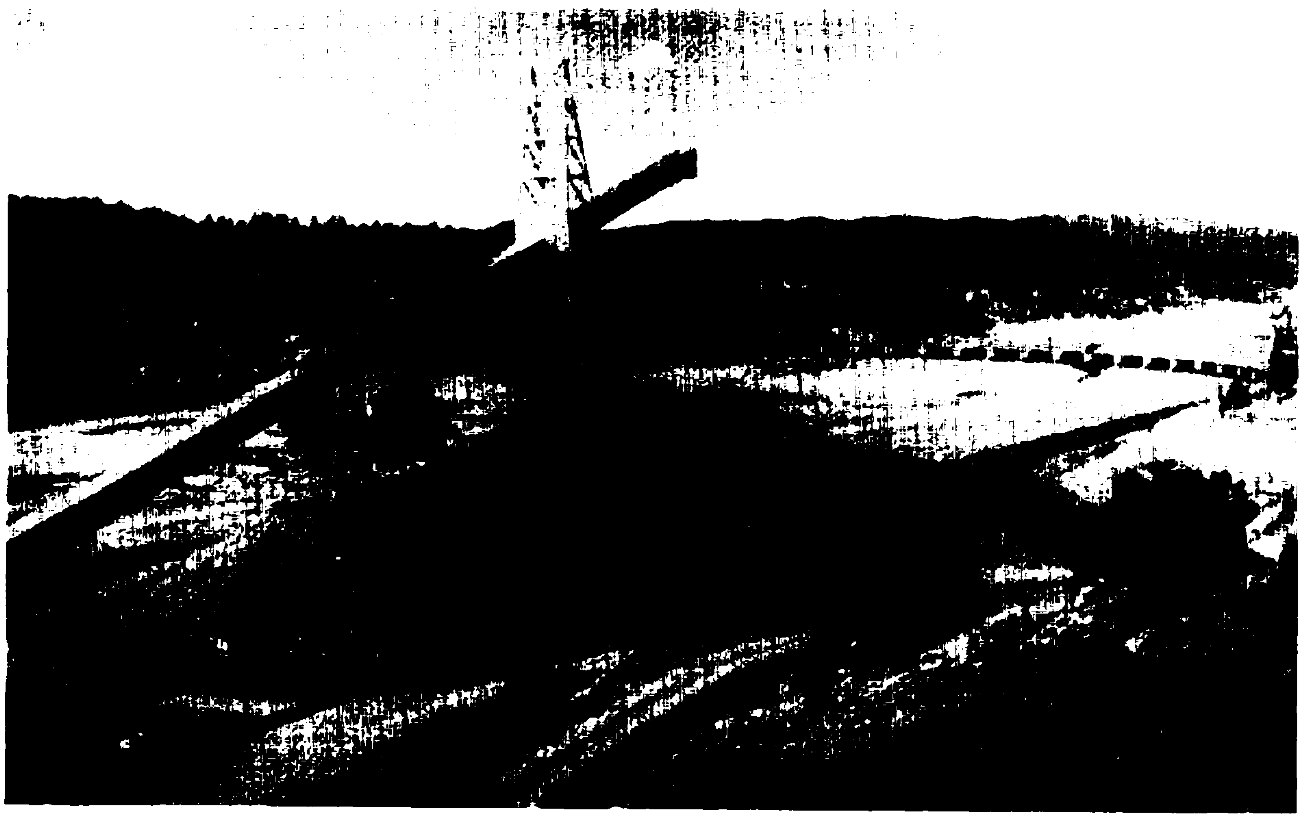

Fig. 14. Unit train being loaded at a New Mexico mine. (*McNally Pittsburgh Mfg. Corp*)

first long distance transportation of coal in water was feasible. The result was construction and operation of the Consolidation Coal Pipeline, 10 inches (~25 centimeters) in diameter and 108 miles (174 kilometers) in length, transporting 1.25 million tons (~1.1 million metric tons) of coal per year from Cadiz, Ohio, to an electrical generating station 20 miles (32 kilometers) east of Cleveland on the shores of Lake Erie. The pipeline was powered by three pump stations, spaced about 35 miles (56 kilometers) apart, where discharge pressures reached 1,000 psi (6.9 mPa). Coal with a graded size consist, 8 mesh by 0, and a concentration of 50% solids was transported. Consist means the size makeup of the solid phase of the coal

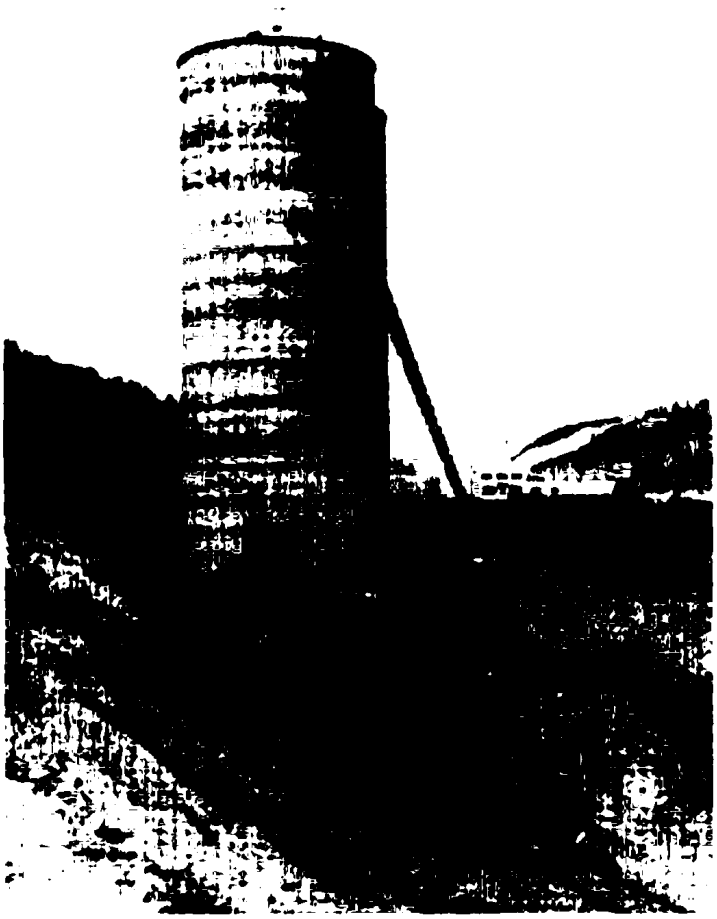

Fig. 15. Unit train is loaded with coal as it passes through base of storage silo

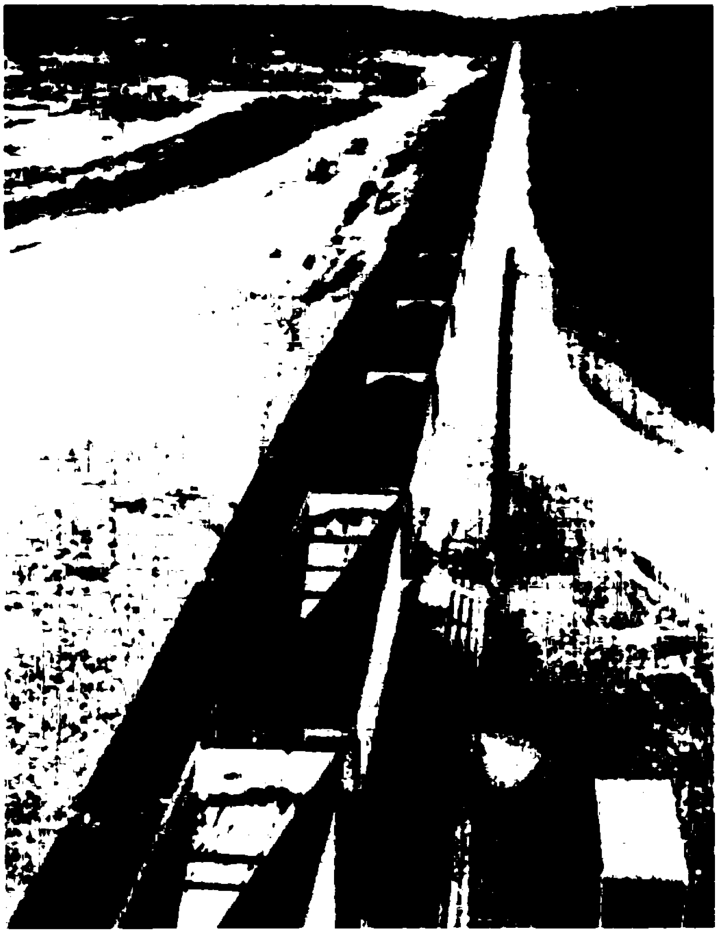

Fig. 16. A unit train with motion unloading of hopper cars being unloaded at large power plant in Tennessee. (*TVA*)

slurry. The term 8 mesh by 0 indicates coal with a graded size makeup in the range of 8 mesh and zero (dust).

Although the Ohio line operated successfully, transporting 7 million tons (6.3 million metric tons) of coal, some unexpected operating problems had to be resolved. Much investigation was conducted with variables, such as size consist and slurry concentration and the resultant effect on slurry stability. After 7 years of operation, the line was shut down in 1963, when the unit train concept resulted in much lower freight rates on significantly higher amount of coal movement.

Economics vary in different locations, however, and slurry pipelines can be particularly, attractive where no railroad facilities exist. Thus, throughout the world today there are about ten operating coal slurry pipelines. The only one (1991) in the United States is the Black Mesa Pipeline, 273 miles (440 kilometers) long, mostly 18-inch (~46 centimeters) diameter, but with some 12-inch (7.6-centimeters) diameter sections.

Coal slurry pipelines have been constructed in several countries, including a 38-mile (61-kilometer) 12-inch (30.4-centimeter) diameter pipeline in Russia, a 51-mile (82-kilometer) pipeline in Poland, as well as others in France and other locations in Europe. The feasibility of slurry transportation depends upon the resolution of a number of variables, the most important of which from a hydraulic standpoint are: (1) Size consist; (2) velocity; and (3) concentration. The selection of a proper size consist (gradation) is important in order that homogeneous flow can be achieved at prudent operating velocities. For coal slurry, such a consist is on the order of 8 mesh by 0 (approximately 0.1-inch (2.5-millimeter) particle size to dust). Homogeneous flow (solids evenly distributed across the pipe diameter) is important if excessive wear in the bottom of the pipe is to be avoided and stable operation achieved.

Of equal importance and directly related to size consist is the proper selection of velocities for transport. The velocity cannot be excessive so as to cause abrasion of pipe wall and inordinately high pressure drops. Conversely, the velocity should not be so low as to cause heterogeneous flow, with resultant excessive wear in the pipe bottom or bed formation which will cause unstable operation.

The two prime disadvantages facing coal slurry pipelines are: (1) An adequate and assured water supply is required. In water-short areas of the western United States, this is a major consideration; (2) dewatering slurry for consumption at a power plant, or for transshipment by barge is required. Centrifuging is the primary method used to date. While reduction of coal particles to the very small size needed for movement by pipeline serves the requirements of a generating station for a finely-ground coal, the fine size makes dewatering difficult.

Testing of Coal

Proximate Analysis. This includes the determination of total moisture, volatile matter, and ash; and the calculation of fixed carbon for coals and cokes. The term "Proximate" should not be confused with the word "approximate," since all Proximate Analysis tests are performed according to rigid specifications and tolerances. Proximate Analysis results may be used to establish the rank of coals; to show the ratio of combustible to incombustible constituents, to provide the basis for buying and selling coal, and to evaluate for beneficiation, or other purposes.

Moisture in coal takes three forms: (1) free or adherent moisture, essentially surface water; (2) physically bound or inherent moisture (that moisture held by vapor pressure and other physical processes); and (3) chemically bound water (water of hydration or "combined" water). The ASTM defines *total moisture* as a loss in weight in an air atmosphere under rigidly controlled conditions of temperature, time, and air flow. Total moisture represents a measurement of all water not chemically combined. Total moisture is determined by a two-step procedure, involving air-drying for removal of surface moisture from the gross sample, division and reduction of the gross sample, and determination of residual moisture in the prepared sample. An algebraic calculation is used to obtain the total moisture value.

Ash is the noncombustible mineral matter left behind when coal is burned under rigidly controlled conditions of temperature, time, and atmosphere.

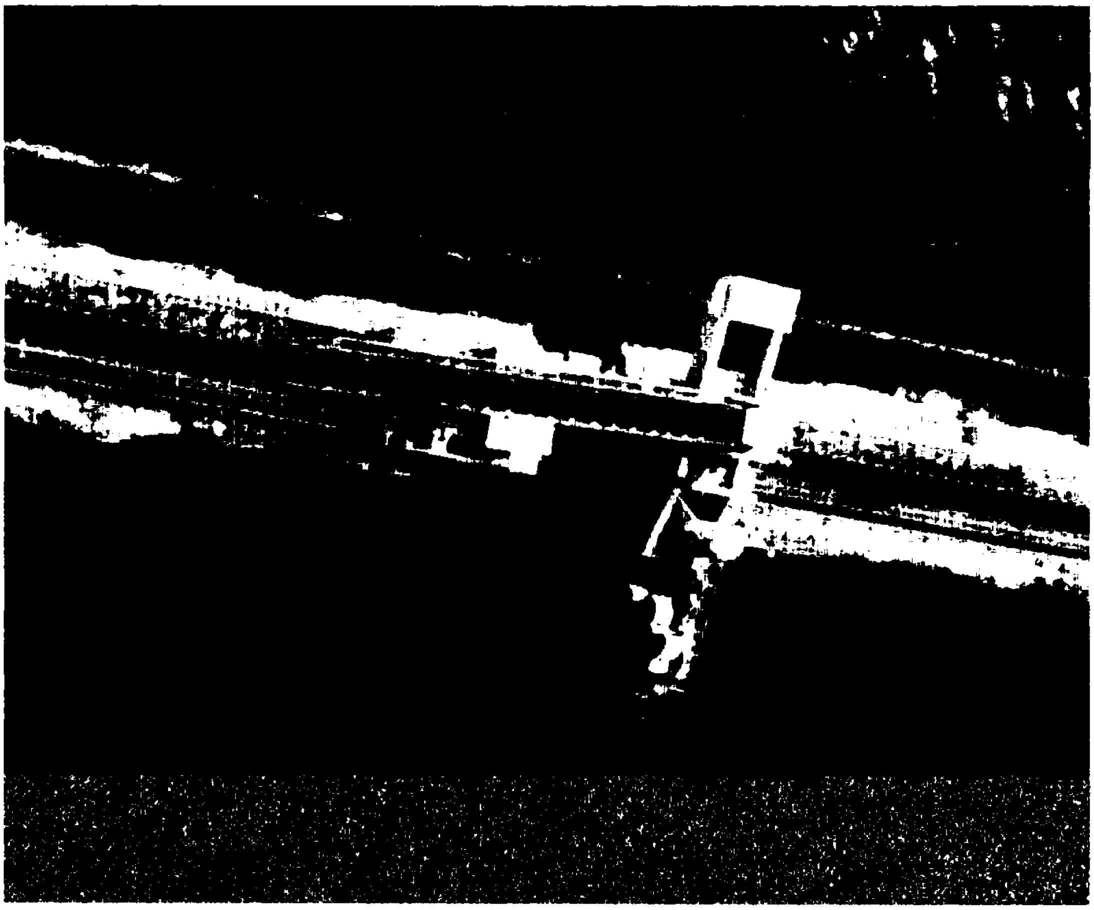

Fig. 17. Looking down on a bucket-wheel stacker-reclaimer for handling coal. The machine is moving along a 1200-foot (366-meter) stockpile near Uniontown, Kentucky. Incoming coal from the conveyor moves to the top of the machine and is dumped into 30-foot (9-meter) trenches beside the tracks which support the machine. Later, the bucket wheel will recover coal from the trench. Excess coal is pushed back and forth from the trench by bulldozer as required. (*Dravo Corporation*)

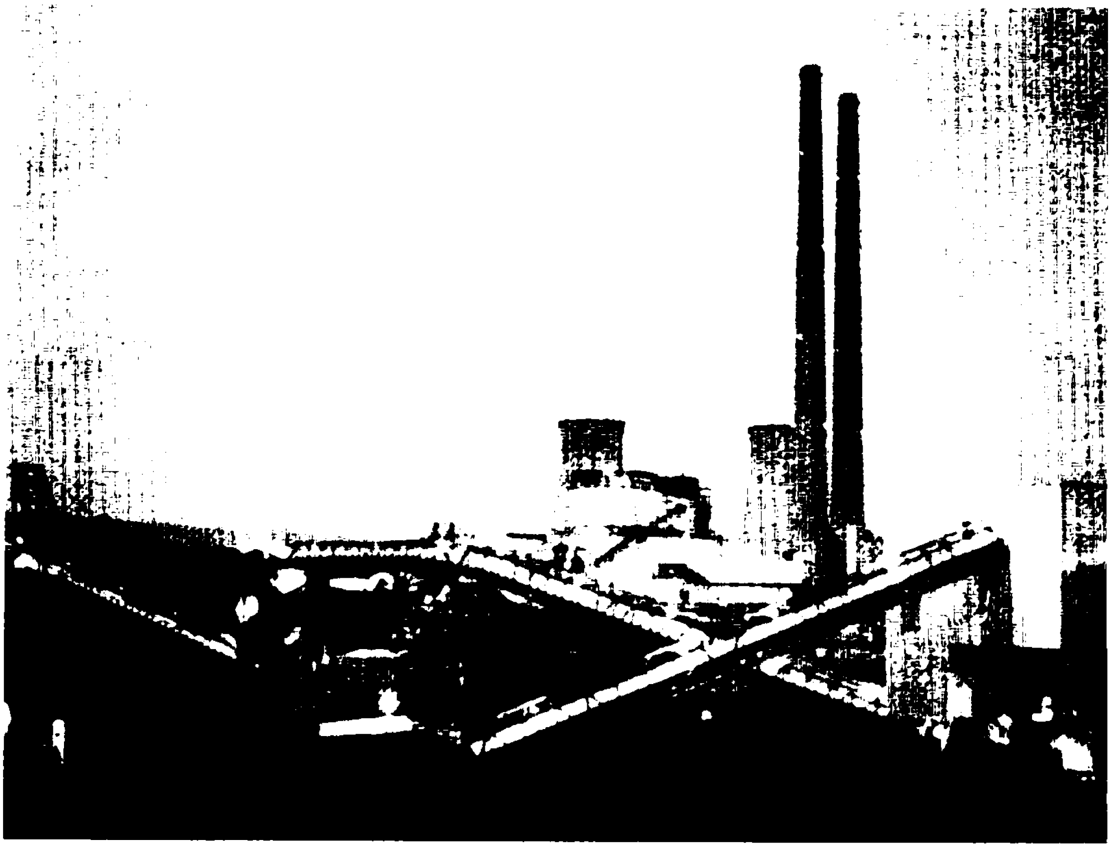

Fig. 18. Electric generating station in central Pennsylvania is one of several large mine-mouth electric power generating plants in the area which consume coal from nearby mines. Clearly visible are the long conveyor lines required to move the coal once it is received at the plant. (*New York State Electric and Gas Corporation*)

Total nitrogen is determined by chemical digestion (Kjeldahl-Gunning) methods.

Oxygen content is determined by calculations, subtracting total carbon, hydrogen, sulfur, nitrogen, and ash from 100%.

Chlorine is commonly included as part of the ultimate analysis.

Other important chemical and physical tests performed to characterize coal include: (1) Heating value (Btu content); (2) sulfur forms; (3) ash fusibility temperatures; (4) ash analysis; (5) trace elements; (6) free swelling index; and (7) hardgrove grindability.

Heating value is determined by burning a coal sample in an oxygen bomb and measuring the temperature rise. See also **Calorimetry**.

Three *sulfur forms* recognized by ASTM are: (1) sulfate sulfur, which may be in the form of calcium or iron sulfate; (2) pyritic sulfur, which is sulfur combined with iron in the form of minerals pyrite and/or marcasite; and (3) organic sulfur, which is bonded to the carbon structure.

Ash fusibility can be defined broadly as the melting temperature of the ash.

Ash analysis is the term used to designate analysis of the major elements commonly found in coal and coke ash. The elements, expressed as oxides, are SiO_2, Al_2O_3, Fe_2O_3, TiO_2, CaO, MgO, Na_2O, K_2O, P_2O_5, and SO_3.

Interest in *trace element analysis* has increased by environmental concerns.

Volatile matter is defined as the gaseous products, exclusive of moisture vapor, driven off during standardized test conditions. The combustible gases are carbon monoxide, hydrogen, methane, and other organic hydrocarbons. Those generally classified as noncombustible are carbon dioxide, ammonia, hydrogen sulfide, and some chlorides. Volatile matter tests are used to establish the rank of coals, to indicate coke yield upon carbonization, and to establish burning characteristics.

Fixed carbon is the solid residue, other than ash, resulting from the volatile matter test. The value is calculated by subtracting moisture, volatile matter, and ash from 100%.

Total carbon is determined by catalytic burning of the sample in oxygen to form carbon dioxide, which can be readily measured.

Total hydrogen also is determined by catalytic burning of a sample in oxygen to form water. The water is absorbed in a desiccant and weighed directly. Hydrogen results as determined include the hydrogen present in both the sample moisture and water of hydration.

Mining Safety and Health. Although steady technological progress has taken place over a number of years concerning the health and safety of coal mining personnel, a strong impetus toward further improvements has come from legislation at the state and national level over the past score of years. Studies and improvement programs continue to be well funded. Efforts have fallen into the following major categories.

Ground Control—with the objective of developing technology to prevent accidental falls of roof, rib and face, and coal bumps. Study areas include: (a) artificial support, (b) hazard detection, and (c) design of mine openings. Horizontal roof strain indicators for detection of unstable roof conditions have been tested. Other research programs have included a microseismic fracture warning system, polymeric roof bolts, and chemical impregnation techniques.

In late 1991 Australian government researchers announced the development of a remote-controlled vehicle that can scout ahead of a rescue crew to locate missing and injured miners. Three stereo-video cameras permit the vehicle to operate in murky areas of a mine. The vehicle also includes gas analysis instrumentation. A fiber-optic cable, wound on a large drum, permits surface operators to convey instructions to the vehicle and to receive the results of gas analysis data and images of what the vehicle "sees." The vehicle is named after a burrowing marsupial, *Numbat*.

Fire and Explosion Prevention—study areas have included: (a) ignition, (b) flame propagation, (c) fire detection and alarm, (d) suppression and extinguishing, and (e) methanometry. Devices and techniques tested have included explosion-proof bulkheads, coal dust and rock dust analyzers, ignition suppression devices for face equipment, and remote sealing techniques.

Industrial-type Hazards—with the objective of identifying hazard sources in electrical, mechanical, illumination, and non-emergency communication fields. Developments have included (a) advanced remote surveillance and communication systems, (b) portable-area illumination systems, (c) trolley-phone wireless systems, and (d) protective canopies for use on underground low-coal machines.

Methane Control—with the objective of developing safe methods for mining methane-laden coalbeds. Study areas have included: (a) predictions of concentrations and flow; (b) control in advance of mining; and (c) control during mining. Techniques tested have included water infusion to reduce methane in the face area, degasification through vertical boreholes, the plugging of oil and gas wells that penetrate coal beds, and the complete degasification of operational mines.

Respirable Dust—with the objective of providing improvements for protecting miners from exposure to respirable coal mine dust. Study areas have included: (a) dust formation; (b) dust control, and (c) dust measurement. Tests have included: the infusion of water into coal beds for control of respirable dust; the use of water-based, high-expansion foaming systems in conjunction with continuous mining machines, to reduce dust at the face; the use of foam systems for dust suppression on conveyors and transfer points; and the use of prototype dust meters. See also **Pneumokonioses**.

Noise—with the assessment of permissible noise levels for communication and warning signals and the development of technology for noise abatement and control. Developments have included an audio dosimeter to replace conventional sound-level meters, discriminating earmuffs, and a noise control muffler system to reduce pneumatic drill noise.

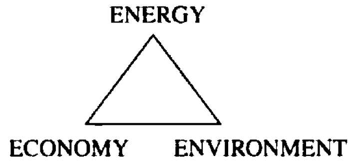
COAL CONVERSION (CLEAN COAL) PROCESSES. Coal, representing a major reserve of energy in the United States and a few other countries (see also **Coal**), currently accounts for well over half of the electricity produced in the United States. Thus, although coal poses environmental threats and problems, until other essentially renewable energy sources can be developed technologically, coal obviously will be a major energy source for well into the 21st century. The problem, then, is to determine how coal can be treated or converted and how coal combustion processes can be altered so that their impact on the environment can be minimized and, of course, fall within the practical economic limitations realistically imposed on the *value of energy*. Among energy alternatives, coal probably is at the apex of the triangle made up of three interacting forces: the energy supply, the environment, and the national economy.



Coal conversion and utilization technology, although less spectacular, rivals the space program's engineering in terms of the numbers and difficulties of problems requiring solution. This is attested to by the scores of approaches suggested, studied, and applied in test situations. Coal has proved to be a very stubborn, scientifically unpliable substance to manipulate. Coal conversion or combustion processes are not amenable to much laboratory benchwork, but usually require fairly large and expensive pilot plants for process testing. Scale-up problems are equally difficult. For example, those coal conversion processes that have reached the large-scale testing phase pose severe materials problems and operate under high temperatures, high pressures, and with severely corrosive and abrasive materials at various stages in the process. Thus, advances in materials engineering (need for new alloys, ceramics, etc.) parallel the other

processing problems of coal conversion. (These are reminiscent of materials problems encountered in the space program—for example, solving the reentry heating problems in the early days of the space shuttle.)

Assuming that coal will be required for several future decades as a major source of energy, what options are open for the near, intermediate, and far term? There is a considerable consensus that converting raw coal into essentially a new form of fuel, as through gasification, liquefaction, or treated solid forms, will provide minimum ultimate impact on the environment. Discounting the obvious conservation of energy (easy to preach; difficult to practice), there are two main avenues of approach for the immediate and short term:

1. Improving coal combustion processes to maximize electric generation efficiency, partially with the obvious target of using less coal/kilowatt and thus directly helping the environment; and
2. Designing processes that either:
   a. Create reduced air pollution; or
   b. Treat pollutants prior to their emission into the air.

Considerable progress along these lines has been made as a result of the Clean Air Act and other forces that are demanding environmental protection. Recent revisions of the Clean Air Act have placed high responsibilities on the operators of electric utilities. Emissions reduction in the absence of an entirely new coal fuel technology is extremely costly. Although the more recent amendments award and penalize operators for emissions reduction performance, the political aspects of which are not described here, the bottom line is higher electricity costs for the consumer, reemphasizing the strong inverse relationship between energy and the environment. Location of electric generating plants that fall within "allowances" program are shown in Fig. 1. This program obviously is tied in with international concerns over $FISO_2$ emissions. See also **Acid Rain**.

For those readers who are not familiar with past achievements in coal conversion, the following several paragraphs and examples are included. The use of coal is tersely reviewed prior to major environmental concerns, which belatedly did not become part of the public psyche until the mid-twentieth century.

Early Chronology of Coal and Steam

As pointed out in the entry on **Coal**, the principal ingredient of coal is carbon and, as described in the entry on **Combustion (Fuels)**, it is the combination of carbon with atmospheric oxygen to produce carbon dioxide (CO_2), an exothermic reaction that releases 14,100 Btu/pound (7840 Calories/kilogram) of carbon, that provides the heat energy derived from burning coal. Depending upon the composition of the coal, other heats of reaction will occur from the combustion of hydrogen and sulfur in the coal with air, but these are secondary factors. The fixed carbon content of coal ranges from about 98% for a Class 1 anthracite or hard coal, as may be mined in Pennsylvania, to as low as about 32% for a Class 17 brown coal or lignite, as may be mined in North Dakota.

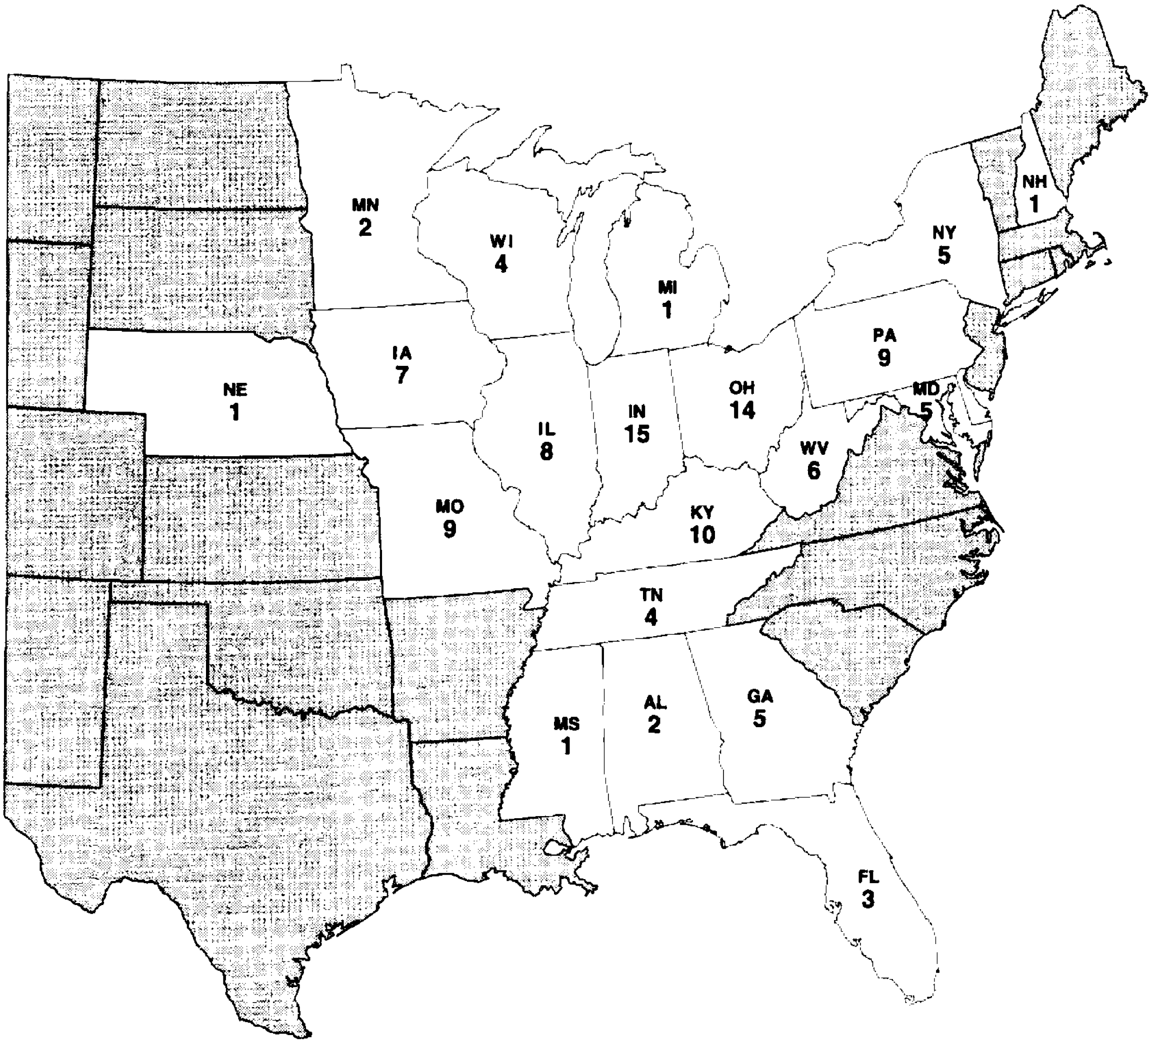


Fig. 1. States with coal-burning electric power plants that are targeted by Clean Air Act revisions, requiring that by 1995 such plants must reduce their emissions of sulfur dioxide (SO_2). Complicated politically, the program is measured in terms of allowances, one allowance equaling 1 ton of SO_2. Depending upon the size of the power plant, allowances range from 1000 to 255,000 units of SO_2. Because of plant size variations, current state of cleanup equipment, and the fact that several plants are under the same management, the program allows for certain trade-offs. In other words, reduction at some plants may be applied to plants not performing as well environmentally. Allowances also may be purchased from other plants. In essence, this will allow some older plants to continue operating for the next few years, while others are modernizing or while new plants are being constructed. Thus, the regulatory targets are for the total 111 plants to accomplish a large regional reduction by 1995

Direct use of coal, as in pulverized form for the firing of boilers in the electric utility industry, poses a number of environmental problems that can be solved only through the use of costly and elaborate antipollution measures and equipment. But, also in considering the expanded use of solid coal as a major source of energy, there are several other limitations over and beyond the environmental.

Aside from coal-powered steam locomotives and seagoing ships, which essentially were retired from most regions of the world over the past several decades, solid coal is quite unsuited for transportation energy. The energy density of raw coal means that a significant portion of the energy obtained from combusting it is required to move it (as part of a transportation vehicle). This is further amplified by the equipment required to burn coal—massive, heavy furnaces and boilers—which also have to be moved with the vehicle.

Transportation power needs dictate high energy density with fuels that are easy and convenient to handle and that can be converted to power by much smaller, lighter-weight engines. It follows, then, that for coal to be a useful energy source for transportation, it must be preconverted in some way to overcome the aforementioned objections.

Even for stationary use, particularly where energy needs are much less concentrated than in the case of a central electric power plant, such as for commercial and residential heating and large numbers of industrial plants, the conversion of coal into liquid or gaseous forms is required to provide the needed convenience, improved cleanliness, and use efficiency. Probably of equal importance is the cost of transporting large amounts of coal from sources to many tens or hundreds of thousands of locations where it can be used. With liquid or gaseous fuels, pipeline transportation, for example, becomes attractive. It is true (see entry on **Coal**) that there has been considerable attention given to coal slurry pipelines, but these are practical only for certain combinations of situations—because of the slurry preparation and handling equipment, costly and elaborate, required at both ends of the pipeline.

Since the time of Watt, the energy of coal has been converted to a gas—in the form of steam. Steam or hot water can be effectively distributed within relatively small areas, as throughout a given manufacturing plant or complex, or even a commercial and residential neighborhood. This type of district heating has been used for domestic and commercial heating in some parts of the world for many years and, in fact, is undergoing a revival in some areas. District heating (although from geothermal energy rather than from coal) has been common in parts of Iceland for many decades. But thermal losses from transporting steam or hot water limit this approach to relatively small distances.

For many years coal has also been converted into possibly the most ideal form of energy of all—electricity. Electricity has been used extensively for powering machines, lighting, communications, etc.

"Artificial" or "City" Gas in Perspective

The concept of synthetic fuels is far from new. In fact, in the mid-to-late 1800s and carrying into the first third of the 20th century, what are now called synfuels were used on a daily basis in many parts of the world. Thus, one might say that synthetic fuels and the role of coal in bringing them about is a situation of revival in technology rather than anything of an entirely new or pioneering nature. Petroleum fuels essentially represent a phenomenon of the automotive age (the spectacular salt dome at Spindletop, Texas was put into crude oil production in 1902). Natural gas as a major and widely distributed fuel really did not get underway on a large scale until the 1930s. Thus, for the greater part of the 20th century, with natural crude and natural gas, both excellent, convenient, generally clean and inexpensive fuels, the question could have been posed, "Who needs synthetic fuels?"

Artificial gas for use as a heating fuel and derived from coal or coke was widely used during the latter part of the nineteenth century and during the first few decades of the twentieth century. Although natural gas had been discovered and used by the Chinese some 2,000 years ago (piped from shallow wells through bamboo poles for burning under large pans for evaporation of sea water to obtain salt), the first hard evidence of commercial use of natural gas dates back to 1802, when it was used for lighting the streets of Genoa, Italy. The first natural gas utility company was formed in 1858 (The Fredonia (N.Y.) Gas Light Company). The numerous advantages of a gaseous fuel that could be piped to industrial, commercial, and residential users for heating purposes were recognized long before natural gas was found on a large scale and made available to communities hundreds and more miles from the originating wells. Thus, for many decades, artificial gas was used. The local gas utility was characterized by having one or more so-called "gas works" in which a rather poor grade of gas (on present standards) was produced essentially from coal or coke and steam. In the manufacture of producer gas, a deep hot bed of coal or coke was blasted continuously with a mixture of air and steam. The products of the process were carbon monoxide, nitrogen (from the use of air), small amounts of hydrogen, and some carbon dioxide. Because of the large percentage of nitrogen in the gas, the heating value was low [125 to 150 Btu per cubic foot (1113 to 1335 Calories per cubic meter) as compared with natural gas having a value of from 900 to 1,200 Btu per cubic foot (8,010 to 10,680 Calories per cubic meter)]. Blue water gas, carbureted water gas, and coal gas were also produced from coal or coke and, in some instances, enriched with oil and later natural gas. Because of the great availability and, at one time, apparent inexhaustible supply of natural gas in the United States (and a few other areas of the world), manufactured gases were phased out rapidly. The use of natural gas increased 730% between 1940 and 1970 in the United States, during which period the gas industry produced 313 trillion cubic feet (8.9 trillion cubic meters) of natural gas. In other areas of the world, however, where natural gas was not available locally, manufactured gas, sometimes referred to as town gas, city gas, etc., persisted. Thus, it is not surprising that the current new coal gasification technology essentially stems from Europe and the United Kingdom, where an interest in improving artificial gas manufacture continued long after such interests mainly disappeared in the United States. During the 1930s and 1940s, only a few projects for converting coal into gas were conducted in the United States—for example, the U.S. Bureau of Mines project at Louisiana, Missouri.

Pre-Energy Crisis Coal Fuel Developments

Prior to the "Energy Crisis" of the 1970s, efforts were made in parts of the world that had no or few petroleum reserves (unlike the United States, for example) to research the conversion of coal into superior fuels. The efforts of the Republic of South Africa were outstanding for that period and, with further improvements, continue successfully today. Germany also retained an interest in coal conversion as an extension of its primary major experiences in designing processes for converting coal into "artificial gas," previously mentioned. Much of the South African program relied upon German technology. South Africa had the motivation because there are no signs of important petroleum deposits in the country.[1] As early as 1927, a White Paper already had been published discussing the processes then available for production of oil from coal. Developments in Germany were closely followed and especially the Fischer-Tropsch process, as its operating conditions did not appear to be very extreme and the process had already been demonstrated in a number of plants. A South African mining corporation, the Anglo Transvaal Consolidated Investment Company, better known as Anglo Vaal, acquired in 1935 the South African rights to the German Fischer-Tropsch process.

During the next few years, Anglo Vaal devoted much attention to the development of a scheme for the production of oil from coal. Tenders were asked for, but because of the complications of World War II, no orders for equipment were placed. However, during the war and in the postwar years, Anglo Vaal remained in close contact with developments. In 1943, negotiations held in America led to the procurement of the rights to the American variation of the Fischer-Tropsch process. In 1946, a new study was undertaken, and an application was made to the government to create a suitable framework within which a long-term industry could be established. During 1947, the Liquid Fuel and Oil Act was passed and, in 1950, an agreement was reached between the South African government and Anglo Vaal in which the Anglo Vaal rights were taken over by the government. The South African Coal, Oil and Gas Corporation Ltd. was formed and incorporated under the Companies' Act as an ordinary public company. The government appoints the majority of directors, including the chairman, and the remaining directors are appointed by the Industrial Development Corporation, which is a government-owned organization with the objective, as the name implies, of stimulating industrial development in the country. Sasol operates like a normal business concern, with an autonomous board of directors, and is subject to South African company law and taxation like any other company.

[1] As partially related by Jan C. Hoogendoorn, Manager, Research and Development, South African Coal, Oil and Gas Corporation Ltd., Sasolburg, Republic of South Africa.

A site for the plant was selected close to the banks of the Vaal River, which is South Africa's major source of water, 50 miles (80 kilometers) south of Johannesburg and on top of a vast coal field. Sasol acquired approximately 8000 acres (3200 hectares) for the plant and its township which was to have the name of Sasolburg. The site was in the middle of an area where cattle grazing and corn (maize) production were the only activities and Sasol had to create its own infrastructure from scratch.

Although it was clear that the plant would be based on the synthesis of hydrocarbons from hydrogen and carbon monoxide as invented and developed by Fischer and Tropsch, it still had to be decided which processes to choose for the individual steps in this integrated complex. For gasification, the Lurgi pressure gasification process with steam and oxygen was selected because this process had already been demonstrated in gasifiers of a smaller size. It had the advantage of being able to work on the rather low-grade, high-ash coal available to Sasol. The fact that it operated at a pressure of approximately 350 psi (2.4 mPa), which is also the desired operating pressure for the Fischer-Tropsch plant, was an additional advantage. This avoided cumbersome compression of large volumes of gas arising from low-pressure gasification. A small part of the Sasol I facility is shown in Fig. 2. Generalized flowsheet for the Sasol II facility is given in Fig. 3.

The production of synthetic motor fuels, pipeline gas, ammonia, and chemicals, where coal gasification is the key to successful production, was first commenced in 1955. Extensive experience was gained from 20 years of operation and a large expansion (Sasol II) was commenced in 1975 and completed in the spring of 1980. The newer facility processes 40,000 metric tons of coal per day and produces the equivalent of 60,000 barrels per day of petroleum-like fuels. New mines were developed nearby to feed coal over a conveyor system into a feed preparation facility. Two huge coal piles have been built up to provide continuous operation in event of a temporary shutdown of the mines. The coal is charged to a gasification section where synthesis gas is prepared in the presence of steam and oxygen. Ash content of South African coal is relatively high (about 25%) and thus some 10,000 metric tons/day of ash are produced in the gasifiers. The gasification section contains 36 Lurgi gasifiers which produce the raw synthesis gas. These are improved versions of the gasifiers used at the original Sasol I plant. The original plant also produced town gas as well as liquids. In the new facilities, no gas will be sold. The oxygen requirements of the new facility are quite high, and six air separation plants, each with a capacity of 2500 metric tons/day, represent one of the largest oxygen facilities in the world. Liquors from the gasification section are charged to a Lurgi Phenosolvan

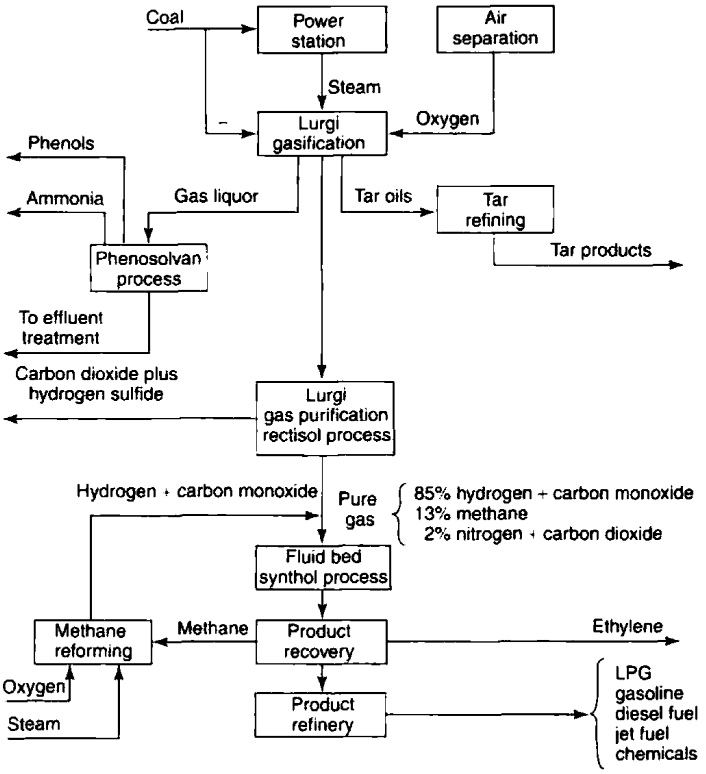

Fig. 3. Generalized flowsheet of Sasol II project. (*South Africa Coal, Oil and Gas Corporation Limited*)

Fig. 2. Gas purification portion of coal gasification complex of Sasol I facility at Sasolburg. (*South Africa Coal, Oil and Gas Corporation Limited*)

unit where ammonia and phenols are recovered and wastewater effluents are cleaned. The raw gas has to be further treated and this is accomplished in a Lurgi Rectisol unit, where carbon dioxide, hydrogen sulfide, and other impurities are removed. The heart of the plant is the liquefaction section. This is where the synthesis gas is liquefied in the presence of an iron-based catalyst. This Fischer-Tropsch reactor technology is proprietary to Sasol but is licensed.

Methane reforming units receive methane-rich gas from a cryogenic product recovery facility and subject the gas to partial oxidation. Some of the carbon dioxide content is removed and the gas recycled to the reactors. Once liquids are recovered, the stream goes to essentially conventional refining units. The plant's production is primarily transport fuels. Most of the gasoline production is currently sold to other refineries for blending with their stocks, but a portion of the product is marketed directly to consumers.

Other early coal conversion processes are shown in Figures 4, 5, 6.

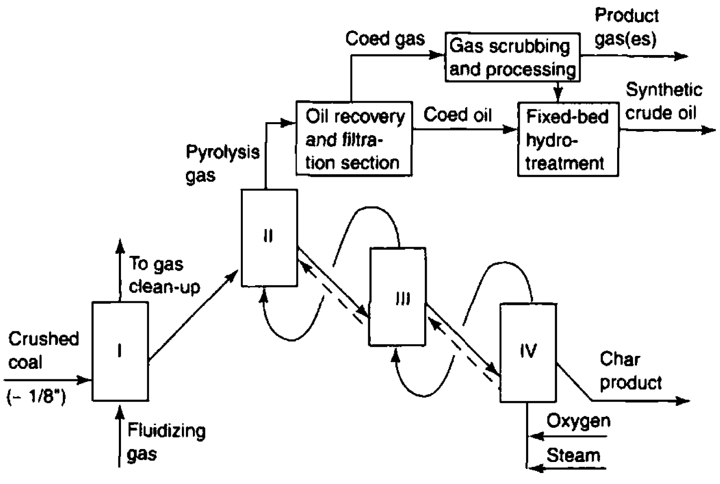

Fig. 4. Early (1970s) process for coal pyrolysis

Synfuels Program

The Arab Oil Embargo (1973) jolted many world governments into developing programs that would make their economies immune to future energy crises. In the United States a *Synfuels Program* was legislated. The primary thrust then was to develop fuels that would substitute for crude petroleum as a starting point. The attention given to coal conversion was mainly to derive petroleum-like fuels from coal rather than simply to process control for the well-established coal burning plants of that day. However, the technology of the Synfuels Program later became the basis for converting coal adaptable to traditional coal combustion power plants—not so much in the interest of meeting an energy crisis, but rather to avoid a future environmental crisis. Thus, current programs directed toward environmental protection had somewhat of a running start because much of the technology previously described, such as the Lurgi processes, was a starting foundation. As international relations improved and oil supplies were again reassured, considerable and progressive complacency on the part of government and the public set in—with the exception of so-called "dirty coal" power plants. Thus, as of the mid-1980s, interest in coal technology had reawakened.

Clean Coal Programs of the 1990s

Traditional coal handling practices that resulted in excessive quantities of pollutants in the air with associated ill effects on the environment, including acid rain in the northeastern United States and parts of Canada are being tackled through the joint cooperation of government and private electric power interests. One of the first major goals to be achieved was set for 1995. Further background is given in Fig. 1 at the start of this article. See also Fig. 7.

Many Options to Consider. In evaluating the use of coal for electric power generation, there are many options that must be considered. Recalling the ENERGY-ENVIRONMENT-ECONOMY interdependent triangle mentioned at the beginning of this article, option preference varies—power consumers (both industrial and public), the coal mine workers, and the environment regulators, among others. This article concentrates on the environment.

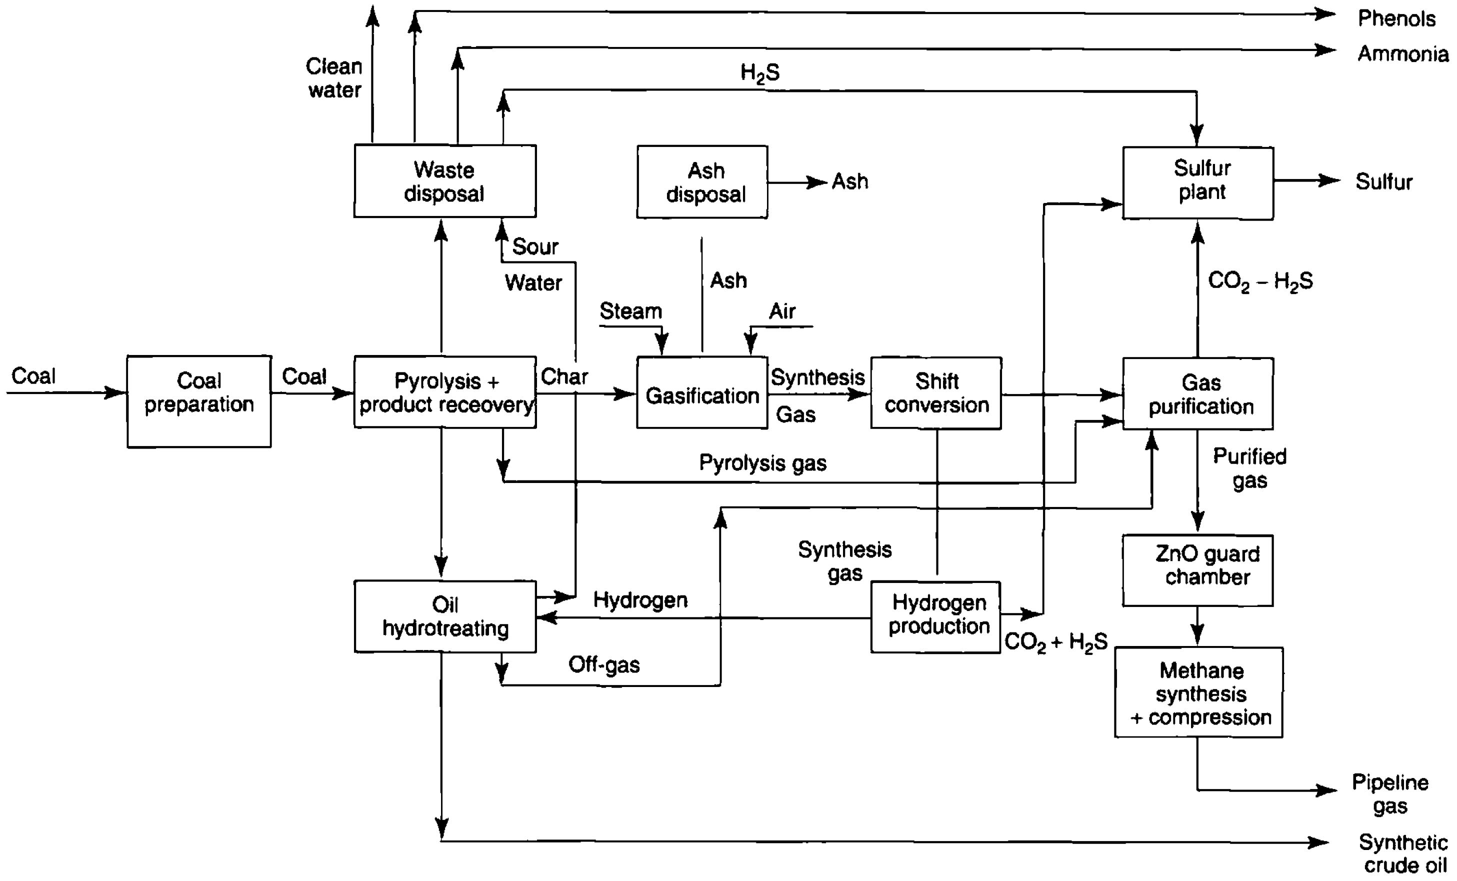

Fig. 5. Early (1970s) process for making pipeline gas from coal

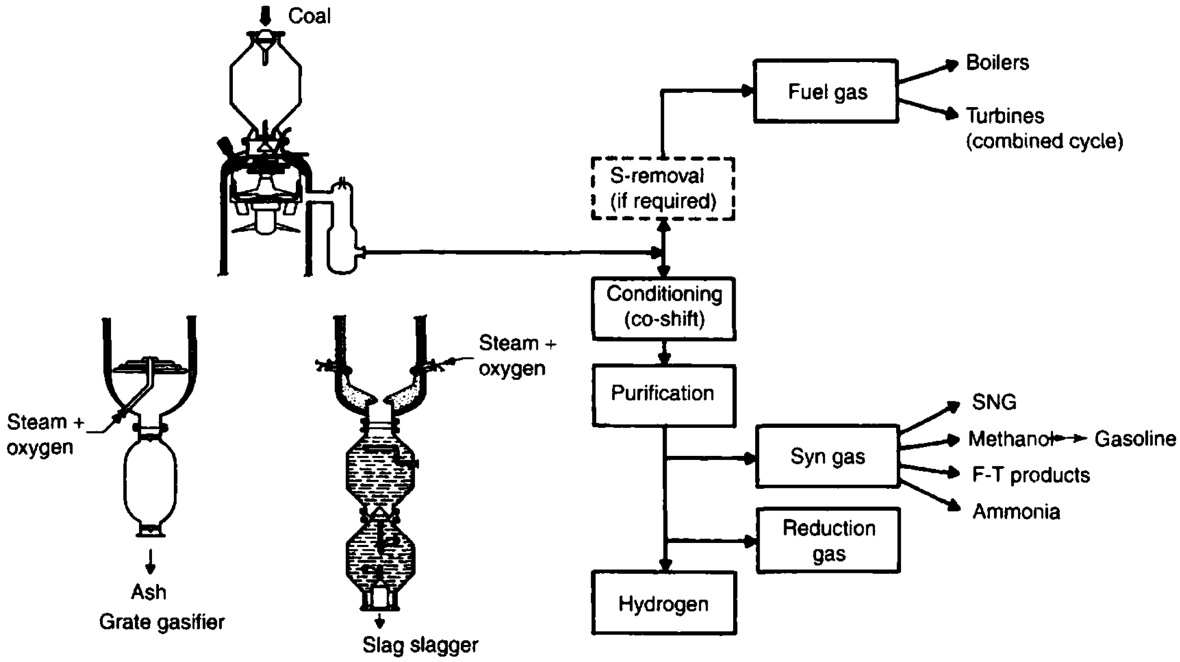

Fig. 6. Basic schemes for Lurgi gas production, the fundamental technology of which dates back to the era of "artificial" gas. The process shown here (circa early 1970s) permitted selection of various gasifiers and/or changing operating pressures to influence the final crude gas composition, as dictated by the end use and economics. (*Lurgi Kohle und Mineralotechnik GmbH, Frankfurt, Germany*)

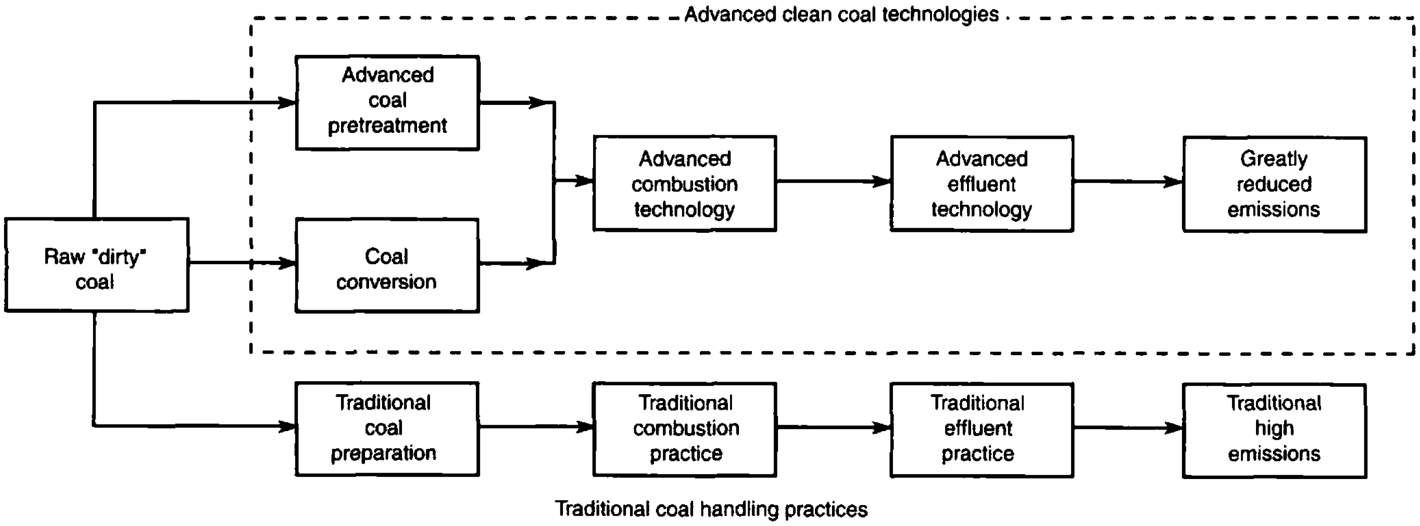

Fig. 7. Overview of coal preparation, conversion, combustion, and effluent treatment technologies that are designed to markedly reduce deleterious emissions and thus protect the environment. The line at the bottom, indicating traditional practices, now *fully* applies only to the very oldest coal-energized electric power plants. The Clean Air Act (U.S.) and the "Clean Coal" program call for progressive upgrading or modernization for achieving major goals by 1995, as described in the text. It should be mentioned that traditional practices have been improved over the years, but these have not been sufficient to meet environmental goals. Better results can be achieved only by way of marked advances in technology

Coal Preparation and Pretreatment Technology

The principal measure of the previously mentioned "allowances" program (see Fig. 1) is expressed in terms of tons of sulfur dioxide (SO_2) emitted. However, close behind the environmental effects of SO_2 are emissions of nitric oxides (NO_x). Unfortunately, the chemistry of SO_2 removal differs from that of NO_x removal.

Targeting SO_2 Emissions. As described in the article on Coal, various types of coal contain different amounts of sulfur. Thus, using low-sulfur coals provides the utility operator with a major headstart. But low-sulfur coals are not as abundant as, for example, subbituminous coal, which costs more. The relative location of a utility and the mine also is a factor because of high transportation costs. Also, when combusted, low-sulfur coals create more ash and yields fewer Btus (thermal energy). Several processes have been or are being developed to lower sulfur content by pretreatment.

Sulfur in Coal. Sulfur occurs in coal in two forms: (1) *organic* sulfur, which is chemically bonded to the coal, and (2) *pyritic* sulfur, which occurs in tiny, iron-associated and separate particles in the coal. This is a physical rather than a chemical impurity.

Pyritic sulfur can be removed by froth flotation, which takes advantage of the differences of specific gravity of the two types of sulfur. To be effective, the coal must be pulverized into particles in the micron region. The process can be enhanced by adding limestone, catalyst, and soda ash to the coal dust. After treatment, the coal is formed into briquettes for ease of handling by conventional conveyors.

By way of genetic engineering, microorganisms with metabolic capacities, unknown of as recently as 15 years ago, have been produced. Coal bioprocessing developments are directed to three objectives:

1. Reduce the sulfur content;
2. Solubilize coal and convert the soluble product to liquid or gaseous fuels; and
3. Convert coal-derived synthesis gas to liquid or gaseous fuels.

In addition to direct operations to remove or reduce sulfur content, coal liquefaction or gasification can accomplish similar results indirectly.

Coal Gasification Processes

U.S. federal and private funding have intensified competition among design engineering firms as well as some universities and government-owned laboratories. This has resulted in a proliferation of proposals and projects. Inasmuch as the objective of reducing air pollution is also strong outside the United States and probably regarded as even more urgent in such countries as Germany, the Netherlands, and Japan. There is a dueling among design firms for what can become a major market for equipment over the foreseeable future. Several of these processes are described in the following paragraphs. As of 1993 most of these projects are in the pilot or demonstration plant phase.

Most of these processes are designed for combined-cycle power plants, which are defined in the footnote.[2]

Texaco Coal Gasification Process. This process uses an oxygen-blown, pressurized, entrained slagging gasifier and a coal/water slurry as the fuel. The process was developed originally to partially oxidize heavy oil. The process was modified to gasify coal. Research to develop practical radiant and convective syngas coolers to recover the high sensible heat in the raw syngas was carried out in Germany by Ruhrkohle Oelund Gas and Ruhrchemie A.G. The first commercial-scale coal-gasification combined-cycle (IGCC) plant was built in Oberhausen, Germany. It is a 165-tons/day demonstration plant.

Shell Coal Gasification Process. This process uses an oxygen-blown, pressurized, entrained slagging gasifier and dry pulverized coal as the fuel. Syngas coolers are used to recover the sensible heat of the raw syngas, and both saturated and superheated steam are produced. Syngas recirculation is used to reduce the temperature of the gas entering the syngas coolers. As of mid-1992 the pilot plant had been in operation 4 years, in which a broad range of coals was tested. The results of the EPRI (Electric Power Research Institute) have shown very favorable results of this oxygen-blown, dry-feed, entrained-flow process. The process offers high cold gas efficiency (a measure of the amount of chemical energy in the clean cold syngas and is expressed as the ratio of the chemical energy of the syngas to that of the feed coal). The process also offers efficient utilization of the sensible heat of the syngas, high carbon conversion, and good selectivity toward the fuel components of the syngas. Carbon monoxide, hydrogen, and methane together make up over 90% (vol) of the dry syngas.

Dow Coal Gasification Process. This design uses an oxygen-blown, pressurized, two-stage entrained slagging gasifier and a coal/water slurry as the fuel. Syngas coolers are used to recover the sensible heat of the raw syngas, and both saturated and superheated steam is produced. The process was tested (36 tons/day) in a pilot plant in 1979 and later in a 1600-tons/day demonstration plant in the early 1980s.

British Gas-Lurgi Process. This is a slagging, moving-bed process that is based on the earlier Lurgi oxygen-blown, pressurized, moving-bed dry-ash gasifier. The Lurgi gasifier was modified by increasing the temperature above the melting point of the coal slag and decreasing steam consumption, thus markedly increasing efficiency. A syngas cooler is not needed because hot gases from the slagging bottom preheat the coal bed above. Tars and other organics produced contribute to difficulties in water treatment.

Kellogg/Rust and Westinghouse Process. An oxygen-blown or air-blown pressurized, agglomerating fluidized-bed gasifier is used. A 35-tons/day pilot plant has been tested. Present research is targeted to modifying the process in an effort to allow high-temperature desulfurization by injecting limestone into the fluidized bed.

[2] Steam turbine systems cannot take full advantage of the high temperatures available from the combustion of fossil fuels because of material limitations, nor of the heat available at the low temperature end of the steam cycle because of economic considerations. The combination of two or more heat engine cycles that cover different parts of the temperature range is referred to as a combined-cycle plant. The combination of two different cycles represents a *binary cycle*. The addition of a second cycle at the high temperature end of the steam cycle is referred to as a *topping cycle*; if added at the low temperature end, it is a *tailing* or *bottoming* cycle. The most common binary cycle power plants are comprised of a steam turbine cycle topped with a gas turbine cycle. In this combined cycle, the hot exhaust gases from the gas turbine are used to generate steam for the steam for the steam turbine generators. Cycle efficiency near 45% can be achieved.

Kilngas Process. This design uses an air-blown agglomerating bed gasifier. The main feature is a rotary kiln, in which the coal is gasified by adding air and steam at moderate pressures (400 to 700 kPa; 60 to 100 psi). A 600-tons/day demonstration plant is being tested by the designer, Allis-Chalmers, in East Alton, Illinois.

High-Temperature Winkler Process. The process employs an oxygen-blown, pressurized, fluidized-bed dry ash gasifier designed for lignite. The process was developed by Rheinische Braunkohle Werke AG, with an 800-tons/day demonstration plant in Germany.

Molten-Iron Pure Gas (MIP) and Klockner Molten Iron Processes. This concept is being developed in a joint effort by Sumitomo Metal (Japan) and Klockner (Germany). Coal is gasified with oxygen in a top- or bottom-blown liquid iron bath. The process accomplishes desulfurization and particulate removal in one step.

Extensive testing in a 40-tons/day pilot plant led to the construction of two 800-tons/day demonstration plants in Germany and Sweden.

VEW Coal Conversion Process. This design uses an air-blown, pressurized, entrained slagging gasifier/combined-cycle unit, in which the coal is only partially gasified. Hot exhaust gases and char from the gasifier are fed into a conventional pulverized coal boiler. After syngas is cleaned, it is combusted in a gas turbine. A 240-tons/day pilot plant is located in Germany.

It will be noted that there are a number of similarities in the various designs. Although several designs may be required to satisfy varying compositions of coal feed, it would appear that ultimately coal gasification processes will be fewer in number in the future, once the demonstration plants complete their tests.

Combustion System Modifications

The foregoing processes incorporate the combustion phase as part of their overall design. The combustion operation also has been studied in a piecemeal manner, the results of which include fluidized-bed technology, bulk mixing of coal and limestone (can reduce SO_2 emissions up to 90%), injection of dry sorbents into boiler (or stack), and the injection of natural gas, among other approaches.

Final Emissions Clean-Up. In addition to engineering processes that create smaller amounts of objectionable pollutants, much research continues to neutralize emissions prior to their introduction into the atmosphere. Improvements are being made almost continuously to precipitation and scrubbing systems. As an example, in a process developed in Japan, flue gases are bubbled through a vessel containing an alkaline slurry. Upon absorption of SO_2, the slurry is centrifugally dried to form solid gypsum ($CaSO_4$).

Coal Liquefaction

In addition to cleaning up coal for use in electric-generating plants, research continues for converting coal into useful liquid fuels that can substitute for petroleum-based products, demanded largely for transportation and for use as raw materials by the chemical industry. Present impetus in this area, however, is much less because reasonable costs of petroleum detract from business incentive.

The basic chemistry of coal in terms of creating liquid fuels is the hydrogen-to-carbon ratio. In raw coal this ratio is less than unity, whereas a ratio of 1.5 to 2 or more is needed to produce desirable liquid fuels. In hydroliquefaction processes, the first step is pyrolysis, followed by the addition of hydrogen from another source.

Underground Coal Gasification. *In situ* gasification of coal was suggested by Siemens in 1868, and the first patent for a process was granted to Betts in 1909. The first experiment was conducted in England prior to World War I and in Russia as early as 1933. Much interest was shown for this concept during the energy crisis of the 1970s, and considerable research was undertaken, for example, at the Lawrence Livermore National Laboratory. In the long term, incentives for the concept include the use of coal seams that are unsuitable for mining and less disturbance of land by comparison with present surface-mining techniques. A proposed system is shown in Fig. 8.

COAL TAR AND DERIVATIVES. [CAS: 65996-93-2]. Coal tar constitutes the major part of the liquid condensate obtained from the "dry" distillation or carbonization of coal (mostly bituminous) to coke. The three major products of this distillation are (1) metallurgical coke, (2) gas which is suitable as a fuel after appropriate chemical treatment, and (3) condensable liquids which leave the coke oven along with the gas and which are constituted principally of ammonia liquor and coal tar. The condensable materials and gas impurities are separated from gas in the condensation and purification train of the coke oven plant. The purified coke oven gas is used as fuel to heat the coke ovens and steel producing furnaces. Prior to the widespread use of natural gas as a domestic fuel, coke oven gas was widely used for this purpose after additional purification as residential fuel.

Since metallurgical coke for use in blast furnaces is the prime product of coal carbonization, coal tar production is tied closely to the demand for metallurgical coke. Although steel production has increased progressively over many years, the demand for metallurgical coke has remained reasonably steady, for several reasons. Large improvements in blast-furnace efficiency have occurred. The amount of coke required to produce one ton of pig iron has dropped from 1760 pounds coke/ton of pig iron (878 kilograms coke/metric ton of pig iron) to 1250 pounds coke/ton of pig iron (624 kilograms coke/metric ton of pig iron) and in some modern blast furnaces, the rate is below 1000 pounds coke/ton of pig iron (500 kilograms/metric ton of pig iron). Further, coke has been partially replaced by lower-cost carbonaceous materials, such as natural gas, petroleum oils, powder coal, and tar. Fundamental changes in the production of steel are expected to further reduce the need for coke.

A number of years ago, coal tar was the primary, if not the sole, source for hundreds of important organic chemicals and derivatives, notably the phenols, cresols, naphthalene, and anthracene, as well as other important coal tar end-products, such as solvent naphtha and pitch. In recent years, synthetic processes for the production of phenol, the cresols and later the xylenols, have been developed and thus, to a large extent, have pushed coal tar into the background as a source of feedstocks for the chemical industry.

Carbonization Process

Present coking processes generally are of two types: (1) *high-temperature* (900–1200°C) carbonization for producing metallurgical coke and (2) low-temperature (500–750°C) carbonization, still practiced in some countries where there is a market for "semi-coke" as a smokeless home fuel and tars as feedstock for synthetic liquid fuels.

Currently, in the United States, slot ovens with byproduct recovery systems are used almost exclusively. These ovens are built in the shape of narrow chambers placed side by side with interspersed flues for heating. Usually, up to 90 chambers are placed together to form a battery. The chambers are charged individually with coal from the top. After carbonization is complete (14–20 hours), the chambers are discharged on one side by pushing with a ram from the opposite side. Each chamber is connected at the top to one or two collecting ducts, or mains, which carry the gas evolved and the distillate (tar) to suitable coolers and receivers. By high-temperature carbonization, one obtains generally from one ton (metric) of coal: 748 kilograms coke, 343 cubic meters of coke oven gas, and 37.9 liters of tar.

Processing of Crude Tar

With reference to Fig. 1, the crude tar, after being separated from ammonia and other gases, is subjected to an initial distillation (called *topping*) which

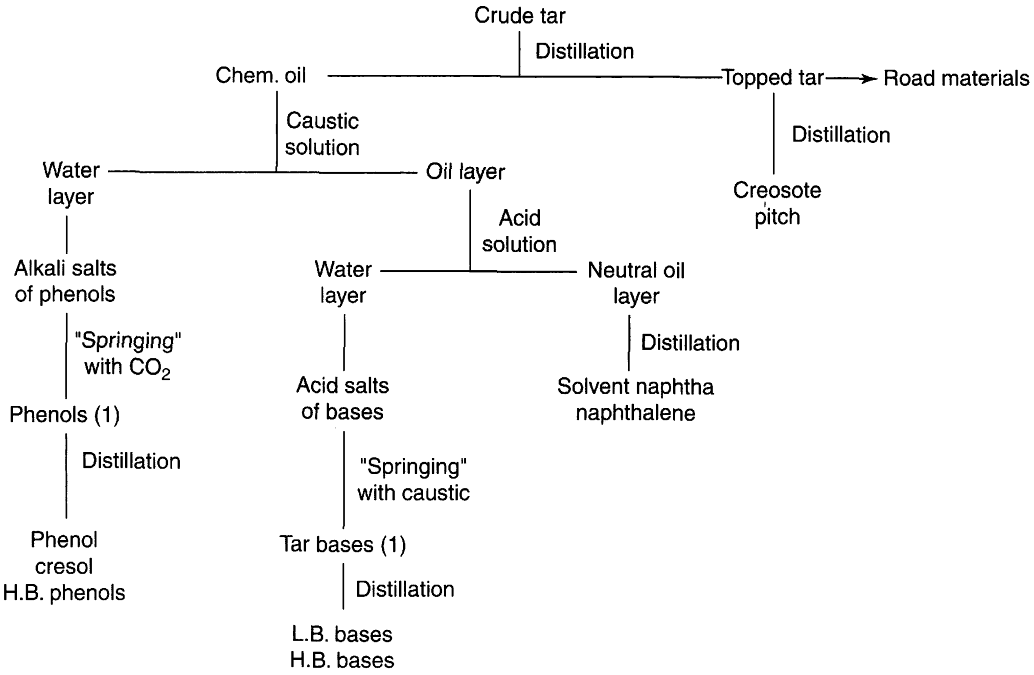

Fig. 1. Bulk fractions from crude coal tar

separates the desired chemical constituents from the higher-boiling, more viscous tar constituents. In a typical case, the distillate from this operation (sometimes referred to as *chemical oil*) has an upper boiling point of about 250°C and contains (1) phenols (*tar acids*), (2) napthalene, which is the most prevalent single constituent of coal tar (6–10%), (3) pyridine-type bases (*tar bases*), and (4) neutral oils. The tar acids constitute about 1.5–3% of the coal tar.

Tar Acids

These materials are recovered by extraction of the chemical oil with aqueous alkali, usually caustic solution. The aqueous layer is separated from the dephenolized (*acid-free*) oil. The phenols then are recovered in crude form by acidification (*springing*) of the aqueous solution, usually by injecting carbon dioxide, followed by gravity settling. The crude phenols then are fractionated to obtain phenol, cresols, and the higher-boiling phenols (mostly xylenols). See also **Phenol**.

Tar Bases

These materials are extracted from the dephenolized oil with aqueous solutions of mineral acids. This operation may be carried out on the entire neutral oil, or it may be done on the solvent naphtha fraction. In the latter case, only the lowest-boiling bases (picolines and lutidines) are recovered, and the higher-boiling bases (mostly quinoline and isoquinoline) can be recovered from postnapthalene fractions or left in the residue for disposal. In European practice, the topping is carried out so that several fractions are obtained: *carbolic oil*, which yields the phenols and lower-boiling bases; and *naphthalene oil*, from which naphthalene is recovered by crystallization.

The tar bases form water-soluble salts with mineral acids which are separated from the oil. They are recovered from their salts by contacting with aqueous alkali (*springing*) and separating the crude bases from the salt solution. The lutidines constitute the major part of the lower-boiling bases. See also **Pyridine and Derivatives**.

Solvent Naphtha

The lower-boiling fraction of the neutral oil is a very powerful solvent, particularly for coatings containing coal tar and pitch. The material also is a source of unsaturated compounds, such as indene and, in a lesser amount, coumarone and homologues of these compounds. Resins are formed *in situ*from these compounds when solvent naphtha is treated with Friedel-Crafts type catalysts. See also **Friedel-Crafts Reaction**. These resins are useful in the manufacture of inexpensive floor tiles and coatings. The remaining solvent is recovered by distillation and used as a solvent.

Naphthalene

This compound finds a ready market principally for the production of phthalic anhydride. There is a great variety of processes to isolate napthalene from the acid-free or neutral oils. Frequently, the naphthalene is first concentrated by distillation, and the enriched oil then is worked up by crystallization. This process is prevalent in Europe. It is also possible to isolate the naphthalene by careful fractionation. Depending on the purity desired, additional chemical treatments may be required. Naphthalene usually is traded with freezing point as a measure of purity (80.3°C) for pure naphthalene. A good quality commonly used is "78°C" naphthalene, which is about 96% pure.

Topped Tar

With reference Fig. 1, it will be noted that topped tar is the residue remaining from the topping operation where the chemicals are separated as the distillate. The principal use of topped tar is in road materials. A number of standard grades (RT-1 to RT-12) are available, the grade depending on the "consistency" or viscosity of the tar. Road tar has excellent weather and skid resistance, but its use is limited by availability and price as compared with asphalt. This is borne out by the respective amounts used for road building (United States) with about 90% using asphalt.

Creosote

Chemically, creosote is a mixture of a great number of compounds, almost exclusively of cyclic structure. Individual compounds present in creosote in concentrations of 2–4% are acenaphthene, fluorene, diphenylene oxide, anthracene, and carbazole. Only one compound, phenanthrene, is present in a larger concentration (12–14%). For many years, chemists in many countries have tried to isolate individual compounds and to find profitable uses for them. Most of these attempts have failed with exception of those involving anthracene. See also **Anthracene**. The principal use of creosote is for preservation of wood. Railroad ties, poles, fence posts, marine pilings, and lumber for outdoor use are impregnated with creosote in large cylindrical vessels. If properly treated, the life of the wood is greatly extended. Materials that are competitive with creosote for wood-preservation purposes include various petroleum oils, and pentachlorophenol. Pentachlorophenol is used in solutions of creosote or of petroleum oils. Blends of creosote with petroleum oils also are used for economic reasons.

Pitch

This is the residue from the processing of coal tar. Since pitch constitutes over 50% of the crude tar, its utilization has a major effect on the economics of tar processing. Coal tar contains an estimated 5,000–10,000 compounds;

it is reasonable to assume that about half of this number is contained in the pitch. Of the roughly 300 compounds identified in coal tar, about one-half must be in the pitch on the basis of their boiling points. It is probable that none of these compounds is present in pitch in concentrations of more than a fraction of 1%. Coal tar pitch is a black, shiny material that is solid and brittle at low temperatures and liquid at high temperatures. Since it is composed of a great number of different compounds, many of which interact to form eutectic mixtures, it does not show a distinct melting or crystallizing point. Pitch usually is characterized by the *softening point*, which can be measured in several ways.

Because of the importance of pitch in various industries, many studies have been made to elucidate its composition. Solvent fractionation has been used to subdivide pitch into fractions by molecular weight, the higher-molecular-weight fractions requiring more powerful solvents. However, even the highest-molecular-weight compounds are only of moderate molecular weights, ranging up to 6 or 7 condensed rings with molecular weights in the range of 350–400. Constituents isolated from pitch have been identified and appear to be crystalline, well-defined substances. It is generally believed that the glasslike state of pitch is caused by association forces and by the mutual melting-point depression exerted by a large number of multiring compounds that tend to form eutectics. The uses of pitch fall in two general classes: (1) applications based upon the binder properties of carbonized pitch (*pitch coke* or *binder coke*); and (2) uses based upon the other physical qualities of pitch.

Carbon pitch is used for carbon electrodes in electrolytic reduction processes, such as aluminum reduction or the production of electro-steels in arc furnaces. Refractory pitch is used in the manufacture of refractory brick, usually burned magnesite or dolomite, the pores of which are filled with pitch by hot impregnation. Upon firing, the pitch in the brick is converted to carbon by carbonization. The remaining pitch coke within the refractory product retards penetration of molten metals and slags, thus prolonging the life of the brick furnace lining. Coke pitch is used in the production of foundry cores.

Roofing Pitch

A substantial amount of pitch is used as covering membrane on flat roofs on industrial plants, large office and apartment buildings, parking garages, and similar structures. Pitches of 50–60°C softening point generally are used.

COATING AGENTS (Foods). Substances that are used to protect the surface (and penetration through the surface) of various materials that are being processed or in final-product format. Coating agents are widely used in the pharmaceutical and food industries.

For example, in the food field, fresh produce requires very little processing. Some fruits may be dipped in 1–2% citric acid prior to freezing. This removes any residual lye from the peeling process and any further destruction of ascorbate is prevented. However, citric acid alone is not always sufficient to prevent deteriorative effects during freezing and thus a sequestrant/antioxidant may be added. A solution of 0.5% citric acid with 0.02% D-erythroascorbic acid may be used to prevent browning of some fruits during freezing and defrosting. The procedure is also useful with some vegetables. Plain wax coatings are applied to many packaged cheeses.

Dried fruits, such as raisins, prunes, and figs, require a residual moisture content because most consumers do not like a thoroughly dry or crispy product in this category. Residual moisture, of course, encourages mold and yeast growth. Protection can be gained by dipping the fruit in solutions of 2–7% potassium sorbate, this leaving a fine coating of antimicrobial agents on the fruit pieces.

Acetostearin products (di- and triglycerides) solidify into wax-like solids and are used in some protective coatings for food products. Researchers have shown these products to be effective against moisture penetration, as well as against atmospheric gases. The coating is applied by dipping; spraying in the case of nuts.

For tablet-like confections and pharmaceuticals, sucrose is one of the most common of coating materials. It is transparent, but can be made opaque, and makes an excellent film-like coating. Gums and resins are also used. Some products such as pills and candies can be multicoated by using approved colorants in the coating agents.

The film-forming characteristics of starch have been used for many years. Numerous products can be protectively and decoratively coated with starch. Starch can be added to sugar solutions to provide a less brittle and moisture-sensitive surface. Starch coatings have the advantage of being oil and grease resistant.

Methylcellulose when incorporated into sweet dough products serves to improve adherence of the glaze.

Red meats, poultry, and fish can be coated with a protective film prior to freezing by dipping into successive solutions of 10–15% sodium alginate, 3–5% calcium chloride, and 10–20% glycerol, the latter used as a plasticizer. This coating improves retention of juices upon freezing or thawing. Sodium alginate coating for sausages, alone or with ethylcellulose, prevents salt rust and increases storage stability. Researchers also have studied the effectiveness of carrageenan as a way to prevent oxidative rancidity after freezing. In a Norwegian process, fish are block-frozen in alginate jelly, forming an air-tight coating, preventing oxidative rancidity.

Coatings. See **Conversion Coatings**; **Paint and Finish Removers**.

COBALT. [CAS: 7440-48-4]. Chemical element, symbol Co, at. no. 27, at. wt. 58.9332, periodic table group 9, mp 1495°C, bp 2870°C, density 8.832 g/cm^3.

There are two allotropic modifications of cobalt, a close-packed hexagonal form (ε) with space group $P6_3/mmc$, stable at temperatures below 417°C; and a face-centered cubic form (α) with space group $Fm3m$, stable at higher temperatures—up to the melting point. The metal is silvery gray in color. The only naturally occurring isotope, ^{59}Co, is stable, but the other twelve known isotopes are radioactive, their mass numbers ranging from 54 to 64. Half lives range from 0.2 second for ^{54}Co to 5.3 years for the industrially and medically important ^{60}Co. See also **Radioactivity**.

Cobalt was identified and described by Georg Brandt in 1735, but had to wait until the last decade of the nineteenth century before the new sources of metal supply from New Caledonia and Canada stimulated its metallurgical usage.

First and second ionization potentials are 7.86 eV and 17.05 eV, respectively; oxidation potential E° is −0.277 V. Further general specifications are given under **Chemical Elements**.

Occurrence

The cobalt content of the earth's crust is estimated to be within the range 10 to 40 ppm. Economic concentrations of the element are the exception so that supply is governed by its byproduct output from ores mined for the recovery of other elements, particularly copper and nickel. For technical reasons, the sulfides, arsenides and oxidized minerals form almost the entire economic source of the metal. Its production is restricted to a relatively few countries, the most important being the Republic of Zaire and Zambia in Africa, Canada, Finland, Morocco, and the United States. The cobaltiferous deposits in the copper belt of central southern Africa vary in content from 1 to 30 parts of cobalt to 100 parts of copper, with an estimated hundreds of millions of tons containing 2 to 15 parts cobalt to 100 parts copper. Sulfide nickel ores the world over have a cobalt content in the range 2 to 5 (very occasionally as high as 10) parts to 100 parts of nickel; oxide nickel ores vary in cobalt content from 1 to 30 parts per 100 parts nickel, with estimated thousands of millions of tons containing 5 to 15 parts cobalt per 100 nickel. The nickel lateritic deposits in the tropical and subtropical areas of the world represent a large potential future source of both nickel and cobalt.

Manheim (1986) reported that ferromanganese oxides in the open oceans are more enriched in cobalt than any other widely distributed sediments or rocks. Concentrations of cobalt in excess of 1% in ferromanganese crusts on seamounts, ocean ridges, and other raised areas of the ocean have been found. Some experts have observed that these cobalt-rich crusts are among the slowest-growing of any material source on earth, with estimates of an accumulation of only one molecular layer over a period of a few months. As observed to date, most of the cobalt-rich crusts are situated within the exclusive economic zone of the United States. This is in contrast with abyssal cobalt nodules, which occur mainly in international waters and are also difficult to recover. The U.S. Department of the Interior is preparing an environmental impact statement pertaining to the recovery of the ferromanganese crusts.

Mining and Recovery

The economically important cobalt-containing minerals exploited at present are listed in Table 1. The metal extraction processes, following the usual pretreatment of the ore, are varied and complicated because the metallurgical properties of cobalt differ insufficiently from those of the associated metals and because the cobaltiferous raw materials comprise the sulfide, arsenide, and oxide, or a mixture of these. The final refining stage invariably involves electrolysis.

Investigators at the Argonne National Laboratory (1985) reported a two-step process for extracting cobalt and manganese from low- and medium-grade ores normally mined for other metals. The new process provides an important secondary source for these strategically important metals. More detail is given in the entry on **Manganese**.

Uses of Metal and Alloys

The metallurgical applications of cobalt consume approximately 70-75% of the world production; the remainder goes into chemicals. Relatively little use has been made of the pure metal, the most important being as the radioisotope ^{60}Co for teletherapy and industrial radiation processing and gamma radiography. The increasing availability of the metal in various wrought forms will stimulate its applications in those areas where the intrinsic properties of cobalt are advantageous, e.g., magnetic devices, wear resistance and bearing properties at elevated temperatures, and the manufacture of heterogeneous welding rods for hardfacing. Major uses of the metal may be classified as follows:

High-temperature Materials. To meet the demand of the gas turbine industry, alloys capable of reliable performance at high temperature and loads have been developed based on cobalt and cobalt-containing nickel and iron-based alloys. The improvement in properties at these very high temperatures (~750-1200°C) has been brought about by the addition to the oxidation- and sulfidation-resistant cobalt-chromium matrix of varying amounts of refractory metals, mainly tungsten, molybdenum, tantalum, and columbium (niobium) to strengthen the matrix further and promote the formation of stable carbides, which makes a substantial contribution to the high-temperature strength. The application of current techniques of vacuum melting and casting insure optimum material properties and improved component reliability. A new family of alloys based on Co-Fe-Cr is being successfully applied in the exacting conditions that exist in metallurgical furnaces and petrochemical plants.

Magnetic Materials. For the past 50 years, apart from iron, cobalt has been the most important constituent of permanent magnet materials. This is because cobalt additions raise the saturation magnetization and the Curie temperature to higher values than are obtained from pure iron. Present advanced Alnico type cast alloys are the results of 40 years of development and are the most widely used permanent magnet materials. More recently, permanent magnet materials based on cobalt-rare-earth (e.g., samarium, praseodymium) compounds have emerged as the most powerful magnets available.

Hardfacing and Wear-resistant Alloys. These materials, essentially quaternary alloys of cobalt; chromium, tungsten (or molybdenum); and carbon, are widely used for industrial hardfacing purposes. They can be deposited by welding techniques, sprayed on as powders, or produced as separate castings. By using the weld deposition technique, a highly alloyed heat-, wear-, and corrosion-resistant surface can be applied to a much cheaper substrate, e.g., mild steel. Used originally as a component reclamation process, these alloys and techniques are now primary design requirements for many engineering items. The feasibility of electrodepositing composite cobalt-carbide coatings from an agitated slurry of solid carbide particles in a conventional plating bath has been demonstrated. These coatings provide excellent wear protection and are now established in the aerospace industry, while other engineering applications are being evaluated.

The demand for wear resistance allied with a low coefficient of friction has been successfully met by cobalt-molybdenum-silicon alloys. Structurally they conform to the well-proven bearing concept of hard intermetallic phases dispersed through a softer cobalt matrix. They offer outstanding bearing performance in conditions of poor lubrication.

As of the early 1990s the historical importance of cobalt in alloys for reducing wear resistance was markedly diminished by the development of *Norem* alloys, which were derived from stainless steel, particularly the Armco *Nitronic 60*, admittedly one of the few stainless steels that has excellent wear resistance. This is an outgrowth of research conducted by EPRI (Electric Power Research Institute) in an effort to lower equipment costs. Initial uses of the new cobalt-free alloys will be power plant valves and turbines. Also, in nuclear reactor applications, the *Norem* alloys will not become activated (Co does), reducing worker-protection and maintenance costs. Tests have confirmed that the new cobalt-free alloys retain their wear-resistant properties when produced as rods and powders, the most common forms used by welders.

Alloy Steels. The addition of cobalt to high-speed tool steel was one of the earliest uses of cobalt. This application is represented by the super-high-speed tool steel grades, which contain 5-12% cobalt. Two other cutting tool materials, the nonferrous cobalt-chromium tungsten-carbon cast alloy and the cemented carbides also provide a steadily growing outlet for cobalt. Hot work die steels are another group of alloy steels which benefit from the effect cobalt has on the tempering characteristics and consequent hot strength retention. The most significant development in recent years, however, is the advent of the Ni-Co-Mo miraging family of steels, which combine very high strength and toughness properties to an unusual degree. This is still an area of active development and growing engineering utilization.

Toxicity. Cobalt, like most other metals, is not entirely harmless, although it is not in any way comparable to the known toxic metals, such as mercury, cadmium, and lead. Inhalation of fine cobalt dust over long periods can cause an irritation of the respiratory organs, which may result in chronic bronchitis. Complete recovery is usually achieved upon removal from the contaminated atmosphere. Cobalt salts can cause benign dermatoses, either in people new to handling them, or after prolonged exposure, usually several years.

Chemistry of Cobalt. The metal in the massive form is not attacked by air or water at temperatures below approximately 300°C; above this temperature it is oxidized in air. The metal combines readily with the halogens to form the respective halides. It combines with most of the other metalloids when heated or in the molten state. It does not combine directly with nitrogen but decomposes ammonia at elevated temperature to form a nitride. It reacts with carbon monoxide at 225-230°C to form the carbide, Co_2C. Cobalt also forms intermetallic compounds with many metals, e.g., Al, Cr, Mo, Sn, Ti, V, W and Zr. Metallic cobalt is readily

TABLE 1. PRINCIPAL ECONOMICALLY IMPORTANT COBALT MINERALS

Group and Name	Ideal Formula	Cobalt Content %	Source Area
Sulfides			
Linnaeite	$(Co, Cu, Ni, Fe)_3S_4$	Up to ~48	U.S.A., Zaire, Finland
Carrolite	$CuCo_2S_4$	Up to ~38	Zambia, Zaire, U.S.A.
Pentlandite	$(Fe, Ni, Co)_9S_8$	Up to ~2	Canada
Cobaltiferous Pyrite	$(Fe, Co)S_2$	Up to ~2	Canada, Finland, Zambia
Arsenides			
Skutterudite	$(Co, Ni, Fe)As_3$	Up to ~28	Canada, Morrocco, U.S.A.
Gersdorffite	(Ni, Co, Fe)AsS	Up to ~12	Canada, Zaire, U.S.A.
Oxides			
Heterogenite	$Co_2O_3 \cdot H_2O$	Up to ~57	Zaire, Zambia
Asbolite	$(Co, Ni)O_2MnO_2 4 \cdot H_2O$	Up to ~27	New Caledonia, Canada

Note: See also **Pentlandite**; and **Skutterudite**.

dissolved in dilute sulfuric, hydrochloric or nitric acids to form cobaltous salts. Like iron, cobalt is passivated by strong oxidizing agents, such as the dichromates. It is slowly attacked by ammonium hydroxide and sodium hydroxide.

Cobalt Compounds. In general the chemical properties are intermediate between those of iron and nickel. The predominant oxidation states of cobalt compounds, except for a large class of organometallic compounds, are 2+ and 3+. Common usage assigns the terms *cobaltous* and *cobaltic*, respectively, to these.

In aqueous solutions and in the absence of complexing agents, cobalt compounds are stable only in the 2+ oxidation (cobaltous) state. In the complexed state the cobaltous ion is relatively unstable, being readily oxidized to the 3+ oxidation (cobaltic) state. An extremely large number of 3+ complex ions have been identified, most of which are quite stable in aqueous media.

Cobalt has an electronic configuration $1s^22s^22p^63s^23p^63d^74s^2$. The two 4_s electrons are readily removed producing the ordinary Co^{2+} ion. In principle, if the odd $3d$ electron were removed the simple cobaltic ion Co^{3+}, would be formed. This however does not occur: the ion exists only in complex ions or crystal lattices in which cases additional electron orbitals are filled.

Cobalt and oxygen form two stable oxides, cobaltous oxide, CoO, stable below 200°C and above 900°C; and cobalto-cobaltic oxide, Co_3O_4, which is stable below 900°C. Between 200 and 900°C the CoO oxidizes partially, or completely, to Co_3O_4.

Cobaltous oxide, [CAS: 1307-96-6], is usually prepared by heating the carbonate. It is insoluble in H_2O, NH_4OH, and alcohol, but dissolves in cold strong acids and in weak acids on heating. Commercial gray oxide, which may contain up to 40% Co_3O_4, is used in the ceramic, glass and enamel industries and also in the production of catalysts. It is also used in the preparation of cobalt metal powder. The Co(III) oxide can also be prepared by calcining oxides, hydroxide and salts. The oxide is insoluble in H_2O and only slightly soluble in acids. The commercial black oxide consists essentially of Co_3O_4 with possibly up to 20% of CoO.

Cobalt(II) hydroxide exists in two allotropic forms, a blue α-Co $(OH)_2$ and a pink β-$Co(OH)_2$. The hydroxide is prepared by precipitation from a cobaltous salt solution by an alkali hydroxide. When the alkali is in excess the pink β-form is produced—the blue α-form is produced when the cobalt salt is in excess. The salt slowly oxidizes in air at room temperature and changes to hydrated cobaltic oxide, $Co_2O_3 \cdot nH_2O$. The hydroxide is practically insoluble in H_2O and in bases, but highly soluble in mineral and organic acids. The commercial salt is used as the starting material in the preparation of drying agents.

Cobaltous halides are formed with the halogen group, but only fluorine forms a stable cobaltic compound. The other cobaltic halides are stable only in complex ions.

Commercial cobaltic fluoride is formed by the reaction of cobalt, its oxides or simple salts with ClF_3 or BrF_5 to yield a brown anhydrous salt. This is a powerful fluorinating agent readily replacing hydrogen in aliphatic and aromatic hydrocarbons. Cobaltous chloride is a pale-blue compound and very hygroscopic. A series of hydrates is known; the hexahydrate is pink but becomes blue on warming. It is extremely soluble in H_2O, and in numerous organic solvents. The commercial salt is used as a starting material in the manufacture of catalysts, in electroplating, agricultural chemicals, and pharmaceuticals. Cobaltous bromide is highly hygroscopic and transforms gradually to the red hexahydrate. The salt is mainly used in the catalysts industry.

A number of sulfides have been reported, the best characterized being Co_4S_3, Co_9S_8, CoS, Co_3S_4, and CoS_2. They are prepared either by metal or salt solution reaction with S or H_2S. The mixed sulfides of cobalt and molybdenum have catalytic properties of hydrogenation and isomerization.

The sulfate, one of the more important industrial salts of cobalt, is usually available as the red heptahydrate, an efflorescent substance. On heating it converts to the dark-blue monohydrate, and after prolonged heating above 250°C the red anhydrous salt. It is widely used in the electroplating and ceramic industries, and in the preparation of drying agents and agricultural pasture top-dressing.

Cobalt and nitrogen form three nitrides, Co_3N_3, Co_2N, and CoN, products of metal/ammonia reaction and compound decomposition. All are gray-black or black in color.

In its commercial form cobalt nitrate appears as the red hexahydrate, $Co(NO_3)_2 \bullet 6H_2O$ formed by dissolving the metal oxide or carbonate in dilute HNO_3 and concentrating the solution. The compound deliquesces in moist air and effloresces in dry air. The pink anhydrous cobaltous nitrate cannot be formed by dehydrating the hexahydrate but by treating the salt with nitrogen pentoxide gas (or in solution in concentrated HNO_3). The salt is used mainly in the preparation of catalysts.

Two discrete carbides have been characterized—Co_3C and Co_2C. The former, which has the same structure as Fe_3C, has been prepared by reacting cobalt with coal gas at temperatures between 500–800°C. Co_2C is formed by the reaction of carbon monoxide at atmospheric pressure on cobalt powder at 225–230°C.

Cobaltous carbonate, $CoCO_3$, is found almost pure in the mineral sphaerocobaltite in the Republic of Zaire and less extensively in Zambia. The pale-red anhydrous salt is obtained by reaction in solution of an alkaline carbonate and a cobaltous salt under a slight pressure of carbon dioxide (up to 1 atmosphere) and subsequent heating at 140°C. The commercial salt is violet-red in color, partially hydrolyzed with an indeterminate composition. It is insoluble in H_2O and alcohol, but dissolves easily in inorganic and organic acids, and is often used for the preparation of other salts. According to the thermal conditions it decomposes to the different types of oxides.

Cobaltous acetate, [CAS: 71-48-7], $Co(CH_3CO_2)_2$, is obtained as a pink salt by the dehydration of the tetrahydrate which is prepared by dissolving the hydroxide or carbonate in acetic acid. The tetrahydrate, which is the commercial form, is widely used in the preparation of catalysts, e.g., OXO synthesis, and dryers for inks and varnishes.

Cobaltous oxalate dihydrate, $CoC_2O_4 \cdot 2H_2O$ (pink), is obtained by adding oxalic acid or an alkaline oxalate to a cobaltous salt solution. This is the commercial form of the salt and is important as the starting material in the preparation of cobalt metal powders.

Cobalt(III) coordination compounds are the classics of coordination chemistry, many of the cobalt(III) amines having been prepared in the nineteenth century. They are invariably colored and undergo reaction slowly. Because of this many isomers have been isolated and studied. Much of the knowledge of isomerism, mechanisms of reaction, and general properties of octahedral species are based on cobalt(III) compounds. The important donor atoms (in order of decreasing tendency to complex) are nitrogen, carbon in the cyanides, oxygen, sulfur, and the halogens. The coordination number is invariably six. An extensive class of amines and compounds of the amines is known ranging from hexamine $[CoN_6]^{3+}$ through to monoamines $[CoNX_5]^{2-}$. The compounds are made in several stages by first oxidizing the cobalt(II) species and then various different substituted species are prepared by substitution reactions on the primary cobalt(III) product. When air is drawn through an aqueous solution containing cobalt(II) and ammonia the solution turns brown. From this mixture can be obtained a variety of products which depend on the initial concentrations of reactants, the pH of the solution, the anion present and the presence of heterogeneous catalysts, such as charcoal. The products are invariably colored ranging from blue-violets and green through various shades of red and brown to yellow. The absorption spectra are characteristic of the various structures. Complex cyanides of the types $[Co(CN)_6]^{3-}$ and $[Co(CN)_5X]^{3-}$ are stable and diamagnetic. The anion $[Co(CN)_6]^{3-}$ is pale yellow and is the ultimate product of the reaction when a solution of cobalt(III) cyanide in aqueous KCN is boiled in air. It is very unreactive, being untouched by chlorine, peroxide, alkali, aqueous HCl and H_2S, although it gives CO when treated with concentrated H_2SO_4.

The only cobalt(IV) compound appears to be $Cs_2[CoF_6]$ which is prepared as a yellow powder by the fluorination of Cs_2CoCl_4.

Evidence for cobalt(I) was first obtained from the electrolytic reduction of cyano-compounds and some of the reduced species have been isolated. There are also many cobalt(I) coordination compounds of the organometallic class carbonyl, isonitriles, and unsaturated hydrocarbon derivatives. The oxidation state cobalt(0) may be represented in the cyano-compound which has been formulated as $K_8[Co_2(CN)_8]$. It has been prepared as an air-sensitive brown-violet compound by reducing a liquid ammonia solution of $K_3[Co(CN)_6]$ with an excess of K metal. The only other known cobalt(0) species are organometallic compounds.

For the role of cobalt in biological systems, see **Cobalt (In Biological Systems)**.

COBALT (In Biological Systems). Although cobalt is regarded as an essential element for animals, including humans, the element can perform its essential functions only after it has been incorporated into the vitamin B_{12} molecule. The microorganisms living in ruminants are the major producers of vitamin B_{12} in the food chain. Green plants do not synthesize the vitamin. The normal intake of this vitamin is by way of milk, cheese, meat, and eggs. Persons who follow a strictly vegetarian diet may become deficient in vitamin B_{12} unless supplementary sources are used. Single-stomach domestic and wild animals receive their vitamin B_{12} from animal flesh or from animal fecal material. See also **Vitamin B_{12} (Cobalamin)**.

Cobalt is present in vitamin B_{12} to the extent of about 4%. Lack of cobalt in the soil and feedstuffs prevents ruminants from synthesizing all of the vitamin B_{12} for their needs. Thus, cobalt can be added to feedstuffs as the chloride, sulfate, oxide, or carbonate. Excessive cobalt intakes are toxic, causing a reduction in feed intake and body weight, accompanied by emaciation, anemia, debility, and elevated levels of cobalt in the liver. It is of interest to note that clinical cobalt toxicity closely resembles clinical cobalt deficiency.

Cobalt is required by the microorganisms that live in nodules on the roots of legumes, such as bean and clover. They convert nitrogen from the air into chemical forms that can be used by higher plants. This is possibly the only well established and understood function of cobalt in plant growth. Legumes may grow normally and the microorganisms on their roots fix atmospheric nitrogen, even though the forage does not contain sufficient cobalt to meet the requirements of ruminants.

Areas of low cobalt content in the United States, where clovers and alfalfa are too low in cobalt content to meet requirements of cattle and sheep, include northeastern Maine, all of New Hampshire, Vermont, Massachusetts, Connecticut, and Rhode Island, much of New York with exception of the central portion, the northwestern portion of the lower peninsula of Michigan, a small area in Illinois with Peoria at its approximate center, all but eastern Iowa, and southwestern Minnesota. The low-cobalt soils of New England are primarily sandy and were formed from glacial deposits near and to the south of the White Mountains of New Hampshire. Along the south Atlantic Coastal Plain, legumes with very low concentrations of cobalt are primarily on the sandy soils formed in naturally wet areas. These soils, which are called spodosols, have light-colored subsurface layers overlying a dark-brown or dark-gray hard-pan layer.

Grasses and cereal grains generally contain less than the 0.07 to 0.10 parts per million of cobalt required by ruminants. Cattle and sheep that are not fed any legumes nearly always require cobalt supplementation.

Adding cobalt to soils, either as cobalt sulfate, or as cobaltized superphosphate, can be used to increase the level of cobalt is plants and prevent cobalt deficiency in cattle and sheep. Cobalt fertilization may not be effective in preventing cobalt deficiency on alkaline soils because in these soils, the added cobalt quickly reverses to forms that are not taken up by plants. Cobalt fertilization is more common in Australia than in the United States. In the United States, cobalt is usually added to mixed feeds, mineral mixes, or salt licks.

Still another method is to place heavy ceramic "bullets" containing cobalt in the animal's rumen. These bullets remain in the rumen and slowly release cobalt to meet the animal's needs for a long period. The diets of hogs and chickens are often supplemented with concentrated forms of vitamin B_{12}.

The relationship of the levels of cobalt in soils and plants to the health of ruminants is one of the striking examples of the importance of a soil and plant relationship to animal health. When some Australian scientists discovered this relationship, new areas in several parts of the world became usable for animal production. The vitamin B_{12} formed within cattle and sheep in these new areas contributed to the vitamin B_{12} nutrition of people, even though adding cobalt to soils does not directly affect human nutrition in the absence of the production of ruminants. Cobalt-deficient grazing soils are found in Australia, New Zealand, and, in the United States, mainly in Florida, although deficient regions are found elsewhere as previously mentioned. Cobalt deficiency can result in a condition known as "pinining disease," where the affected animals are quite listless. The disease is also known as "bush sickness" and "salt sickness."

COBALTITE. The mineral cobaltite is a sulfarsenide (see **Arsenic**; and **Sulfur**) of cobalt, corresponds to the formula CoAsS, crystallizing in the isometric system as cubes or pyritohedrons, also may be massive. Cobaltite has a very good cleavage parallel to the cube faces; uneven fracture; brittle; hardness, 5.5; specific gravity, 6.33; metallic luster; color, silvery-white to reddish, sometimes steel gray or violet to grayish-black; streak, grayish-black. Cobaltite is found with cobalt and nickel minerals deposited commonly by metasomatic processes. It is found in Sweden, Norway, England and the Province of Ontario. It is an ore of cobalt.

COENZYMES. A nonprotein substance that is closely associated with or bound to the protein component (*apoenzyme*) of an enzyme. Together, the coenzyme and apoenzyme form the complete enzyme known as the *holoenzyme*. The presence of a coenzyme is necessary for enzyme activity. Coenzymes are organic molecules of a size intermediate between the small-molecule intermediary metabolites, which serve as the substrates of enzymatic reactions, and the macromolecular proteins. Each coenzyme acts usually as acceptor or donor of some specific type of atom or group of atoms to be removed from or added to a small-molecule substrate in a reaction catalyzed by the holoenzyme.

Coenzyme A (CoA)

Pantothenic acid is a constituent of coenzyme A, which participates in numerous enzyme reactions. CoA (Fig. 1) was discovered as an essential cofactor for the acetylation of sulfanilamide in the liver and of choline in the brain. It has been established that CoA is involved in many biochemical reactions in the body as an "activator" of normally less reactive carbon fragments and a "transferer" of these fragments to different molecules. CoA is particularly important in the initial reaction of the citric acid cycle of carbohydrate metabolism and energy production. After oxidative decarboxylation of pyruvic acid, CoA combines with the two-carbon acetate fragment to form acetyl-CoA or "active" acetate.

$$\underset{\text{(Pyruvic acid)}}{CH_3-\overset{\overset{O}{\|}}{C}-COOH}-CoA+CH_3 \longrightarrow \underset{\text{Acetyl-CoA ("active acetate")}}{CH_3-\overset{\overset{O}{\|}}{C}-CoA}+CO_2$$

Coenzyme A is necessary for the activation, synthesis, and degradation of fatty acids. Synthesis of cholesterol and ultimately the production of steroid hormones are also coenzyme A dependent.

Nicotinic Acid Coenzymes

Nicotinic acid can be converted to nicotinamide in the body and, in this form, is found as a component of two oxidation-reduction coenzymes (Fig. 2): *nicotinamide adenine dinucleotide* (NAD); and *nicotinamide adenine dinucleotide phosphate* (NADP). The nicotinamide portion of the coenzyme transfers hydrogens by alternating between an oxidized quaternary nitrogen and a reduced tertiary nitrogen. See Fig. 3.

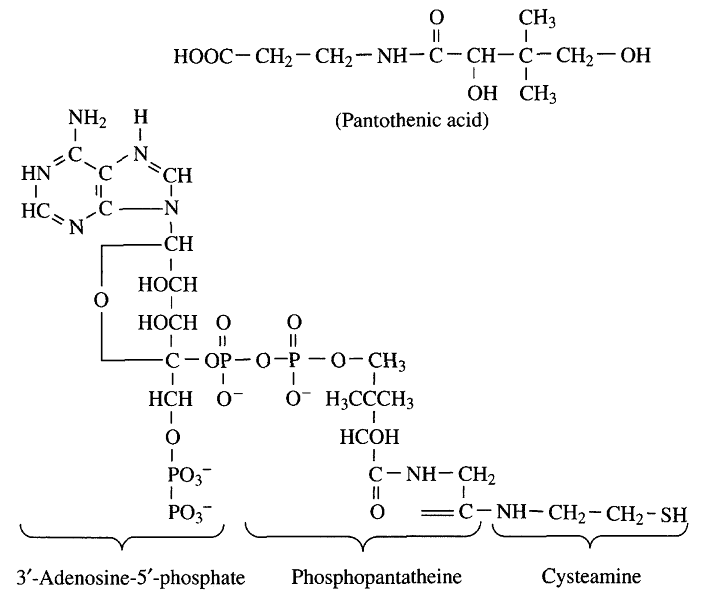

Fig. 1. Structure of CoA, composed of three parts: a nucleotide part derived from 3′-adenosine-5′-phosphate, forming a phosphodiester bond with a 4-phospho derivative of pantothenic acid, and a third part derived from the amino acid, *cysteine*. The side chain SH group of the latter is free in this compound and is readily acylated, and thus able to act as a carrier for acyl groups in biochemical reactions in which it transfers that group between two substrates

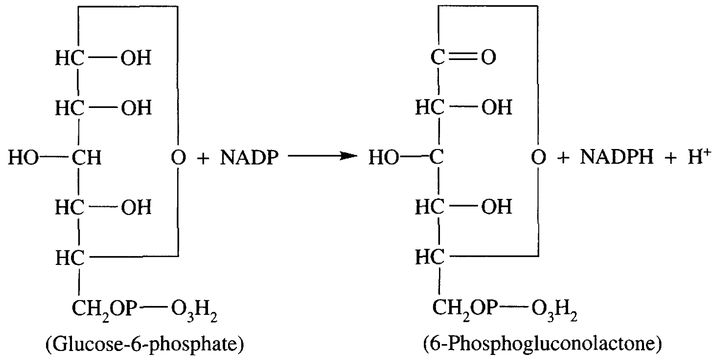
Enzymes that contain NAD or NADP are usually called *dehydrogenases*. In excess of fifty NAD-dependent enzyme systems are known to exist. They participate in many biochemical reactions of lipid, carbohydrate, and protein metabolism. An example of an NAD-requiring enzyme is lactic dehydrogenase, which catalyzes the conversion of lactic acid to pyruvic acid. NADP is an essential coenzyme for glucose-6-phosphate dehydrogenase which catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconic acid. This reaction initiates metabolism of glucose by a pathway other than the citric acid cycle. The alternate route is known as the phosphogluconate oxidative pathway, or the hexose monophosphate shunt. The first step is:



In the biological oxidation-reduction system, reduced NAD (i.e., NADH) is reoxidized to NAD by the riboflavin-containing coenzyme FAD (*flavin-adenine dinucleotide*).

Riboflavin Coenzymes

Riboflavin has been shown to be a constituent of two coenzymes: *flavin mononucleotide* (FMN) and *flavin adenine dinucleotide* (FAD). See Fig. 4. FMN was originally discovered as the coenzyme of an enzyme system that catalyzes the oxidation of the reduced nicotinamide coenzyme, NADPH, to NADP. Most of the many other riboflavin-containing enzymes contain FAD. FAD is an integral part of the biological oxidation-reduction system, where it mediates the transfer of hydrogen ions from NADH to the oxidized cytochrome system. This is illustrated in Fig. 5. FAD can also accept hydrogen ions directly from a metabolite and transfer them, either to NAD, a metal ion, to a heme derivative, or to molecular oxygen. The various mechanisms of action of FAD are probably due to differences in the protein apoenzymes to which it is bound. The oxidized and reduced states of the flavin portion of FAD are shown in Fig. 6.

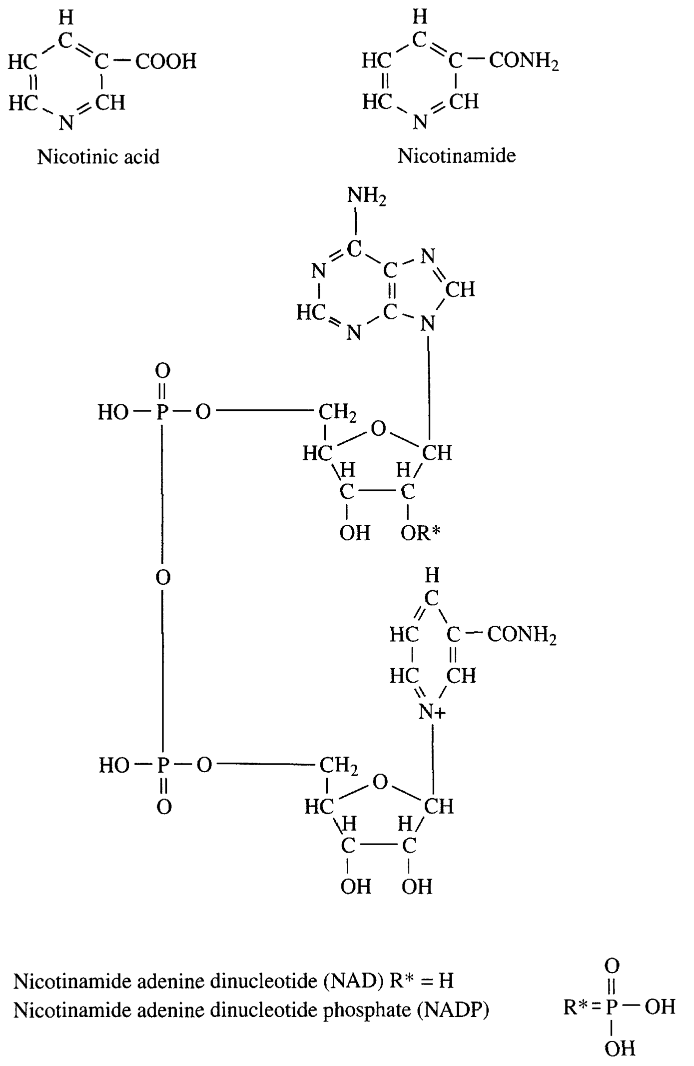


Fig. 2. Structures of nicotinic acid, nicotinamide, and nicotinamide coenzymes

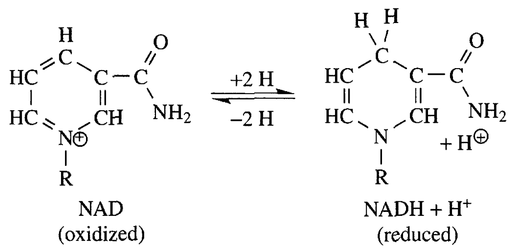

Fig. 3. Oxidized and reduced states of nicotinamide coenzymes as shown in Fig. 2

Decarboxylation Coenzymes

Thiamine, biotin and pyridoxine (vitamin B) coenzymes are grouped together because they catalyze similar phenomena, i.e., the removal of a carboxyl group, COOH, from a metabolite. However, each requires different specific circumstances. Thiamine coenzyme decarboxylates only alpha-keto acids, is frequently accompanied by dehydrogenation, and is mainly associated with carbohydrate metabolism. Biotin enzymes do not require the alpha-keto configuration, are readily reversible, and are concerned primarily with lipid metabolism. Pyridoxine coenzymes perform nonoxidative decarboxylation and are closely allied with amino acid metabolism.

Folic Acid Coenzymes

The coenzyme forms of folic acid are derivatives of tetrahydrofolic acid, FH_4. See Fig. 7. Folic acid functions as a coenzyme in enzyme reactions which involve the transfer of one-carbon fragments at various levels of

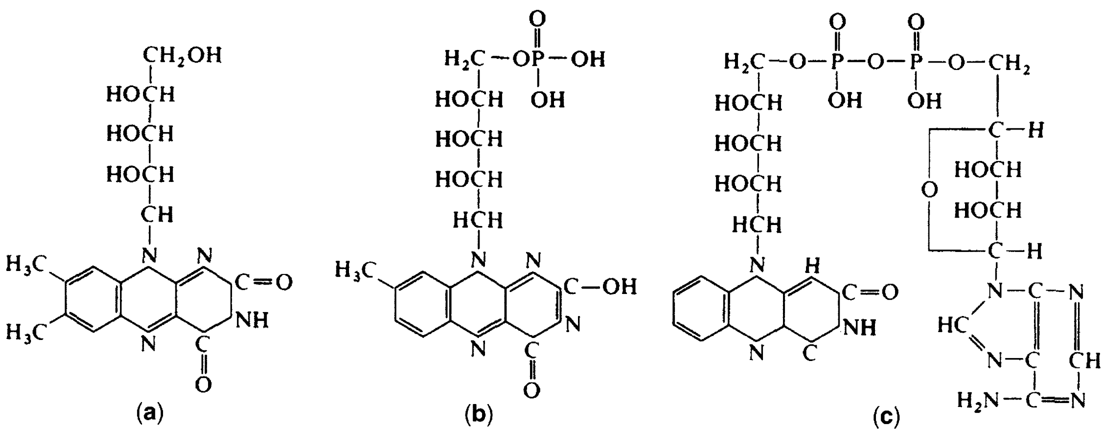

Fig. 4. (a) Riboflavin; (b) Flavin mononucleotide (FMN); (c) Flavin-adenine dinucleotide (FAD)

oxidation. Vitamin B_2 (*cobalamin*) may be interrelated with folic acid in these reactions. Folic acid and vitamin B_{12} are also considered together since certain clinical anemias can be corrected by administration of either of the two vitamins.

Coenzyme Q

A series of quinones which are widely distributed in animals, plants, and microorganisms, these quinones have been shown to function in biological electron transport systems which are responsible for energy conversion with living cells. The nature and significance of coenzyme Q was first recognized in 1957. In structure, the coenzyme Q group closely resembles the members of the vitamin K group and the tocopherylquinones, which are derived from tocopherols (vitamin E), in that they all possess a quinone ring attached to a long hydrocarbon tail. The quinones of the coenzyme Q series which are found in various biological species differ only slightly in chemical structure and form a group of related, 2,3-dimethoxy-5-methylbenzoquinones with a polyisoprenoid side chain in the 6-position which varies in length from 30 to 50 carbon atoms. Since each isoprenoid unit in the chain contains five carbon atoms, the number of isoprenoid units in the side chain varies from 6 to 10. The different members of the group have

been designated by a subscript following the Q to denote the number of isoprenoid units in the side chain, as in coenzyme Q_{10}. The members of the group known to occur naturally are Q_6 through Q_{10}.

Coenzyme Q functions as an agent for carrying out oxidation and reduction within cells. Its primary site of function is in the terminal electron transport system where it acts as an electron or hydrogen carrier between the flavoproteins (which catalyze the oxidation of succinate and reduced pyridine nucleotides) and the cytochromes. This process is carried out in the mitochondria of cells of higher organisms. Certain bacteria and other lower organisms do not contain any coenzyme Q. It has been shown that many of these organisms contain vitamin K_2 instead and that this quinone functions in electron transport in much the same way as coenzyme Q. Similarly, plant chloroplasts do not contain coenzyme Q, but do contain *plastoquinones* which are structurally related to coenzyme Q. Plastoquinone functions in the electron transport processes involved in photosynthesis. In some organisms, coenzyme Q is present together with other quinones, such as vitamin K, tocopherylquinones, and plastoquinones; and each type of quinone can carry out different parts of the electron transport functions.

COLD-WORKED METAL. When metals are plastically deformed at a relatively low fraction (frequently < 0.5) of their absolute melting temperatures, they are normally said to be *cold-worked*. An increase of *hardness* or strength is normally associated with such deformation. This hardening can be relatively stable as long as the metal is not heated high enough to cause extensive recovery and recrystallization to occur. See also **Annealing**. In metals with high melting points, such as the alloys of iron, copper, and nickel, deformation at room temperature is normally considered to be cold-working. On the other hand, room temperature deformation of a low melting point metal such as lead is more properly designated hot-working. In this regard, it is interesting to note that lead is not normally hardened by room temperature deformation.

Cold-working is frequently used for hardening of commercial metal products. Thus, piano wire and the wire used in bridge construction obtain their hardness as a result of the final wire drawing operations. Sheet stock is often supplied in different degrees of hardness obtained by cold-rolling to the desired hardness. Mechanical working is sometimes the only feasible way to harden specific metals and alloys.

COLEMANITE. The mineral colemanite is a borate of calcium corresponding to a formula that is perhaps best represented as $Ca_2B_6O_{11}\cdot 5H_2O$. It occurs either as massive deposits or in monoclinic crystals. It has a subconchoidal fracture; hardness, 4–4.5; specific gravity, 2.42; vitreous to adamantine luster, may be colorless to milky white, grayish or yellowish; transparent to translucent. Colemanite was found originally in Death Valley, Inyo County, California, and has since been found rather widely distributed in San Bernardino, Los Angeles, Kern and Ventura Counties, California, as well as in Clark, Esmeralda and Mineral Counties in Nevada.

Colemanite was, until the discovery of kernite, the chief source of borax. Kernite, $Na_2B_4O_7\cdot 4H_2O$, because of its easy solubility in water, has displaced very largely other boron-bearing minerals as a source of borax. Colemanite, kernite and inyoite (probably $Ca_2B_6O_{11}\cdot 5H_2O$); are lake deposits associated with other and rarer boron minerals, laid down during periods of volcanic activity or resulting from the leaching of the adjacent Tertiary sedimentary formations. Colemanite was named for Mr. William T. Coleman of San Francisco; kernite and inyoite were named from Kern and Inyo Counties, California.

COLLAGEN. The major protein component of connective tissue. In mammals, as much as 60% of the total body protein is collagen. It comprises most of the organic matter of skin, tendons, bones, and teeth, and occurs as fibrous inclusions in most other body structures. Collagen fibers are easily identified on the basis of the following characteristic properties: They are quite inelastic; they swell markedly when immersed in acid, alkali, or concentrated solutions of certain neutral salts and nonelectrolytes; they are quite resistant to most proteolytic enzymes, but are specifically attacked by the collagenases; they undergo thermal shrinkage to a fraction of their original length at a temperature which is characteristic of the collagen from a given animal, but this varies from one species to another; and they are converted in large part to soluble gelatin by prolonged treatment at temperatures above the thermal shrinkage level. Collagen fibers are not unique to mammals; collagen has been identified in the tissues of almost all multicellular animals, ranging from the primitive porifera and coelenterates, through the annelids and echinoderms, and up to the vertebrates.

As a protein, collagen is unusual in both chemistry and structure. Nearly one-third of its residues are glycine, and an additional 20–25% are imino acids (proline and hydroxyproline). In terms of sequence, glycine occurs regularly in essentially every third position, following as a steric requirement of the secondary-tertiary structure.

It appears that specific side-chain interactions between polar residues on adjacent collagen macromolecules are largely responsible for ordering the macromolecules into fibers. Specific cooperative interactions between functional groups on appropriately oriented macromolecules seem to be involved in the heterogeneous nucleation of hydroxyapatite crystals, and thus the initiation and control of mineralization in bones and teeth. As collagen fibers age, *in vivo*, they seem to become progressively more intermolecularly cross-linked, perhaps by the "ester-like" bonds formed. Little or no soluble collagen can be extracted from most mature connective tissue because of this extensive cross-linking, although the material can be converted into soluble gelatin by drastic thermal treatment.

Collagen and gelatin are of commercial importance. As insoluble collagen, this material may be cross-linked further by tanning and thus converted to leather. The soluble gelatins are used in the manufacture of foodstuffs, film emulsions, and glue.

COLLOID CHEMISTRY. A subdivision of physical chemistry comprising the study of phenomena characteristic of matter when one or more of its dimensions lie in the range between 1 millimicron (nanometer) and 1 micron (micrometer). It thus includes not only finely divided particles but also films, fibers, foams, pores, and surface irregularities. Dimension, rather than the nature of the material, is characteristic. Colloidal particles may be gaseous, liquid, or solid, and occur in various types of suspensions (imprecisely called solutions), e.g., solid-gas (aerosol), solid-solid, liquid-liquid (emulsion), gas-liquid (foam). In this size range, the surface area of the particle is large with respect to its volume so that unusual phenomena occur, e.g., the particles do not settle out of the suspension by gravity and are small enough to pass through filter membranes. Macromolecules (proteins and other high polymers) are at the lower limit of this range; the upper limit is usually taken to be the point at which the particles can be resolved in an optical microscope. The first specific observations were made by Thomas Graham in approximately 1860 and were extended by Ostwald, Hatchek, and Freundlich. Though the term is often used synonymously with *surface chemistry*, in a strict sense it is limited to the size range noted in at least one dimension, whereas surface chemistry is not. Natural colloid systems include rubber latex, milk, blood, egg white, etc.

See also **Colloid Systems**; **Fibers**; **Film**, **Foam**; **Emulsions**; and **Surface Chemistry**.

COLLOID SYSTEMS. Colloids are usually defined as disperse systems with at least one characteristic dimension in the range 10^{-7} to 10^{-4} centimeter. Examples include: *sols* (dispersions of solid in liquid); *emulsions* (dispersion of liquids in liquids); *aerosols* (dispersions of liquids or solids in gases); *foams* (dispersion of gases in liquids or solids); and *gels* (system, such as common jelly, in which one component provides a sufficient structural framework for rigidity and other components fill the space between the structural units or spaces). All forms of colloid systems are encountered in nature. Products of a colloidal nature are commonly found in industry and are notably extensive in the food field. Foams, widely used in industrial products, but also the causes of processing problems are described in entries on **Foam**; and **Foamed Plastics**.

Early Background

Thomas Graham's investigations of diffusion (1861) led him to characterize as *crystalloids* substances, such as inorganic salts which in water solutions would diffuse through a parchment membrane; and as *colloids*

(Greek word for glue) substances, such as starch and gelatin, which would not diffuse through the membrane. Sols with a given weight percent of dispersed material scatter light more strongly than a solution with the same weight percent of dissolved inorganic salt, i.e., a true solution. The Tyndall effect, in which the path of a beam of light through a turbid solution (or through dusty or smoke-filled air) is clearly defined through scattered light, is characteristic of sols. The slow diffusion and strong light scattering, together with the fact that the boiling-point elevation, freezing-point depression, and osmotic pressure caused by a given weight percent of dispersed material in sol form are much less than the corresponding magnitudes caused by the same weight percent of common inorganic salts—these observations indicated to early investigators that the particles dispersed in the sol must be larger than those resulting from dissolving inorganic salts in water.

Development of the ultramicroscope (Siedentopf and Zsigmondy, 1903) permitted particles substantially smaller than the wavelength of light to be observed in scattered light and were thus capable of counting. Invention of the ultracentrifuge by Svedberg (1924) made it possible to cause particles in sols to sediment at observable rates, to measure these rates with reasonable precision, and to infer particle sizes from these rate measurements. The ultramicroscope and ultracentrifuge permitted validation of the early conclusions that colloidal particles are much larger than ions resulting from dissolving metal salts in water.

Svedberg found that in some sols the particles were highly uniform in size. For example, he found that the gram particle weight of insulin (a *protein*) was 40,900 and that apparently all insulin particles had this gram particle weight. This made it extremely likely that the insulin particles were either single molecules (albeit giant ones), or aggregates of a very definite number of smaller (but still quite large by ordinary standards) molecules. The research of Staudinger (commencing about 1920) and of Carothers (1929) opened up the field of macromolecular chemistry, leading to the recognition that giant molecules were not only abundant in nature, but could be prepared by established principles of chemistry. See also **Macromolecular Science**.

The pioneering work of Svedberg and other early researchers, as continued over the years through the application of much improved instrumentation (scattered laser light, electron microscopy, among other methods for investigating microstructure) are described briefly later in this article.

It is interesting to note that Wolfgang Ostwald, in the late 1800s, stated, "There are no sharp differences between mechanical suspensions, colloidal solutions, and molecular (true) solutions. There is a gradual and continuous transition from the first through the second to the third."

Some colloidal systems are *thixotropic*, i.e., they differ in their fluid behavior from *pseudoplastic* substances in that the flow rate increases with increasing duration of agitation as well as with increased shear stress. When agitation is stopped, internal shear stress exhibits hysteresis. Upon reagitation, generally less force is required to create a given flow than is required for the first agitation. Examples of thixotropic materials include silica gel, most paints, glue, molasses, lard, fruit juice concentrates, and asphalts. By rhythmically shaking or tapping certain thixotropic suspensions, the suspensions will "set" or build up very rapidly. This type of non-Newtonian substance is said to be *rheopectic*. Bentonite sols and suspensions of gypsum in water are rheopectic. *Dilatant fluids* often are termed *inverted plastics* or inverted pseudoplastics. Initial flow under a low shear stress is at a high rate; further increases in shear stress, however, result in lower flow rate. Some liquids may change from thixotropic to dilatant or vice versa as the temperature or concentration changes. Examples of dilatant materials include quicksand, peanut (groundnut) butter, and many candy compounds. For comparison, it should be recalled that a Newtonian substance is a liquid or suspension which, when subjected to a shear stress, undergoes deformation wherein the ratio of shear rate (flow) to shear stress (force) is constant. These varying behavioral patterns of colloidal materials become important considerations in specifying pumps and other process handling equipment. See also **Gold Number**.

Role of Water Molecule—Cluster Theory

Because a very large number of colloid systems involve water, particularly in connection with biological systems, comprehension of the structure and behavior of water is paramount. Notably since the 1950s much progress has been made concerning the physical and chemical nature of water. Long established observations have shown water to be a low-molecular-weight compound, similar in structure and molecular weight to several compounds, such as methane, ammonia, and hydrogen fluoride, among others. However, water has a number of anomalous properties when compared with other structurally similar compounds. Such comparison shows that water has unusually high melting and boiling points, dielectric constant, and density. Water also has a very high surface tension and specific heat, and a high heat of vaporization were this characteristic extrapolated from data on similar substances. That liquid water is a highly structured substance has been supported for many years through x-ray and neutron diffraction studies, as well as Raman and nuclear magnetic relaxation (NMR) techniques. That water molecules have a V-like structure with an HOH bond angle of 104.5° has long been established. Similarly it has been known that the highly electronegative oxygen atom polarizes the OH bond, thus giving the molecule an unsymmetrical charge distribution. See also **Water (Hard)**.

The apparent simplicity of structural and behavioral aspects of water disappeared with the observations of Frank and Wen (1957), the first investigators to describe water as a *mixture of monomer and polymerized molecules*. As pointed out by Busk (1984), Frank and Wen found that the formation of a single hydrogen bond enhances the ability of the other hydroxyl groups on the molecules involved to form hydrogen bonds. They described water structure as cooperative in nature. The formation of hydrogen bonds, however, restricts the molecular motion of H_2O molecules and results in a loss of entropy. Initially, the loss in entropy is more than compensated for by the gain in enthalpy of bond formation. The size that a cluster of molecules will grow to is thus a result of a balance between these two forces.

Numerous investigators have contributed to the cluster theory of water and the model proposed (Nemethey-Scheraga Flickering Cluster Model) incorporates the names of some of these investigators. The current description of the model suggests that water is composed of monomeric H_2O molecules, polymeric structures 20–90 molecules in size, and a minor amount of ions, isotopes, etc. Up to 90% of the molecules in liquid water may be in clusters at any one time. The number of clusters increases with temperature; the size decreases. The model predicts the density maximum and some of the other solid-like properties. The model forecasts the lifetime of the cluster to be very short (about 10–11 second) and the bonding forces within each cluster to be quite weak. The latter leads to accurate predictions of the liquid-like characteristics of water. Some molecules (nonbonded monomers) are present only to about 1% of the total. Computer simulations by Del Bene and Pope determined that cyclic water structures are the most stable (e.g., trimers, tetramers, pentamers, and hexamers). This study also indicated that the branching structure needed to support a continuum structure is not entropically favored.

Molecules may interact with water in at least four main ways—hydrogen bonding, ionic bonding, hydrophobic association (nonpolar molecules placed in the polar environment of water), and London dispersion or van der Waals forces.

Inasmuch as water-macromolecule interactions are complex and still not fully understood, other postulations concerning water bonding have been proposed. Fennema (1978), for example has suggested three structural states of water: (1) *constitutional water* (held in interior of folded macromolecules); (2) *interfacial water* (located at or near the surface of a macromolecule); and (3) *bulk phase water* (chemical properties identical to those of free water or water of dilute salt solutions). In making these distinctions, Fennema asserted that the categories do not imply any distinct boundaries between them. Another researcher (Labuza, 1977) proposed two additional types of forces: (1) the effects of trapping water in polymer capillaries, and (2) solute effects due to entropy considerations.

Sols

It is convenient to classify sols into three types: (1) *lyophilic* (solvent loving) colloids, for example, are solutions of gelatin or starch in water; (2) *association* colloids, of which a solution of soap in water at moderate concentration is an example; and (3) *lyophobic* (solvent repelling) colloids, for example, sulfur in water. Both lyophilic and association colloids can be prepared in thermodynamic equilibrium, so that when solvent is removed and then returned to the system, the original properties of the system are regained.

Lyophobic colloids are not (or at most, rarely) equilibrium systems. When solvent is removed and then returned to the system, the original dispersed material fails to redisperse, and it is usually convenient to regard such a system as one in which the dispersed particles are continuously

aggregating. A lyophobic sol thus appears to be stable if the aggregation rate is slow; and unstable if it is fast. The terms lyophilic and lyophobic entered the literature before the characteristics of these systems were well understood and thus are somewhat anachronistic; they are nonetheless well-established.

Lyophilic sols are true solutions of large molecules in a solvent. Solutions of starch, proteins, or polyvinyl alcohol in water are representative of numerous examples. Properties of these solutions at equilibrium (for example, density and viscosity) are regular functions of concentration and temperature, independent of the method of preparation. The solvent-macromolecule compound system may consist of more than one phase, each phase in general containing both components. Thus, if a solid polymer is added to a solvent in an amount exceeding the solubility limit, the system will consist of a liquid phase (solvent with dissolved polymer) and a solid phase (polymer swollen with solvent, i.e., a polymer with dissolved solvent).

The foregoing characteristics also are found with solutions of small molecules. But properties of solutions, one of whose components is macromolecular, differ from those having only small molecular components in quite understandable ways. For example, where small molecules are involved, molecular distortion is minor. Quite generally, the shapes of small molecules are little affected by environment unless the small molecules react chemically. In contrast with small molecules, there is a considerable variation in polymer conformation with environment. See also **Molecule**; and **Polymers**.

A polymer dissolved in a good solvent will tend to stretch out, and the resulting entanglement of polymer chains and interference with solvent movement will lead to a high viscosity. If the solvent is a poor one, the polymer molecule will tend to form a small ball, and the viscosity for a given weight percent will be much less. A side group of a polymer may be ionizable. Ionization of this group distributes a charge along the backbone and charge repulsion causes the macromolecule to tend toward a rod shape. If there is a moderate salt concentration in the solution, the backbone charge will be partly shielded by ions from the salt of opposite charge. Thus, the tendency toward rod formation will be less pronounced. The tendency of oppositely charged macromolecules to aggregate is much greater than the tendency of oppositely charged small ions to pair simply because the charges involved are greater in the former case.

The foregoing special properties of solutions of large molecules are relatively easy to describe in qualitative terms, but a difference of a more subtle nature occurs when the system forms two liquid phases. In a macromolecular solution, both phases tend to be rich in the (small molecule) solvent, whereas in systems formed from two molecules of comparable size, one phase is rich in one component, while the other phase is rich in the second component. The formation of two liquid phases from a solvent-macromolecule system is sometimes call *coacervation*; and the phase with the higher percentage of macromolecule is sometimes called the *coacervate*. See also **Coacervation**.

Association Colloids

These are generally encountered in solutions of soaps and detergents in water. These matters become important, of course, to procedures for cleaning and sterilizing equipment (food processors, biochemical manufacturers, hospitals, etc.), but the principles also apply to other association colloids also encountered industrially, notably in the food processing field. A typical soap, such as sodium stearate, $C_{17}H_{35}COONa$, or a detergent, such as sodium dodecyl benzene sulfonate, $C_{12}H_{25}C_6H_4 \cdot SO_3Na$, consists of a long hydrocarbon tail and a polar (in the examples cited, ionizable) head group. The solubility of the soap in water is largely conferred by the head group. As the soap concentration is increased, the soap molecules tend to cluster in aggregates called *micelles*, with hydrocarbon tails in the interior of the micelles and the polar groups in contact with water. The formation of micelles is favored by the interaction between hydrocarbon tails and is opposed by charge repulsion of the polar group which are placed close together at the micelle surface.

Micelle formation becomes pronounced at soap concentrations exceeding the critical micelle concentration. As hydrocarbon tail length is increased, the interaction of tails is increased, and as salt concentration is increased, the repulsion of head groups is reduced because their charges are partly shielded by ions of the salt. Both of these factors favor micelle formation, causing micelles to be larger and the critical micelle concentration to be smaller. Typically, a micelle might contain about 50 soap molecules. The micelle interior is a hydrocarbon, and as such is receptive to other molecules soluble in hydrocarbons. Hence, a soap solution can 'dissolve' such molecules (taking them up in micelle interiors) even if the molecules are quite insoluble in water. This phenomenon is called *solubilization* and is a factor in detergency.

Lyophobic Sols and Aerosols

These products can be viewed most simply and, in most cases, with sufficient as two-phase systems in which the dispersed particles are steadily and irreversibly aggregating according to a second-order rate law. Thus, where C is the number of particles per cubic centimeter (an aggregate of many primary particles being counted as one particle) at time t, and where C_0 is the number of particles per cubic centimeter at zero time, and K is a constant, C depends on t according to

$$\frac{C_0}{C} - 1 = KC_0t$$

and will be one-half its value at zero time when $KC_0t = 1$. The time required for this is longer, the smaller K and the smaller C_0. If the time required is weeks, the sol will appear quite stable over a period of days. If there is no barrier to aggregation, so that the particles aggregate as fast as diffusion brings them in contact, the rate constant K can be calculated approximately from diffusion theory and is $8kT/3\eta$, where k is Boltzmann's constant, T is the absolute temperature, and η the viscosity of the medium. Initial sol concentrations (particles per cubic centimeter) giving one-minute half-lives at room temperature are 1.4×10^9 in water; and 2.7×10^7 in air in the absence of aggregation barriers.

Although these numbers may appear large, they correspond to quite small volume percentages of dispersed particles. A particle of radius 5×10^{-5} centimeter is at the upper limit of the colloidal range; and 1.4×10^9 such particles occupy 0.07% of space. The behavior of smokes, fogs, and many dispersions of uncharged particles in water accords well with the rate equation and theoretical rate constant given. In contrast, the dispersed particles in many sols are electrically charged, manifesting this charge through electrophoresis (motion of colloidal particles under the influence of an electric field). In fact, Tiselius developed electrophoresis to a high degree, successfully fractionating and classifying proteins thereby. Evidently like charges on two colloidal particles will contribute to a repulsion between them, which will be greater, the greater the charge on each particle and the smaller the concentration of salts in solution (since ions from the salt will tend to mask the charges on the particle).

The theory of interaction between colloidal particles with a surface electrostatic potential (due to surface charges) surrounded by an electrical double layer (one layer of which is the layer of surface charges, the other a diffuse cloud of charges of opposite sign due to ions from salts in the solution) was developed by Derjaguin and Landau and independently by Verwey and Overbeek, and is generally known as the DLVO theory after the first letters in the names of these scientists. The DLVO theory shows how a barrier sufficient to reduce the rate constant K (and so to increase the half-life at a given initial concentration) by many powers of ten may arise from the interaction of charged particles in a solvent, and the magnitudes calculated agree rather well with experiment.

It is evident why the properties of lyophobic sols depend so critically on the chemistry of the interface between dispersed particle and solvent, for this chemistry establishes the means by which the surface charge can be established or altered. Particles of silver halide dispersed in water will acquire a positive charge if silver ion is in slight excess in the water, because the silver ion can readily add to the silver halide lattice. A negative charge is similarly acquired if the halide ion is in slight excess. The silver ions and halide ions are called *potential-determining ions* for the silver halide sol. They can lose their waters of hydration and adsorb on the particle side of the electrical double layer, conferring a charge on the particle. Hydrogen ion and hydroxyl ion are similarly potential-determining ions for many oxide sols, such as silica and alumina, including particles, such as carbon and many metals, which are ostensibly not oxides, but in fact usually have oxidized surfaces. Finally, charge can be conferred by the adsorption of charged macromolecules, such as gelatin, which are called *protective colloids*. Salts added to the sol form ions, which tend to mask the particle charges and so tend to promote flocculation. The ion whose charge is opposite to the particle charge (the counter ion) is of particular importance, and the greater its charge the lower the concentration at which its flocculating effect is evident.

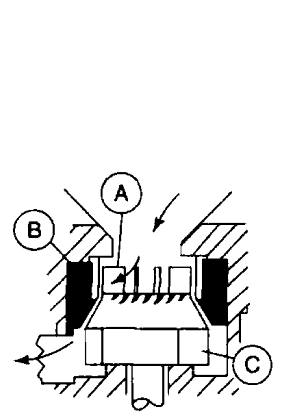

Fig. 1. One type of colloid mill. Rotor blades A break up slurry. Serrations in rotor and stator provide mechanical shear and force material into adjustable gap (0.0005–0.125 inch; 0.013–3.2 millimeters) between rotor and stator B for intense hydraulic shear. Lower part of rotor C adds further whirling action

Emulsions

These are dispersions of one liquid in another. Most commonly, one phase is an oil which is at most slightly miscible with water. The disperse phase can either be oil (an oil-in-water emulsion) or water (a water-in-oil emulsion). For apparent stability, an emulsifying agent is almost invariably required. The emulsifying agent has an oil-soluble tail and a polar head. The emulsifying agent concentrates (adsorbs) at the interface between oil and water, lowering the interfacial tension and frequently conferring a charge on the dispersed droplets. The film of emulsificant thus formed is usually only one molecule thick, but it is essential to emulsification. Mixed emulsificants, such as a mixture of sodium stearate and octadecyl alcohol, may be more effective in emulsification than either component alone, and there is a great deal of art and experience required in the formulation of emulsions. Lecithins and some proteins are effective natural emulsificants, and a mixture of lecithin and cholesterol is an effective natural mixed emulsificant. It should be noted that the difference between solubilization (described in connection with association colloids) and emulsification is not sharp, particularly insofar as large, extensively swollen micelles and ultrafine emulsions are concerned. See also **Emulsions**.

Gels

These substances involve the formation of a three-dimensional structure. A gel is a colloidal disperse system in which is contained a dispersed component and a dispersion medium, both extending continuously throughout the system. Further, the system has equilibrium-elastic (time-dependent) deformation. Thus, since they have a shear modulus of rigidity, gels are like solids, but in most other physical respects, they behave like liquids. It is conceived that the three-dimensional network is kept together by bonds or junction points, which essentially have an unlimited lifetime. Junction points may be described as primary valence bonds, attractive forces of long range, or secondary valence bonds, which maintain an association between parts of polymer chains or form submicroscopic crystalline regions. A gel may be defined as a flocculant and gelatinous precipitate. A jelly is a transparent elastic mass. Upon standing, a gel may shrink—a process known as *syneresis*.

In 1861, Thomas Graham first used the term syneresis to describe the phenomenon of exuding small quantities of liquid by gels. By definition, syneresis is the spontaneous separation of an initially homogeneous colloid system into two phases—a coherent gel and a liquid. The liquid is actually a dilute solution whose composition depends upon the original gel. When the liquid appears, the gel contracts, but there is no net volume change. Syneresis is reversible if the colloid particles do not become too coagulated immediately after their formation.

In 1937, Heller classified three types of syneresis as to cause: (1) syneresis of desorption, caused by the particle becoming less hydrophilic with time; (2) syneresis of aggregation, whereby discrete gel particles may unite into a denser gel portion; and (3) syneresis of contraction, where a gel with fibrillar structure contracts and squeezes out the intermicellar liquid. Most commonly, syneresis is the visible manifestation of further slow coagulation that follows the initial setting of the gel, the gel-forming process itself being an enmeshing of the hydrous particles into a network. It may be further explained as the exudation of liquid held by capillary forces between the heavily hydrated particles constituting the framework of the gel. Ostwald noted that the phenomenon is one of the most characteristic of the properties of gels.

A common example of syneresis is found when a mold of gelatin remains under refrigeration for a period. A general shrinkage of the body of the gel occurs and a liquid collects around the edge of the mold. The liquid is a dilute solution of the original composition. Since the total volume of the system remains the same, syneresis should not be considered simply as the opposite of imbibition (absorption). Extending the onset of syneresis in various products, notably foods, is of obvious importance.

Dispersion Processes

1. The simplest method of accomplishing dispersion is by grinding the solid (or liquid) material with the liquid medium until particles of the required size are ultimately obtained. The colloid mill (Plauson, 1921) is used for such purpose, as in mixing paints and pastes, regenerating milk from milk powder, dispersing cellulose in sodium hydroxide and carbon disulfide for the production of xanthates for viscose, and in emulsifying fats and waxes. See Fig. 1.
2. Zinc sulfide, cupric hexacyanoferrate(II), stannic acid, silver chloride are examples of precipitates which, when washed on the filter paper until the accompanying soluble electrolyte has been removed, form colloidal solutions and pass through the pores of the paper. Since this is usually to be avoided in practice, the washing is then done with an electrolyte, which does not conflict with the treatment to follow. Frequently ammonium nitrate solution is used.
3. A peptizing agent is frequently employed. Tannin is peptized by water, and by glacial acetic acid. Soaps are peptized by water. Gelatin swells in cold water but is not peptized, but is peptized in warm water. Starch, although insoluble in cold water, behaves similarly to gelatin with warm water (63 to 74°C, depending upon the kind of starch). Cellulose nitrate swells in ethyl alcohol and not in ether, but is peptized in ethyl alcohol-ether mixture. Clay is peptized by ammonium hydroxide, and it is held by some that the action of sodium hydroxide on zinc, aluminum, and chromium hydroxides is one peptization.
4. Water-peptizable colloidal substances such as gelatin, dextrin, gum arabic, and soap peptize many precipitates, and are often called protective colloids. Gelatin in the solution prevents the precipitation of silver dichromate upon mixing silver nitrate and potassium dichromate solutions. (See Condensation Processes, below.)
5. When dilute silver nitrate and dilute potassium bromide solutions are mixed so that there is a slight excess of either solution, silver bromide is peptized. Acheson's oil-dag and aqua-dag are suspensoids of graphite in oil or water containing a protective colloid, tannin. Oil-dag contains about 15% of a "deflocculated graphite," and is used in dilute solution in lubricating oil (about 0.1% graphite). Bearings gradually become coated with a thin layer of graphite.

Sonic methods also are used to create emulsions. Liquids are pumped under pressure through an orifice of special design and impinge on the edge of a blade causing it to vibrate at ultrasonic frequencies. Cavitation takes place continuously in the stream, causing violent pressure changes to be generated locally. The result is a uniform and stable emulsion and a dispersion of a very high order. See also **Cavitation**.

Condensation Processes

1. When a solution of ferric chloride is poured into a relatively large volume of boiling water, colloidal ferric hydroxide is formed. The ferric hydroxide sol does not react with hydrogen sulfide nor with potassium hexacyanoferrate(II), and like all colloidal substances does not pass readily through animal membranes or parchment.
2. When hydrogen sulfide is passed into a solution of arsenious oxide, arsenious sulfide sol is formed which in the absence of an electrolyte may be made of the high concentration of 60 grams of arsenious sulfide per 100 grams of water. Upon addition of hydrochloric acid, arsenious sulfide coagulates and is precipitated.
3. When hydrochloric acid is added to sodium silicate solution either silicic acid sol or silicic acid gel is formed.
4. When hydrogen sulfide solution is treated with an oxidizing agent, for example, the proper concentration of nitric acid, sulfur sol is formed.

5. When gold chloride very dilute solution (0.01 to 0.001% of gold chloride) is made slightly alkaline (say by the addition of magnesium oxide) and then treated with a reducing agent, for example, formaldehyde or sodium hydrosulfite $Na_2S_2O_4$, red gold sol is formed.
6. Use of a protective colloid in solution prevents the formation of the ordinary and expected precipitate in many cases, and causes the formation of the expected substance as colloidal sol. Silver nitrate (0.6 gram per liter) and potassium dichromate (0.5 gram per liter) to one of which is added 0.1 volume of hot gelatin solution (2 grams per 100 milliliters of water) are mixed with stirring silver dichromate sol is formed.
7. When an electric arc is formed under water between two metallic rods, particles of the metal of colloidal size are formed along with more or less separation of free metal. A protective colloid increases the stability. If the metal vaporizes and then condenses to the colloidal state this is strictly speaking a condensation process, if otherwise, a dispersion process.

The disappearance of the colloidal state of a substance may be accomplished in either of two directions, namely, by the colloid passing into solution or into suspension. Practically, the latter is the more important method. Coagulation, agglomeration or precipitation is readily brought about by discharge of the electric charge on the particles. Ions carrying a charge of opposite sign to that carried by the colloidal particles are active precipitants, and the higher the valency of the ion the more effective (Linder-Picton-Hardy). When the colloidal particles are made neutral the conditions are least favorable to their stability. For colloidal arsenious sulfide, which is negatively charged in water, the coagulating power of potassium iodide K^+I, calcium chloride $Ca^{2+}Cl_2$, aluminum chloride $Al^{3+}Cl_3$ is in the ratio of 1:80:1500 (Svedberg); and for colloidal ferric hydroxide, which is positively charged in water, the coagulating power of potassium chloride KCl , potassium sulfate $K_2SO_4^{2-}$ is in the ratio of 1:45. The active ion is carried down with the precipitated particles. Oppositely charged colloids, e.g., arsenious sulfide and ferric hydroxide, when mixed, precipitate each other. Other methods of coagulation are by migration of colloidal particles to and their discharge at electrodes, and by heating, as in the case of egg albumin. Coagulation is usually irreversible, especially when caused by electrolytes.

An interesting case, operating on a large scale in nature, of the precipitation of a colloidal system by an electrolyte is that of the action of sea water on the mud and silt of river water entering the ocean. When river water flows into the ocean the former, on account of its lower specific gravity, tends to flow over the latter and spread out in widening range. As the current diminishes some of the suspended mud and silt settles out, but the finer colloidal particles are coagulated by the electrolyte of the sea water and form deltas at the mouths of rivers.

Importance of Colloidal State

All living matter, whether animal or plant, are made up of many colloidal materials and are largely sustained by colloidal processes. Of similar importance is colloidal chemistry in everyday living, in almost all of our foods, such as proteins and starches, in our clothing, whether of natural or synthetic origin, and in our shelter materials, such as wood, bricks, and concrete. When there is added to these, other common things and operations of everyday life, such as pottery and porcelain, paper, rubber and leather, and cooking and washing, where colloidal matter and processes operate, it is evident how broad is the scope and how great is the importance of the field. To these there must also be added other applications in the realm of industry, such as dyeing, printing, photography, water purification, smoke prevention, ore flotation, sewage disposal and soil preparation, paints, varnishes and lacquers, plastics, adhesives, and innumerable other operations and materials.

Advanced Microstructural Analysis

In connection with gelling systems, Davis and Gordon (1984) point out that the *macrostructural* evaluation of a gel usually involves the evaluation of some chemical or physical property of the system as a whole, such as total water and protein or solids content, gel strength, turbidity changes during gelation, pH range at which gelation occurs, and degree of syneresis after gelation and storage. In contrast, in microstructural analysis, the investigator is interested in molecular isolation and characterization of the components of the system. As reported by numerous researchers, molecular changes and interactions result in the association, aggregation, flocculation, coagulation, and gelation of the system. There are three broad areas of microstructural analytical techniques: (1) microscopic, especially electron microscopy, where water must either be removed or immobilized in the gel system prior to viewing; (2) spectroscopic; and (3) thermal analytical. The smallest resolvable size ranges from individual molecules or groups of molecules in differential thermal analysis, differential scanning calorimetry, and thermogravimetric analysis. Light microscopy and ultraviolet microscopy are limited to sizes in the range from 1000 to 3000 angstroms. Resolution of scanning electron microscopy is approximately 150 to 200 angstroms, while transmission electron microscopy has a limit of from 2 to 5 angstroms. The range of resolution of spectroscopic absorption and spectroscopic scattering techniques is from somewhat less than one angstrom to hundreds and even thousands of angstroms. Davis and Gordon report in some detail on the use of the foregoing techniques in gelatinization studies of starch, carrageenan, soy protein isolate, and other similar substances that are encountered in the food processing industries.

COLORANTS (Foods). Color, as a component of appearance, is important in the sensory evaluation of a food substance, including beverages. Color affects the degree of acceptability of a food product in the marketplace. Color also is a frequently useful indicator of the degree of wholesomeness of a foodstuff. Many foodstuffs are attractively colored as the result of their naturally occurring pigments. In these instances, a major objective of the food grower and processor is to protect and preserve the natural colors as long as may be required by the distribution network, considering such factors as temperature and humidity to which the food substance may be subjected before reaching the consumer.

Considering the expectations of consumers, particularly in countries that have an advanced food technology, colorants, along with flavorings and texture modifiers, are important. These factors are particularly stressed in connection with modern fabricated foods, substitute foods, and food analogues. Many years have passed since final approval was given to margarine producers to use colorants and artificial flavorings. Even though artificial flavors are used in some products, ice creams and ices, as well as soft drinks, are color matched to their fruit flavors. Yellow colorings provide a note of richness in cake mixes, eggnogs, and other products associated with their content of eggs; cheese snacks are both colored and flavored to simulate cheese; popcorn oil is usually colored; iron oxide can be added to pet foods to simulate the color of meat; the red coloration of cherries is intensified by using red colorants in the processing of maraschino cherries. Caramel colorings are widely used in both alcoholic and nonalcoholic beverages.

Particularly during the past several decades, regulatory agencies in various countries have scrutinized colorants (along with other food

additives) against a backdrop of consumer health. Since the early 1900s, several countries have approved colorants for use in foods only after thorough physiological testing. In recent years, analytical instrumentation and research methodologies have become sophisticated and measurements of minute quantities are now practical. With improved analytical tools and a heightened awareness of the effects of foods upon health, a number of colorants that once were considered perfectly safe have come under question. In some countries, most or all synthetic colorants have been banned. Generally, the limitations on the use of colorants have become much more stringent.

In the United States, the first rather complete legislation involving such matters was the Food and Drug Act of 1906. As a result of that legislation, the list of colorants permitted was reduced to only seven dyes. Because the remaining seven dyes did not provide sufficient flexibility in the formulation of food products, considerable research went forth to find additional colors, not only with more desirable hues, but easier to use (solubility in oil/water, less temperature sensitivity, etc.). During the 66-year period from 1906 to 1971, several additional colors were added. In 1938, the Food, Drug, and Cosmetic Act was passed. The common names of dyes previously used were given color prefixes and numbers. For example, Amaranth became FD & C Red No. 2. Under the new act, certification became mandatory.

The color situation in the food industry was relatively without incident until the early 1950s, when, as the result of a few cases of excessive levels of usage in some candies and popcorn, two colors (FD & C Orange No. 1 and FD & C Red No. 32) were delisted. After much controversy and considerable litigation, more colors were delisted. To rectify legal complexities and unworkability of the 1938 Act, the Color Additives Amendments of 1960 were passed. Nevertheless, as pharmacological studies continued, a number of other colors were de-listed during the interim. Much more recently, FD & C Red No. 3 Lake colors were banned in the United States. The foregoing paragraphs relate largely to the use of synthetic colorants. Natural colorants include the anthocyanins, annatto colors, the betalaines, the carotenoids, cochineal, saffron, turmeric, and titanium dioxide. Caramel coloring also falls into this category. Paprika is used in some foods for its coloring attributes.

Anthocyanins are water-soluble pigments that account for many of the red, pink, purple, and blue colors found in higher plants. Most plants contain more than one of these pigments and they occur most prevalently as glycosides. Several hundred different anthocyanins are known. These compounds are most stable at a pH range of 1 to 4, thus limiting the spectrum of usage. As compared with synthetic colorants, the anthocyanins produced to date generally are less stable, have less tinctorial potency, and lack some color uniformity. They are degraded by light, heat, enzymes, and interact with ascorbic acid. They also tend to form complexes with metal ions to produce off-colors. Their main advantage stems from the fact that they are naturally derived and thus not regarded with suspicion as health deterrents as are many synthetic materials. On the other hand, attempts to alter and modify them to make up for their fundamental disadvantages could also move them toward a suspicious category—a factor which researchers on anthocyanins are taking into consideration.

Numerous commercial sources for the anthocyanins have been and are continuing to be investigated. These sources include grape anthocyanins, apparently with good potential in the carbonated beverage field. Roselle plants, native to the West Indies, have been studied and appear to have potential for use in apple and pectin jellies, but not for carbonated beverages, such as ginger ale. Cranberry pomace and blueberries have been investigated. Considerable interest has been shown in the red anthocyanin pigments of miracle fruit (*Synsepalum dulcificum*, Schum), a tropical plant that produces a red berry.

Red cabbage as a colorant source has been studied for many years. As of 1990 at least one firm has introduced San Red RC, the first commercially available food color derived from red cabbage. The color can be used alone or in combination with other colors to create strawberry, cherry, raspberry, and blueberry tones. By way of proprietary technology, the new dye is claimed to be free of flavor and odor defects, which in the past have been associated with red cabbage. The dye is pH dependent. The color tones move toward blue-red as the pH value increases. San Red RC ranks between cochineal and grape juice in percent of color retention.

Betalaines are sometimes referred to as beetroot pigments. They are made up of two main groups: (1) *betacyanins*, the principal component of which is betanin; and (2) *betaxanthins*, the principal component of which is vulgaxanthin-I. The betacyanins contribute a red color, whereas the betaxanthins are yellowish. Another yellow pigment, betalamic acid, derives directly from cleavage of betanin and is probably the key intermediate in the biogenesis of all betalaines.

A factor of concern in connection with the betalaines is the earthy flavor associated with beets. To date, beets have been regarded as the primary source for these substances.

Carotenoids

These yellow-orange colorants are described in entry on **Carotenoids**.

The other natural colorants previously mentioned have been used for many years and are familiar to nearly everyone. Annatto colors are described in a separate entry, **Annatto Food Colors**.

Synthetic Colorants. Perkin, in 1856, synthesized the first synthetic dye, *mauve* or *mauveine*, by the oxidation of crude aniline. In that time and for about 80 years, coal tar was the principal source of aromatic compounds, which, in turn, were the sources of numerous synthesized dyes used primarily in textiles, but some of which were found to be adapted to other uses, including the coloring of food substances. This generally gave rise to the term "coal tar color" used commonly in the food and cosmetics industries for many years. Of course, with the development of more sophisticated organic syntheses and the petrochemical field, the association with coal tar no longer had a direct meaning. The term was finally eliminated from legislation in connection with the Color Additives Amendments of 1960. It is interesting to note, however, that prior to the first Act of 1906, it is estimated that some 80 such dyes were being used in a large number of food products, at a time when there were no regulations regarding the nature and purity of colorants used in foods.

Lakes. In the United States, FD & C lakes were accepted for the approved list of certified color additives for the first time in 1959. As defined by the FDA, a lake is an "Extension on a substratum of alumina, of a salt prepared from one of the water-soluble straight colors by combining such a color with the basic radical aluminum or calcium." Because the substratum of alumina hydrate or aluminum hydroxide is insoluble, the lake provides an insoluble form of the dye, i.e., a pigment. Colors from dyes result from solution in a solvent; whereas colors from pigments result from dispersion of that pigment throughout the food substance. Prior to the acceptance of lakes, insoluble colorants were formed by absorbing them on materials (insoluble), such as cellulose, flour, and starch. Generally, these forms were inadequate because of relatively low coloring power.

When utilized in solid or semisolid vehicles, dyes must be added in solution to achieve effective coloring. Thus, color migration is a problem. Dyes can migrate with the solvent during various drying or processing operations. Because lakes are insoluble, color migration is negligible in applications where distinct interfaces are required. Striped candy pieces provide an example. Where opacity is required, titanium dioxide can be added to lakes. In high-quality lakes, nearly all particles will pass through a 325-mesh screen when wet-tested. Shades of coloration can be produced by blending the various FD & C Lake Colors.

Extending Natural Colors. For some natural foods, such as meat and fish, colorants are not added, but natural colors can be extended over a longer time span by adding various approved chemicals. For example, the bright red color that consumers prefer in fresh meat is due to oxygenated myoglobin, with iron on the heme group in its ferrous state. When oxidation occurs due to exposure, the ferric form is produced which imparts a brown discoloration to the meat. A mixture of tetrasodium pyrophosphate, sodium erythorbate, and citric acid, when combined with modified-atmosphere packaging, will extend the life of the bright red coloration of the meat. Care must be exercised to avoid "masking" microbial problems that develop when meats are held too long.

COLOR CENTERS. Certain crystals, such as the alkali halides, can be colored by the introduction of excess alkali metal into the lattice, or by irradiation with x-rays, energetic electrons, etc. Thus sodium chloride acquires a yellow color and potassium chloride a blue-violet color. The absorption spectra of such crystals have definite absorption bands throughout the ultraviolet, visible and near-infrared regions. The term *color center* is applied to special electronic configurations in the solid. The simplest and best understood of these color centers is the F center. Color centers are basically lattice defects that absorb light.

COLORIMETRY. A method of chemical analysis that deals with the measurement of the light absorption by colored solutions. Since light absorption depends upon the concentration of a specific constituent in solution, colorimetry is frequently used by geologists to determine qualitatively the trace quantities of many elements.

The fundamental principle of colorimetry states that the amount of light absorbed by a given substance in solution is proportional to the intensity of incident light and to the concentration of the absorbing species. This is expressed mathematically in the *Lambert-Beer law*:

$$\log I_0/I = abc$$

where I_0 = intensity of incident light
I_0 = intensity of transmitted light
a = absorptivity of the substance
b = light path length
c = concentration of colored substance
I/I_0 = transmittance
$\log I_0/I$ = absorbance

The term colorimetry is generally restricted to the visual comparison and matching of the color of a standard solution with that of an unknown one, whereas *spectrophotometry* involves the use of a photoelectric cell which measures a narrow band of wavelengths for transmittance.

Visual colorimetry is a simple method and is fairly precise. Essentially it requires the matching of the color of a standard solution with that of an unknown sample so that when they become identical, they must contain the same amount of colored substance in columns of equal cross-section. At this point

$$C_x b_x = C_s b_s \text{ and } C_x = C_s b_s / b_x$$

where C_x = concentration of unknown solution
b_x = length of light path of unknown solution
C_s = concentration of standard solution
b_s = length of light of standard solution

A standard series of solutions is prepared, each with a known concentration, having the same volume as the unknown, and being contained in identical flat-bottomed tubes of equal diameter (*Nessler tubes*). The solutions should be compared in daylight and examined against a white background.

A more refined method uses the Duboscq colorimeter. This instrument features a dual-matched optical system. Uniformly intense light is incident upon both colorimeter tubes and the difference in absorption of the standard and unknown solutions is compensated for by adjusting the thickness of solution through which light passes. When the two colors match $C_x = C_s b_s / b_x$.

Spectrophotometry (q.v.) is the most precise method of measuring light transmittance. It involves the use of a photoelectric cell that measures a narrow band of wavelengths for transmittance, and a prism or grating to give monochromatic light. At each wavelength, three readings are made: (1) sample cell filled with solvent, which gives the value of I_0, (2) the cell filled with standard solution, and (3) cell filled with unknown. The ratio of meter readings of the cell filled with pure solvent and sample is the I_0/I ratio. Spectrophotometry may be used analytically to measure the absorption at a single wavelength, or to determine the whole absorption spectrum of liquids and solutions in the visible and ultraviolet regions.

COLUMBITE. A mineral oxide of iron, manganese, niobium (columbium), and tantalum; $(Fe,Mn)(Nb,Ta)_2O_6$. Crystallizes in the orthorhombic system. Hardness 6; sp gr 5.20; color, red to brown.

COMBUSTION (Fuels). The rapid chemical combination of oxygen with the combustible elements of a fuel. There are three combustible chemical elements of major significance—carbon, hydrogen, and sulfur. However, as a source of heat, sulfur is of minor concern. Sulfur is of particular importance in the combustion of several fuels because of the corrosion and pollution problems that its presence creates.

Carbon and hydrogen when burned to completion with oxygen unite according to:

$$C + O_2 = CO_2$$
$$+ 14,100\text{Btu/pound (7840Calories/kilogram) of carbon}$$
$$2\,H_2 + O_2 = 2\,H_2O$$
$$+ 61,100\text{Btu/pound (33,972Calories/kilogram) of hydrogen}$$

Air is the usual source of oxygen for boiler furnaces. These combustion reactions are exothermic as indicated by the foregoing equations.

The objective of good combustion is to release all of the indicated heat while minimizing losses from combustion imperfections and superfluous air. The combination of the combustible elements and compounds of a fuel with all the oxygen requires *temperature* high enough to ignite the constituents, mixing or *turbulence*, and sufficient *time* for complete combustion. These factors sometimes are referred to as the "three Ts" of combustion.

This description* deals with the basic chemistry necessary for understanding the phenomena of combustion in boiler furnaces. Ability to calculate the release of heat in combustion and to determine the amount and nature of the combustion products is essential for the design, for example, of a steam generating plant and determination of its performance characteristics.

Table 1 lists the chemical elements and compounds found in fuels generally used in the commercial generation of heat with their molecular weights, heats of combustion, and other combustion constants. The term "100% total air" used in Table 1 and figures and examples that appear elsewhere in this entry means 100% of the air theoretically required for combustion without excess. Higher percentages indicate the theoretical plus excess air, e.g., 125% total air means 100% theoretical air plus 25% excess air.

* Basic information for this entry from "Steam—Its Generation and Use," copyright The Babcock & Wilcox Co., New York (39th edition, 1978).

TABLE 1. COMBUSTION CONSTANTS OF CHEMICAL ELEMENTS AND COMPOUNDS GENERALLY FOUND IN FUELS

							Heat of combustion				For 100% total air moles per mole of combustible or volume units of air per volume units of combustible						For 100% total air weight units of air per weight units of combustible

Concept of the Mole

The mass of a substance in weight units equal to its molecular weight is a mole of the substance. For example, carbon (C) has a molecular weight of 12. Therefore, a pound-mole of carbon weighs 12 pounds, a gram-mole of carbon weighs 12 grams, etc. In the case of gases, the *volume* occupied by a mole is called the *molal volume* and this is constant for "ideal" gases. A pound-mole of a gas at 80°F and atmospheric pressure (1 atmosphere or 14.7 psia or 30 inches of mercury) occupies 394 cubic feet. These concepts of mass and volume are useful in combustion calculations. Pound-moles are commonly used in power plant calculations in the United States and a number of other English speaking countries. Useful metric conversions will be found in the entry on **Units and Standards**.

Fundamental Laws

Several fundamental physical laws apply to combustion calculations. These are reviewed briefly as follows:

Conservation of Matter. This is the familiar statement that "matter is neither destroyed nor created." There must be a weight balance between the sum of the weights entering a process and the sum leaving. In other words, A pounds of fuel combined with B pounds of air will always result in $A + B$ pounds of products. (It should be noted that when a pound of a typical coal is burned, releasing 13,500 Btu, the quantity of mass converted to energy amounts to only 3.5×10^{-10} pound, a loss too small to be measured or considered in conventional combustion calculations. Obviously, this conversion is of significance to nuclear reactions.)

Conservation of Energy. This is the familiar statement that "energy is neither destroyed nor created." The sum of the energy (potential, kinetic, thermal, chemical, and electrical) entering a process must equal the sum of energy leaving, although the proportionate amounts of each may change. In combustion, chemical energy is exchanged for energy in the form of heat. The parenthetical observation made in the prior paragraph also applies to this relationship.

Ideal Gas Law. The volume of an ideal gas is directly proportional to its absolute temperature and inversely proportional to its absolute pressure. The proportional constant is found to be the same for one mole of any ideal gas, so this law may be expressed as:

$$v_M = \frac{RT}{p}$$

where v_M = volume, cubic feet/mole of gas
p = absolute, pressure, pounds/square foot
T = absolute temperature, degrees Rankine = °F + 460
R = universal gas constant, 1545 foot pound/mole

The equation states that one mole of all ideal gases occupies the same volume for the same pressure and temperature conditions—394 cubic feet at 14.7 psi and 80°F. Experiments indicate that most gases approach this ideal.

Law of Combining Weights. All substances combine in accordance with simple definite weight relationships. These relationships are exactly proportional to the molecular weights of the constituents. For example, carbon (atomic weight = 12) combines with oxygen (molecular weight = 32) to form carbon dioxide (molecular weight = 44) so that 12 pounds of carbon plus 32 pounds of oxygen unite to form 44 pounds of carbon dioxide.

Avogadro's Law. Equal volumes of different gases at the same pressure and temperature contain the same number of molecules. From the concept of the mole, a pound-mole of any substance contains a mass equal in pounds to the molecular weight of the substance. Thus the ratio of mole weight to molecular weight is a constant, and a mole of a chemically pure substance contains the same number of molecules, no matter what the substance may be. Since a mole of any ideal gas occupies the same volume at a given pressure and temperature (ideal gas law), it follows that equal volumes of different gases at the same pressure and temperature contain the same number of molecules.

Dalton's Law. The total pressure of a mixture of gases is the sum of the partial pressures that would be exerted by each of the constituents if each gas were to occupy alone the same volume as the mixture. In other words, for equal volumes, V, of three gases (A, B, and C) all at the same temperature, T, but at different pressures, P_a, P_b and P_c, when all three gases are placed in the space of the volume, V, then the resulting pressure, P, is equal to $P_a + P_b + P_c$. For gases, each gas in a mixture fills the entire volume and exerts a pressure independent of the other gases.

Amagat's Law. The total volume occupied by a mixture of gases is equal to the sum of the volumes that would be occupied by each of the constituents when at the same pressure and temperature as the mixture. This law is related to Dalton's Law, but considers the additive effects of volume instead of pressure. If all three gases are at pressure, P, and temperature, T, but at volumes V_a, V_b and V_c, then, when combined so that T and P are unchanged, the volume of the mixture, $V = V_a + V_b + V_c$.

Application of Fundamental Laws

Table 2 summarizes the molecular and weight relationships between fuel and oxygen and lists the heat of combustion for the substances commonly involved in combustion. Most of the weight and volume relationships in combustion calculations can be determined by using the information in this table and the seven fundamental laws.

The data for C and H_2 can be expressed as follows:

C	+	O_2	=	CO_2*
1 molecule	+	1 molecule	→	1 molecule
1 mole	+	1 mole	=	1 mole
		1 cubic foot	→	1 cubic foot
12 pounds	+	32 pounds	=	44 pounds
$2H_2$	+	O_2	=	$2H_2O$
2 molecules	+	1 molecule	→	2 molecules
2 moles	+	1 mole	=	2 moles
2 cubic feet	+	1 cubic foot	→	2 cubic feet
4 pounds	+	32 pounds	=	36 pounds

While there is a weight balance in these equations, there is not a molecular or volume balance; for example, 2 cubic feet of H_2 unite with

*When 1 cubic foot of oxygen combines with carbon, it forms 1 cubic foot of carbon dioxide. If carbon were an ideal gas instead of a solid, 1 cubic foot of carbon would be required.

TABLE 2. COMMON CHEMICAL REACTIONS OF COMBUSTION

Combustible	Reaction	Moles	Pounds	Heat of combustion (High) Btu pound of fuel
Carbon (to CO)	$2 C + O_2 = 2 CO$	2 + 1 = 2	24 + 32 = 56	4,000
Carbon (to CO_2)	$C + O_2 = CO_2$	1 + 1 = 1	12 + 32 = 44	14,100
Carbon Monoxide	$2 CO + O_2 = 2 CO_2$	2 + 1 = 2	56 + 32 = 88	4,345
Hydrogen	$2 H_2 + O_2 = 2 H_2O$	2 + 1 = 2	4 + 32 = 36	61,100
Sulfur (to SO_2)	$S + O_2 = SO_2$	1 + 1 = 1	32 + 32 = 64	3,980
Methane	$CH_4 + 2 O_2 = CO_2 + 2 H_2O$	1 + 2 = 1 + 2	16 + 64 = 80	23,875
Acetylene	$2 C_2H_2 + 5 O_2 = 4 CO_2 + 2 H_2O$	2 + 5 = 4 + 2	52 + 160 = 212	21,500
Ethylene	$C_2H_4 + 3 O_2 = 2 CO_2 + 2 H_2O$	1 + 3 = 2 + 2	28 + 96 = 124	21,635
Ethane	$2 C_2H_6 + 7 O_2 = 4 CO_2 + 6 H_2O$	2 + 7 = 4 + 6	60 + 224 = 284	22,325
Hydrogen Sulfide	$2 H_2S + 3 O_2 = 2 SO_2 + 2 H_2O$	2 + 3 = 2 + 2	68 + 96 = 164	7,100

Source: "Steam—Its Generation and Use," 39th edition, The Babcock and Wilcox Company, New York, 1978.

1 cu ft of O_2 to form only 2 cubic feet of H_2O. This relationship is based on Avogadro's law and the law of combining weights.

The Mole in Combustion Calculations. Combustion calculations involving gaseous mixtures can be simplified by the use of the mole. Since equal volumes of gases at any given pressure and temperature contain the same number of molecules (Avogadro's law), the weights of equal volumes of gases are proportional to their molecular weights. If M is the molecular weight of the gas, 1 mole equals M pounds. Actual values are available from Table 1, e.g.:

1 mole of O_2 = 32 pounds oxygen

1 mole of H_2 = 2 pounds hydrogen

1 mole of CH_4 = 16 pounds methane

Data from Table 1 can be used to demonstrate that the volume of 1 mole at a given pressure and temperature is approximately fixed and independent of the kind of gas.

At 60°F and atmospheric pressure (30 inches of mercury), the specific volume of oxygen is 11.819 cubic feet per pound. Therefore, 1 mole of oxygen has a volume of $32 \times 11.819 = 378.21$ cubic feet. Similarly, at 60°F and atmospheric pressure, the specific volume of hydrogen is 187.723 cubic feet per pound, and 1 mole has a volume of $2.016 \times 187.723 = 378.45$ cubic feet. This volume, usually taken as 379 cubic feet, therefore approximates the volume of 1 mole of gas at 60°F and atmospheric pressure.

The mole fraction of a component of a mixture is the number of moles of the component divided by the sum of the number of moles of all the components of the mixture. As a mole of every ideal gas occupies the same volume, it follows by Avogadro's law that in a mixture of ideal gases the mole fraction of a component will exactly equal the volume fraction:

$$\frac{\text{Moles of component}}{\text{Total Moles}} = \frac{\text{Volume of Component}}{\text{Volume of Total Mixture}}$$

This is a valuable concept, since the volumetric analysis of a mixture of gases automatically gives the mole fractions of the different components.

In power plant practice, the practical source of oxygen is primarily air, which includes, along with the oxygen, a mixture of nitrogen, water vapor, and small amounts of inert gases, such as argon, neon, and helium. Data on the composition of air are given in Table 3.

The information in Table 2 can be used for air instead of O_2 if 3.76 moles of nitrogen (N_2) are added to both left and right side of each equation for every mole of O_2 involved. For example, the burning of CO in air becomes:

$$2\,CO + O_2 + 3.76\,N_2 = CO_2 + 3.76\,N_2$$

TABLE 3. COMPOSITION OF AIR

	Composition of dry air	
	% by volume	% by weight
Oxygen, O_2	20.99	23.15
Nitrogen, N_2	78.03	76.85[a]
Inerts	0.98	—

Equivalent molecular weight of air = 29.0[a]

% Moisture = 1.3% by weight. Standard for boiler industry (ABMA)[b]

Moles air/mole oxygen

$$\text{Cubic feet air/cubic feet oxygen} = \frac{100}{20.99} = 4.76$$

$$\text{Moles } N_2\text{/mole oxygen} = \frac{79.01}{20.99} = 3.76$$

$$\text{Pounds air (dry)/pound oxygen} = \frac{100}{23.15} = 4.32$$

$$\text{Pounds nitrogen/pound oxygen} = \frac{76.85}{23.15} = 3.32$$

[a] It is convenient in combustion calculations to account for inerts as equivalent nitrogen. The equivalent weight percentage of 76.85 and the equivalent molecular weight of 29.0 have been corrected to account for the extra weight of the inerts.

[b] Air containing 0.013 pound water/pound dry air is often referred to as standard air.

Source: "Steam—Its Generation and Use," 39th edition, The Babcock and Wilcox Company, New York, 1978.

or for methane:

$$CH_4 + 2\,O_2 + 2(3.76)\,N_2 = CO_2 + 2\,H_2O + 7.52\,N_2$$

As indicated by the following example for a fuel gas, molal calculations have a simple and direct application to gaseous fuels, where the analyses are usually reported in percent on a volume basis.

FUEL GAS ANALYSIS
(% by Volume)

CH_4	85.3
C_2H_6	12.6
CO_2	0.1
N_2	1.7
O_2	0.3
Total	100.0

This analysis may also be expressed as 85.3 moles of CH_4 per 100 moles of fuel; 12.6 moles of C_2H_6 per moles of fuel; and so on.

The elemental breakdown of each constituent may also be designated in moles per 100 moles of fuel, as follows:

C in CH_4	=	85.3 × 1	=	85.3	moles
C in C_2H_6	=	12.6 × 2	=	25.2	moles
C in CO_2	=	0.1 × 1	=	0.1	mole
Total C per 100 moles fuel			=	110.6	moles
H_2 in CH_4	=	85.3 × 2	=	170.6	moles
H_2 in C_2H_6	=	12.6 × 3	=	37.8	moles
Total H per 100 moles fuel			=	208.4	moles
O_2 in CO_2	=	0.1 × 1	=	0.1	mole
O_2	=	0.3 × 1	=	0.3	mole
Total O_2 per 100 moles fuel			=	0.4	mole
N_2 per 100 moles fuel			=	1.7	moles

An analysis of the flue gas produced by burning a gas fuel of the composition given above could be:

Constituent	% by volume
CO_2	10.4
O_2	2.8
N_2	86.8
Total	100.0

Analyses of flue gases are always reported on a volume basis, *dry*, when an Orsat or other type of gas analysis is used. Flue gases are cooled to room temperature and bubbled through water in most gas analyses, so that the gas becomes saturated with water vapor. This would occur even if no water vapor were formed during combustion. Proportionate parts of the water vapor content of the gas will be absorbed with the different constituents of the gas so that the resulting analysis may be safely assumed to be that of dry gas. These percentages may also be expressed as 10.4 moles CO_2, 2.8 moles O_2, and 86.8 moles N_2; each per 100 moles of dry flue gas.

For each mole of C burned, one mole of CO_2 is formed. From the fuel analysis used there are 110.6 moles C per 100 moles of fuel, and there are also 110.6 moles of CO_2 formed from the 110.6 moles C in the fuel. From the flue gas analysis, there are $100/10.4 = 9.62$ moles of dry flue gas per mole of CO_2. The 100 moles of fuel will then yield $110.6 \times 9.62 = 1{,}064$ moles of dry flue gas. By the application of the mole method, an important value has been quickly determined through knowing only the flue gas analysis and the fuel analysis.

From the flue gas analysis, the molecular weight of the dry flue gas can be easily determined, as follows:

10.4 moles of CO_2 weight			
10.4 × 44 pounds	=	457.6	pounds
2.8 moles of O_2 weight			
2.8 × 32 pounds	=	89.6	pounds
86.8 moles of N_2 weight			
86.8 × 28 pounds	=	2,430.4	pounds
100.0 moles of dry flue gas		2,977.6	pounds

Therefore, 1 mole equivalent of dry flue gas = 29.8 pounds, or the equivalent molecular weight of the dry flue gas = 29.8. Hence, the weight of 1,064 moles of dry flue gas is $1,064 \times 29.8 = 31,700$ pounds, or 100 moles of fuel yields 31,700 pounds of dry flue gas.

The weight of 100 moles of fuel is the sum of the products of each constituent in the fuel and its molecular weight.

CH_4	85.3	×	16	=	1,365	
C_2H_6	12.6	×	30	=	378	
CO_2	0.1	×	44	=	4.4	
N_2	1.7	×	28	=	47.6	
O_2	0.3	×	32	=	9.6	
	100.0 moles			=	1804.6	pounds

Thus, 1,805 pounds of gas fuel yield 31,700 pounds of dry flue gas, and each pound of gas fuel yields $31,700/1,805 = 17.6$ pounds dry flue gas.

Heat of Combustion

In a boiler furnace (where no mechanical work is done) the heat energy evolved from the union of combustible elements with oxygen depends on the ultimate products of combustion and not on any intermediate combinations that may occur in reaching the final result.

A simple demonstration of this law is the union of 1 pound of carbon with oxygen to produce a specific amount of heat (about 14,100 Btu, Table 2). The union may be in one step to form the gaseous product of combustion, CO_2, or under certain conditions, the union may be in two steps, first to form CO, producing a much smaller amount of heat (4,345 Btu) and, second, the union of the CO so obtained to form CO_2, releasing 9,755 Btu. However, the sum of the heats released in the two steps equals the 14,100 Btu evolved when carbon is burned in one step to form CO_2 as the final product.

That carbon may enter into these two combinations with oxygen is of utmost importance in the design of combustion equipment. Firing methods must assure complete mixture of fuel and oxygen, to be certain that all of the carbon burns to CO_2 and not to CO. Failure to meet this requirement will result in appreciable losses in combustion efficiency and in the amount of heat released by the fuel, since only about 28% of the available heat in the carbon is released if CO is formed instead of CO_2.

Measurement of Heat of Combustion. In boiler practice, the heat of combustion of a fuel is the amount of heat, expressed in Btu, generated by the complete combustion (or oxidation) of a unit weight (1 pound in the United States) of fuel. *Calorific value* or *fuel Btu value* are other terms used.

The amount of heat generated by complete combustion is a constant for any given combination of combustible elements and compounds and is not affected by the manner in which the combustion takes place, provided that it is complete.

The heat of combustion of a fuel is usually determined by direct measurement in a calorimeter of the heat evolved during combustion. See entry on **Calorimetry**.

The heat of combustion of most gases encountered in boiler practice is given in Table 1. If the content of any gas mixture is known, its heat of combustion can be accurately determined by adding the products of the volume percentage of each constituent times its heat of combustion.

For accurate heat values of solid and liquid fuels calorimeter determinations are required. However, approximate heat values may be determined for most coals if the ultimate chemical analysis is known. Dulong's formula gives reasonably accurate results (within 2 to 3%) for most coals and is often used as a routine check of values determined by calorimeter:

$$\text{Btu/pound} = 14,544C + 62,028(H_2 - O_2/8) + 4050\,S \qquad (1)$$

In this formula, the symbols represent the proportionate parts by weight of the constituents of the fuel—carbon, hydrogen, oxygen and sulfur—as determined by an ultimate analysis; the coefficients represent the approximate heating values of the constituents in Btu per pound. The term $O_2/8$ is a correction applied to the hydrogen in the fuel to account for the hydrogen already combined with the oxygen in the form of moisture. This formula is not generally suitable for calculating the Btu values of gaseous fuels.

High and Low Heat Values. Water vapor is one of the products of combustion for all fuels containing hydrogen. The heat content of a fuel depends on whether this water vapor is allowed to remain in the vapor state or is condensed to liquid. In the bomb calorimeter the products of combustion are cooled to the initial temperature and all of the water vapor formed during combustion is condensed to liquid. This gives the high, or gross, heat content of the fuel with the heat of vaporization included in the reported value. For the low, or net heat of combustion, it is assumed that all products of combustion remain in the gaseous state.

While the high, or gross, heat of combustion can be accurately determined by established (ASTM) procedures, direct determination of the low heat of combustion is difficult. Therefore, it is usually calculated using the following formula:

$$Q_L = Q_H - 1040\,w \qquad (2)$$

where Q_L = low heat of combustion of fuel, Btu/pound
Q_H = heat of combustion of fuel, Btu/pound
w = of water formed per pound of fuel
1040 = factor to reduce high heat of combustion at constant volume to low heat of combustion at constant pressure

In the United States the practice is to use the high heat of combustion in boiler combustion calculations. In Europe the low heat value is used.

Ignition Temperatures

Ignition temperature may be defined as the temperature at which more heat is generated by combustion than is lost to the surroundings so that the combustion process becomes self-sustaining. The term usually applies to rapid combustion in air at atmospheric pressure.

Ignition temperatures of combustion substances vary greatly as indicated in Table 4, which lists minimum temperatures and temperature ranges in air for fuels and for the combustible constituents of fuels commonly used in the commercial generation of heat. Many factors influence ignition temperature so that any tabulation can be used only as a guide. Pressure, velocity, enclosure configuration, catalytic materials, air-fuel-mixture uniformity, and ignition source are only a few of the variables. Ignition temperature usually decreases with rising pressure and increases with increasing moisture content in the air.

The ignition temperatures of the gases of a coal vary considerably and are appreciably higher than the ignition temperatures of the fixed carbon of the coal. However, the ignition temperature of coal may be considered as the ignition temperature of its fixed carbon content, since the gaseous constituents are usually distilled off but not ignited before this temperature is attained.

Adiabatic Flame Temperature

The adiabatic flame temperature is the maximum theoretical temperature that can be reached by the products of combustion of a specific fuel and air (or oxygen) combination assuming no loss of heat to the surroundings until combustion is complete. This theoretical temperature also assumes no dissociation, a phenomenon discussed later under this heading. The heat of combustion of the fuel is the major factor in the flame temperature, but increasing the temperature of the air or of the fuel will also have the effect of raising the flame temperature. As would be expected, this adiabatic temperature is a maximum with zero excess air (only enough air chemically required to combine with the fuel), since any excess is not

TABLE 4. IGNITION TEMPERATURES OF FUELS IN AIR (APPROXIMATE VALUES AND RANGES AT ATMOSPHERIC PRESSURE)

Combustible	Formula	Temperature, °F
Sulfur	S	470
Charcoal	C	650
Fixed carbon (bituminous coal)	C	765
Fixed carbon (semibituminous coal)	C	870
Fixed carbon (anthracite)	C	840–1115
Acetylene	C_2H_2	580–825
Ethane	C_2H_6	880–1165
Ethylene	C_2H_4	900–1020
Hydrogen	H_2	1065–1095
Methane	CH_4	1170–1380
Carbon Monoxide	CO	1130–1215
Kerosine	—	490–560
Gasoline	—	500–800

involved in the combustion process and only dilutes the temperature of the products of combustion.

The adiabatic temperature is determined from the adiabatic enthalpy of the flue gas as follows:

$$h_g = \frac{\begin{pmatrix}\text{heat of}\\ \text{combustion}\end{pmatrix} + \begin{pmatrix}\text{sensible heat}\\ \text{in fuel}\end{pmatrix} + \begin{pmatrix}\text{sensible heat}\\ \text{in air}\end{pmatrix}}{\text{weight of products of combustion}}$$

where h_g = adiabatic enthalpy (adiabatic heat content of the products of combustion), Btu/pound

Knowing the moisture content of the products of combustion and its enthalpy, the theoretical flame or gas temperature can be obtained from published graphs.*

The adiabatic temperature is a fictitiously high temperature that does not exist in fact. Actual flame temperatures are lower for two main reasons:

1. Combustion is not instantaneous. Some heat is lost to the surroundings as combustion takes place. The faster the combustion occurs the less heat is lost before combustion is complete. If combustion is slow enough, the gases may be cooled sufficiently for combustion to be incomplete with some of the fuel unburned. This is related to the time factor in the "three T's" of combustion mentioned previously.
2. At temperatures above 3,000°F (1,649°C), some of the CO_2 and H_2O in the flue gases dissociates, absorbing heat in the process. At 3,500°F (1,926°C), about 10% of the CO_2 in a typical flue gas dissociates to CO and O_2 with a heat absorption of 4,345 Btu/pound of CO formed, and about 3% of the H_2O dissociates to H_2 and O_2, with a heat absorption of 61,100 Btu/pound of H_2 formed. As the gas cools, the CO and H_2 dissociated recombine with the O_2 and liberate the heat absorbed in dissociation, so the heat is not lost. However, the effect is to lower the maximum actual flame temperature.

Combustion Calculations

The combustion calculations are the starting point for all design and performance determinations for boilers and their related component parts. They establish (a) the quantities of the constituents involved in the chemistry of combustion, (b) the quantity of heat released, and (c) the efficiency of the combustion process under both ideal and actual conditions.

Combustion Air. Since carbon, hydrogen, and sulfur are the only major combustible elements found in the fuels used for commercial steam generation, the air (pounds) theoretically required for the complete combustion of 1 pound of fuel is:

$$11.53\ C + 34.34(H_2 - O_2/8) + 4.29\ S \qquad (3)$$

where C, H_2, O_2 and S represent the fraction by weight (percent/100) of carbon, hydrogen, oxygen and sulfur, and the constants are those given in Table 1. The factor $O_2/8$ in the term $(H_2 - O_2/8)$ is a correction for the hydrogen already combined with the O_2 in the fuel to form water vapor.

With gaseous fuels, instead of breaking down the hydrocarbons into their constituent elements, it is simpler to use the amount of air for the various compounds directly as given in Table 1. For instance, for a gaseous fuel containing the combustible gases indicated in the expression below, the theoretical air required for complete combustion (pounds air/pounds fuel) is:

$$2.47\ CO + 34.34\ H_2 + 17.27\ CH_4 + 13.30\ C_2H_2$$
$$+ 14.81\ C_2H_4 + 16.12\ C_2H_6 + 6.10\ H_2S - 4.32\ O_2 \qquad (4)$$

Again, the molecular symbols represent the fraction by weight of the gaseous compounds and elements.

If, as is the usual custom, the analyses of gaseous fuels are given on a volumetric basis, the cubic feet of combustion air required as given in Table 1 should be used. Thus for a gaseous fuel containing the combustible gases indicated in the following expression, the number of cubic feet of theoretical air required per cubic foot of fuel for complete combustion is:

$$2.38(CO + H_2) + 9.53\ CH_4 + 11.91\ C_2H_2 + 14.29\ C_2H_4 + 16.68\ C_2H_6 + 7.15\ H_2S - 4.76\ O_2 \qquad (5)$$

where the molecular symbols represent the fraction by volume of the gaseous compounds and elements. Note that the total air requirement is reduced if oxygen is one of the constituents of the fuel.

The products of combustion can also be determined from the data given in Table 1. Assuming complete combustion with theoretical air of the fuels ordinarily used for commercial steam generation, the products of combustion in pounds (including the nitrogen carried with the combustion air) per pound of fuel are:

$$CO_2 = 3.66\ C$$
$$H_2O = 8.94\ H_2 + H_2O^{**}$$
$$SO_2 = 2.00\ S$$
$$N_2 = 8.86\ C + 26.41(H_2 - O_2/8) + 3.29\ S + N_2^{\dagger}$$

The moisture introduced with the combustion air must be added to this theoretical quantity to obtain the total weight of combustion products. The molecular symbols represent the fraction by weight of the constituents in the fuel.

Energy Losses. Not all of the Btu in the fuel are converted to heat and absorbed by the steam generation equipment. Some of the fuel may be unburned, leaving carbon in the ash or carbon may be burned incompletely to form some CO instead of all CO_2. Usually all of the H_2 in the fuel is burned. By far the greatest heat loss is the loss up the stack. Since the heat in the fuel is determined from a base of ambient temperature, all of the products of combustion must be cooled to the same temperature if all of the heat is to be utilized. Higher temperatures then represent a loss, which is the sum of four items: (1) the sensible heat in dry flue gas, (2) the sensible heat in the moisture in the air, (3) the sensible heat in the H_2O in the fuel, and (4) the latent heat of the moisture in the fuel.

It is necessary practically to use more than the theoretical air requirements to assure sufficient oxygen for complete combustion. Excess air would not be required if it were possible to have an ideally perfect union of air and fuel. It is necessary, however, to keep the excess at a minimum in order to hold down the stack loss. The excess air that is not used in the combustion of the fuel leaves the unit at stack temperature. The heat required to heat this air from room temperature to stack temperature serves no purpose and is lost heat. Table 5 gives realistic values of excess air for the fuel-burning equipment which experience has shown is required to assure complete combustion for various fuels and methods of firing.

TABLE 5. USUAL AMOUNTS OF EXCESS AIR SUPPLIED TO FUEL-BURNING EQUIPMENT

Fuel	Type of furnace or burners	Excess air % by weight
Pulverized coal	Completely water-cooled furnace for slag-tap or dry-ash-removal	15-20
	Partially water-cooled furnace for dry-ash removal	15-40
Crushed coal	Cyclone furnace—pressure or suction	10-15
Coal	Spreader stoker	30-60
	Water-cooled vibrating-grate stoker	30-60
	Chain-grate and traveling-grate stokers	15-50
	Underfeed stoker	20-50
Fuel oil	Oil burners, register-type	5-10
	Multifuel burners and flat-flame	10-20
Acid sludge	Cone and flat-flame type burners, steam-atomized	10-15
Natural, coke-oven, and refinery gas	Register-type burners	5-10
	Multifuel burners	7-12
Blast-furnace gas	Intertube nozzle-type burners	15-18
Wood	Dutch oven (10-23% through grates) and Hofft-type	20-25
Bagasse	All furnaces	25-35
Black liquor	Recovery furnaces for kraft and soda-pulping processes	5-7

** Fraction by weight of H_2O (percent/100) in the fuel as moisture.

† Fraction by weight of N_2 in the fuel as nitrogen.

In most furnaces operating under suction, there is also some leakage of air into the setting and, consequently, the excess air leaving the furnace and the unit is greater than that at the fuel-burning equipment. Another loss that must be considered is the radiation loss from the unit setting.

In summary, there are certain inherent heat losses over which there is no control, and others that are subject to some control. The inherent losses are the result of: (1) the discharge of the products of combustion at a temperature higher than ambient; and (2) the moisture content of the fuel plus the combination of some of the hydrogen with the oxygen in the fuel. The avoidable heat losses, or those that can be controlled by good design and careful operation, can be minimized by: (1) careful control of excess air; (2) tolerating virtually no unburned solid combustible matter in ash or refuse; (3) permitting no unburned gaseous combustibles in the exit gases; and (4) a well-insulated setting for the steam generating unit to reduce radiation loss.

The efficiency of combustion in a heat exchanger or boiler is 100 minus the sum of the heat losses expressed in percent

COMMON ION EFFECT. The reversal of ionization which occurs when a compound is added to a solution of a second compound with which it has a common ion, the volume being kept constant. The degree of ionization of the second compound then is lowered, i.e., it retrogresses. The common ion effect also can markedly affect solubility.

COMPARATIVE BIOLOGY. In any division of biological science, the comparative treatment focuses attention upon a limited subject, such as anatomy, but introduces into its treatment data drawn from many species. This method of study has been applied widely to the vertebrates; hence, comparative anatomy is likely to mean comparative anatomy of the vertebrates unless otherwise qualified.

The comparative method is valuable in determining the evolutionary development of organs and the relationship of species.

Comparative biochemistry may be defined as the study of the nature, origin, and control of biochemical diversity. This definition suggests that: (1) biochemical differences are to be found among organisms; (2) such differences arise during the evolving processes of organisms; and (3) the biochemical properties of organisms are under a variety of controls in nature, and presumably may be modified when the biochemical properties and their natural controls are understood.

In the approach to comparative biochemistry, popular before the 1950s and exemplified by the books of Baldwin and Florkin, biochemists studied the similarities and differences among higher organisms, mainly among animals. The compounds, such as the various phosphagens, blood-transport pigments, carotenoids, and the A vitamins, were correlated with the postulated phylogenetic position of the animals possessing these substances. The comparative aspects of nitrogenous excretion products and of salt and water balance have also been studied in great detail. Such types of studies have revealed metabolic differences among the *Metazoa*, differences related to their evolving nature and ecological niches. More recently, the distributions of the alkaloids and flavones of plants, organic acids of lichens, and the pterins of *Drosophila*, among other biochemical markers, have been analyzed in detail to help in establishing genetic and evolving interrelations.

Since about 1945, biochemistry has concentrated largely on cellular metabolism, and these studies tend to emphasize the uniformity of cellular biochemistry. Thus, almost all cells contain proteins built of the same 20 amino acids, RNA and DNA containing their characteristic constituents, common coenzymes ATP, NAD, coenzyme A, and so on. Also, many similarities could be detected in the metabolic events relating to energy and biosynthesis in many cell types, i.e., microorganisms, plants, and animals. This experience was soon interpreted by the school of Kluyver and van Niel and their students to signify a *uniformity of biochemistry*, a unity inferred to derive from a monophyletic process of organisms as they evolve from a primitive cellular type. In this view, biochemical differences among organisms are considered to reflect relatively late evolving divergences of which the metabolic differences among the *Metazoa*, e.g., patterns of nitrogen excretion, such as ammonotelism, ureotelism, and uricotelism, are clear examples. It is recognized that the biochemical differences found to exist between organisms are not only considered to be relatively late in their evolving processes, but are usually stated to represent minor alterations in the broad biochemical pattern common to many cells.

Thus comparative studies, while always remaining important as an investigative tool, have given ground to what appears to be the more important *uniformity* approach, with concentration on the fundamental aspects of biology which affect all life forms.

COMPLEX COMPOUND. See **Ligand.**

COMPOSITE MATERIALS. A mixture of mechanical combination on a macroscale of two or more materials that are solid in the finished state, are mutually insoluble and differ in chemical nature. The major types are (1) Laminates of paper, fabric, or wood (veneer) and a thermosetting material (resin, rubber, or adhesive); examples are tire carcasses, plywood, and electrical insulating structures. (2) Reinforced plastics, principally of glass fiber and a thermosetting resin; other types of fibers such as boron, aluminum silicate, and silicon carbide may be used. (3) Cermets, which are mixtures of ceramic and metal powders, heat treated and compressed. (4) Fabrics, e.g., woven combinations of wool or cotton and a synthetic fiber. (5) Filled composites in which a bonding material i.e., linseed oil, resin, or asphalt, is loaded with a filler in the form of flakes or small particles; examples are linoleum, glass flake-plastic mixtures for battery cases, and asphalt-gravel road-surfacing mixtures.

COMPOUND (Chemical). A homogeneous, pure substance, composed of two or more essentially different chemical elements, which are present in definite proportions; compounds usually possess properties differing from those of the constituent elements.

An *addition compound* is one that is formed by the junction or union of two simpler compounds. Effectively the same as a molecular compound (see definition on the following page).

An *additive compound* is formed by an additional reaction, or by the saturation of a double bond, triple bond, or more than one of them.

An *alicyclic compound* is an organic compound containing a saturated ring of carbon atoms, such as a cycloparaffin or other hydroaromatic compound.

An *aliphatic compound* is an organic compound without ring structures, i.e., with straight chain arrangement of carbon and, possibly other, atoms. In the narrower sense, an aliphatic compound is a member of the paraffin series of hydrocarbons, or one of their derivatives.

An *aromatic compound* is an organic compound containing a ring of carbon atoms, usually unsaturated, such as a benzene, naphthalene, anthracene, and acenaphthylene ring.

An *associated compound* is a compound formed by the union of two or more molecules, usually of the same or similar chemical composition, to form a single complex molecule.

Berthollide compound

See nonstoichiometric compound in this entry.

A *binary compound* is made up of two elements in a definite molecular ratio.

A *catenation compound* has a molecular configuration resembling a linked chain, in which the atoms forming one ring pass through, but are not joined by valence forces to, the ring formed by another group of atoms. Since the two rings, while spatially interlocked, are not joined by valence forces, the application of the word compound to such aggregates may be questioned.

H.L. Frisch of AT&T Bell Laboratories has made extensive calculations of ring sizes necessary to permit the formation of various catenation compounds. He found that 20 is the minimum number of $-CH_2-$ groups in an alicyclic ring through which another ring can be catenated (threaded) without encountering excessively great repulsive forces from the alicyclic ring atoms. For threadings of two rings through a third ring, the probable minimum alicyclic ring size of the latter is 33 $-CH_2-$ groups: Borromean rings, formed by the interlocking of three rings (with no two of them locked separately), require a minimum of 30 $-CH_2-$ groups.

A laboratory preparation of the simplest of these catenation compounds, two interlocking rings, has been carried out at AT&T Bell Laboratories. They started with the dimethyl ester of a 34-carbon paraffinic dicarboxylic acid, $CH_3OOC-(CH_2)_{32}-COOCH_3$, which was reacted in a suspension of metallic sodium in xylene with acetic acid to condense the terminal ester groups to form an aceloin ring compound.

$$O{=}C-(CH_2)_{32}-CHOH$$

Treatment of the latter with deuterated hydrochloric acid reduced it to a 34-carbon alicyclic (ring) compound,

$$HDC-CHD-CD_2-CHD-(CH_2)_{30}$$

containing five deuterium atoms. This hydrocarbon was added to the suspension of metallic sodium in xylene, and then more of the 34-carbon dimethyl ester was added. Ring formation of the latter compound to form the aceloin occurred as before, and a small percentage of the aceloin rings were found to be threaded through the deuterated rings in the solvent, yielding a catenation compound consisting of the 34-carbon aceloin ring and the 34-carbon deuterated alicyclic hydrocarbon threaded together, but without any atoms in one ring being joined by valence bonds to those in the other.

Separation and identification of this catenation compound was effected by chromatography and infrared spectroscopy, the latter being the reason why the hydrocarbon portion of the catenation compound was deuterated.

Chelation compound

See entry on **Chelates and Chelation**.

A *clathrate compound* means, literally, an enclosed compound, a term applied to a solid molecular compound in which a molecule of one component is physically enclosed in the crystal structure of a second compound, so that the properties of the aggregate are essentially those of the enclosing compound. Examples of such "cage compounds" are those of the small molecules of SO_2, CO_2, CO and the noble gases with ice and hydroquinone, which have very open crystal structures. Another example is the clathrate of benzene with nickel cyanide.

A *complex compound* is made up structurally of two or more compounds or ions. See also **Ligand**.

A *condensation compound* is formed by a reaction in which the largest parts, constituting the essential structural elements, of two or more molecules combine to form a new molecule, with elimination of minor elements, such as those of water.

Coordination compound

See also **Coordination Compounds**.

A *covalent compound* is formed by the sharing of electrons between atoms; as distinguished from electrovalent compounds, in which there occurs a transfer of electrons.

A *cyclic compound* has some or all of its atoms arranged in a ring structure.

An *electrovalent compound* is formed by ions, or by atoms which become ions by transfer of electrons between them. (See ionic compound below.)

An *endothermic compound* is a compound whose formation is accompanied by a positive change in heat content, i.e., by the absorption of heat.

An *epoxy compound* contains an oxygen bridge, as

$$CH_2-CH_2-CH_2-CH_2 \quad (\text{ring closed through } O)$$

which is 1, 4 epoxy butane.

An *exothermic compound* is a compound whose formation is accompanied by a negative change in heat content, i.e., with the liberation of heat.

A *heterocyclic compound* contains one or more rings composed of atoms some of which are of dissimilar elements. A few inorganic substances fall into this classification, but by far the majority of them are carbon compounds. In organic chemistry substances of cyclic structure, as acid anhydrides, lactides, lactams, lactones, cyclic ethers, and cyclic derivatives of dicarboxylic acids which are formed by the elimination of water from aliphatic compounds, are not considered among the heterocyclic substances. Derivatives of pyridine, quinoline, thiophene, thiazole, pyrone, etc., which contain heterocyclic rings that persist in the compound through chemical reactions, are considered the true members of this class. Heterocyclic rings that contain nitrogen, sulfur, and oxygen members. The noncarbon members of the ring are termed "heteroatoms," and their number is indicated by the prefixes mono, di, tri, tetra, etc. The number of members in the ring may reach as high as sixteen, as in tetrasalicylide.

A *homocyclic compound* contains a homocyclic ring, i.e., a ring composed of atoms of the same element.

The term *inclusion compound* was once used for the clathrate compounds described in this entry.

In an *inner compound* an additional valence bond has been formed between two atoms of an already existing structure, usually by loss of the elements of water or other simple substance. Inner compound formation commonly results in the formation of a ring. The inner esters, inner anhydrides, and inner coordination compounds are well-known classes of inner compounds.

An *inorganic compound* means, in general, a compound that does not contain carbon atoms. Some very simple carbon compounds, such as carbon monoxide and dioxide, binary metallic carbon compounds (carbides) and carbonates, are also included in the group of inorganic compounds.

An *intermetallic compound* consists of metallic atoms only, which are joined by metallic bonds. Such compounds may be made semiconducting if the two metals between them contribute just sufficient electrons to fill the valence bond, e.g., InAs. See also **Alloys**.

An *interstitial compound* consists of a metal or metals and certain metalloid elements, in which the metalloid atoms occupy the interstices between the atoms of the metal lattice. Compounds of this type are, for example, TaC, TiC, ZrC, NbC, and similar compounds of carbon, nitrogen, boron, and hydrogen with metals.

An *ionic compound* is one of a class of compounds formed when atoms combine to produce molecules having stable configurations by the transfer of one or more electrons within the molecule. This type of combination is illustrated by the combination of sodium atoms and chlorine atoms to form sodium chloride. The sodium atom loses the single electron in its outer shell, and thus is left with the stable configuration of eight electrons; the chlorine atom acquires an electron to increase the number of electrons in its outer shell from seven to eight; as a result of the loss and gain of the electrons, the atoms have acquired the positive and negative charges, respectively, which constitute an electrovalent bond.

A *molecular compound* is formed by the union of two or more already saturated molecules apparently in defiance of the ordinary rules of valence. The class includes double salts, salts with water of crystallization, and metal ammonium derivatives. These salts are usually formed by Van der Waals attraction between the constituent molecules. They do not differ in any characteristic manner from compounds formed in strict accordance with the concept of valence. They are also called addition compounds.

A *nonpolar compound* is a compound in which the centers of positive and negative charge almost coincide, so that no permanent dipole moments are produced. The term nonpolar also applies to compounds in which the effect of oppositely directed dipole moments cancel. Nonpolar compounds

may contain polar bonds, if their effect is canceled by opposing bonds, as may occur in a perfectly symmetrical molecule. Nonpolar compounds do not ionize or conduct electricity. Most organic compounds are to be classed as nonpolar compounds.

A *nonstoichiometric compound* has a composition not in accord with the law of definite proportions, which is therefore also called a berthollide compound. Nonstoichiometric compounds occur among the binary compounds of Group 6b, as exemplified by $TiO_{1.8}$, $Cu_{1.7}S$ and $Cu_{1.6}Se$; among the hydrides, e.g., $CeH_{2.7}$ and especially among the intermetallic compounds.

An *organic compound* is one of the great number of compounds consisting of carbon linked in chains or rings; such compounds usually also contain hydrogen and may contain elements such as oxygen, nitrogen, sulfur, chlorine, etc. Some of the simpler carbon compounds are classified as inorganic compounds.

An *organometallic* (or *metal-organic*) *compound* is an organic compound in which one or more hydrogen atoms have been replaced by a metallic atom or atoms, usually with the establishment of a valence bond between the metal atom and a carbon atom. A metallic salt of an organic acid, in which the hydrogen atoms of a COOH group is replaced by a metal atom, is not classified as an organometallic compound.

A *polar compound* is, in general, a compound that exhibits polarity, or local differences in electrical properties, and has a dipole moment associated with one or more of its interatomic valence bonds. Polar compounds have relatively high dielectric constants, associate readily in most cases, and include the substances that exhibit tautomerism. In the most general use of the term, polar compounds include all electrolytes, most inorganic substances, and many organic ones. Specifically, the term polar compound is frequently applied to the extreme type of polarity which arises in the presence of an electrovalent bond or, in wave-mechanical terms, to cases in which one ionic term dominates in the orbital function of the molecule. Such compounds are exemplified by the inorganic acids, bases, and salts which possess, to a greater or lesser degree the power to conduct electricity, associate, form double molecules and complex ions, etc.

In a *saturated compound* the valence of all the atoms is completely satisfied without linking any two atoms by more than one valence bond.

A *spiro-compound* contains two ring structures having one common carbon atom.

A *tracer compound* is a compound which, by its ease of detection, enables a reaction or process to be studied conveniently. Wide use has been made of isotopes, including radioactive isotopes of common elements, which are added in small quantities, in the form of the proper compound, to follow the course of an atom or a compound through a complicated series of reactions; or conversely, to determine the properties of a tracer—that is available only in quantities too small to handle alone—by adding it to a system containing chemically related elements, and then following its course throughout a given series of reactions. Considerable use of tracer compounds is made in the study of physiological reactions.

Unsaturated compound is a term specifically applied to a carbon compound containing one or more double bonds or triple bonds. One consequence of the presence of these double bonds or triple bonds, from which a broader concept of unsaturation stems, is the relative ease with which such bonds are split, and other constituents linked to them.

See also **Organic Chemistry**.

COMPRESSION (Gas). The compressibility of a gas is defined as the rate of volume decrease with increasing pressure, per unit volume of the gas. The compressibility depends not only on the state of the gas, but also on the conditions under which the compression is achieved. Thus, if the temperature is kept constant during compression, the compressibility so defined is called the isothermal compressibility β_T:

$$\beta_T = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T = \frac{1}{\rho}\left(\frac{\rho}{\partial P}\right)_T \tag{1}$$

If the compression is carried out reversibly without heat exchange with the surroundings, the *adiabatic compressibility* at constant entropy, β_S, is obtained:

$$\beta_S = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_S = \frac{1}{\rho}\left(\frac{\partial\rho}{\partial P}\right)_S \tag{2}$$

Here P is the pressure, V the volume, ρ the density, T the temperature, and S the entropy.

In adiabatic compression, the temperature rises, thus the pressure increases more sharply than in isothermal compression. Therefore β_S is always smaller than β_T.

The *compressibility factor* of a gas is the ratio PV/RT. This name is not well chosen since the value of the compressibility factor by itself does not indicate the compressibility of the gas.

Experimental values for the compressibility of gases can be obtained in several ways, most of which are indirect.

Since the compressibility is proportional to the pressure derivative of the volume, any experiment that establishes the P-V-T relation of a gas with sufficient accuracy also yields data for the isothermal compressibility. For obtaining the adiabatic compressibility from the P-V-T relation, some additional information is necessary [see section (c)], for instance specific heat data in the perfect gas state of the substance considered. A more direct way of determining the adiabatic compressibility is by measuring the speed of sound v, the two quantities being related by

$$v^2 = \frac{1}{\rho\beta_S} \tag{3}$$

This relation is valid only when the compressions and expansions of the sound wave are truly reversible and adiabatic. This is the case if the frequency is fairly low and the amplitude small.

Dilute gases obey the laws of Boyle and Gay-Lussac, $PV = RT$, to a good approximation. Thus, it can readily be shown that the following relations hold for the compressibility:

$$\begin{aligned}\beta_T &= 1/P = V/RT \\ \beta_S &= 1/\gamma P = V/\gamma RT\end{aligned} \tag{4}$$

where $\gamma = c_P/c_V$, the ratio of the specific heats at constant volume and at constant pressure, respectively, and R is the gas constant.

Compressed gases show large deviations from the behavior predicted by equation (4). This is demonstrated by Fig. 1, where the isothermal compressibility of argon, divided by the corresponding value for a perfect gas at the same density, is pictured as a function of density for various temperatures. It is seen, first, that at all temperatures the compressibility at high densities falls to a small fraction of the value for a perfect gas, and second, that supercritical isotherms show a maximum in the ratio $\beta/\beta_{\text{perfect}}$ as a function of density, which maximum is the more pronounced the closer the critical temperature. It occurs roughly at the critical density ρ_c. Since at the critical point $(\partial P/\partial P)_T$ equals zero, the isothermal compressibility becomes infinite at this point. The adiabatic compressibility, however, remains finite. Qualitatively, all gases show the same behavior as pictured for argon in the diagram.

The molecular theory can explain the general features of the compressibility in its temperature and density dependence. The pressure of the gas is caused by the impact of the molecules on the wall. If the volume is decreased at constant temperature, the average molecular speed and force of impact remain constant, but the number of collisions per unit area increases and thus the pressure rises. If the gas is compressed adiabatically, the heat of compression cannot flow off, thus the average molecular speed and force of impact increase as well, giving rise to an extra increase of pressure. Therefore $\beta_S < \beta_T$. The actual magnitude of the temperature rise depends on the internal state of the molecules: the more internal degrees of freedom available, the more energy can be taken up inside the molecule and the smaller the temperature rise on adiabatic compression. Thus for gases consisting of molecules with many internal degrees of freedom, adiabatic and isothermal compressibilities differ but little.

If the gas is assumed to consist of molecules of negligible size and without interaction, then the gas can be shown to follow the laws of Boyle and Gay-Lussac; therefore its isothermal and adiabatic compressibilities must be given by Equation (4). For a perfect gas, the percentage pressure rise is proportional to the percentage volume decrease if the change is small; thus the compressibility is inversely proportional to the pressure.

To explain the very different behavior of real gases, the model must be modified. Suppose the molecular volume is small but not negligible. In states of high compression, where the total molecular volume becomes of the order of the volume available to the gas, the free space available to the molecules is only a fraction of what it would be in a perfect gas, and thus the real gas is much harder to compress than the perfect gas. This explains the low compressibility of dense gases and liquids (diagram).

Furthermore, one assumes that molecules, on approaching each other, experience a mutual attraction before they collide; this mutual attraction

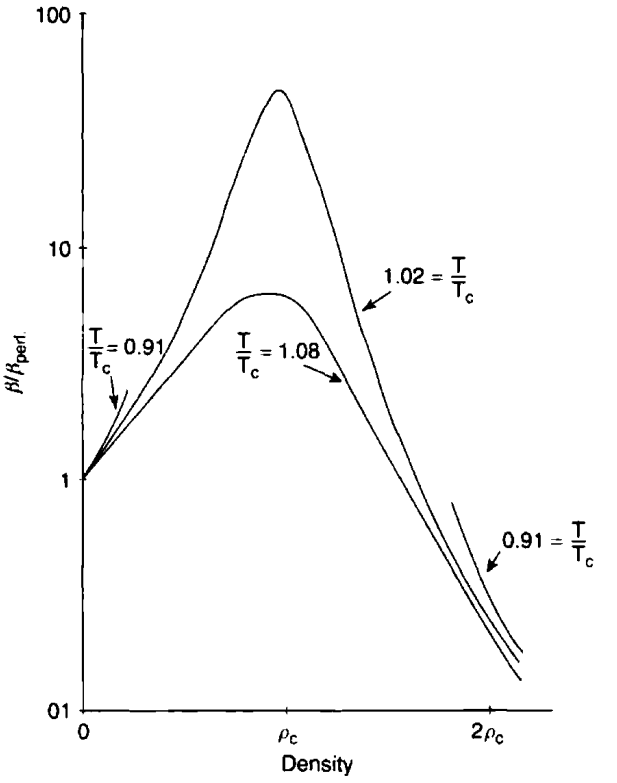

Fig. 1. The ratio β/β_{perf} of the isothermal compressibility of argon to that of a perfect gas at the same density, as a function of the density, at 0.91, 1.02 and 1.08 times the critical temperature. The critical density is indicated by ρ_c

makes it easier to compress a real gas than a perfect gas. This explains the initial rise of the compressibility of a real gas over that of a perfect gas at temperatures not too far above the critical.

When compressed at subcritical temperatures, the gas condenses; that is, macroscopic clusters or droplets are formed under the influence of the attractive forces. During condensation, the pressure remains constant while the volume decreases, giving rise to an infinite compressibility in the two-phase region. At the critical point the system is on the verge of condensation and the compressibility is also infinite.

Theoretical predictions for the isothermal compressibility can obviously be obtained from any theory of the equation of state. If, in addition, data for the specific heat are supplied, the adiabatic compressibility can be derived in the same way. Thus the compressibility can be derived from the virtual expansion of the equation of state which expresses the ratio *PV/RT* in a power series in the density, the coefficients being related to the interactions of groups of two, three, etc., particles.

In the dense system the convergence of the virtual expansion is doubtful. In any case the higher coefficients are hard to calculate; here approximate theories have been developed, of which the cell model is an example.

Many semiempirical equations of state with varying degree of theoretical foundations are in use. The Van der Waals equation, a two-parameter equation that gives a qualitatively correct picture of the *P-V-T* relations of a gas and of the gas-liquid transition, is an example.

Modern developments are centered around the calculations of the radial distribution function g (r), which is the ratio of the density of molecules at a distance r from a given molecule, to the average density in the gas. The compressibility can be expressed straightforwardly in terms of g (r) as follows.

$$KT\beta_T = 1/P + \int_0^{\infty} [g(r) - 1]4\pi r^2 dr \qquad (5)$$

Approximate evaluations of the radial distribution function in dense systems are being obtained as solutions to integral equations derived from first principles under well-defined approximations.

COMPUTATIONAL CHEMISTRY. Use of computers in organic synthesis and in chemical engineering as a more efficient means of research than conventional laboratory experimentation. The capacity of sophisticated computers for fast mathematical calculations has made then an invaluable aid in exploring and evaluating the more likely pathways for a given organic synthesis, for which there may be innumerable possible sequences. The term *heuristic* is applied to such procedures. Computers can also handle the vast complexity of quantum-mechanical calculations and aid in the elucidation of the complicated molecular structures that occur in pharmaceutical compounds and recombinant-DNA research. The Quantum Chemistry Program Exchange at Indiana University offers many programs in this field, from subroutines to major computational systems. Chemical engineers utilize computers to develop more thermodynamically efficient procedures and to consolidate overall plant operations, especially in the areas of energy consumption, reaction rates, and hazardous waste problems.

Note: Notwithstanding the immense capability of computers to point the way to solutions of chemical and engineering problems, experimentation will remain the ultimate proof of theory. It is interesting to speculate how much time and effort such empirical scientists as Goodyear and Edison could have saved had computers been available to them.

CONANT, JAMES BRYANT (1893–1978). An American chemist and educator, born in Boston, who received his doctorate in chemistry from Harvard in 1916 and was president of Harvard for 20 years (1933–1953). His major scientific activities included pioneering research on chlorophyll and important contributions to the Manhattan Project. Perhaps his greatest achievements lay in the educational field, in which he exerted a strong liberalizing influence at both the collegiate and secondary school levels. He also was ambassador to postwar Germany and educational adviser to Berlin. He wrote many books on science and education, including basic chemical tests, and received a number of scientific and educational awards.

CONCENTRATION (Chemical). The quantity of matter or of a particular type of matter that exists in a unit volume, as the strength of a solution in mass of solute per unit mass of solution; or in the number of moles, hydrogen ions, etc., contained per unit volume or per unit mass.

The most commonly used method of expressing concentration is by stating the percentage, that is, parts by weight of the given substance in 100 parts by weight of the stated material. There are several exceptions to this method of expressing concentration, and the units used should be carefully recorded or observed, depending on whether the reader is operator or reader respectively. Ethyl alcohol, in water mixtures, is commonly reported as a stated percent by volume, where 50.0% by volume is equivalent to 42.47% by weight. Beverage and industrial alcohol also is rated in terms of proof, 200 proof indicating pure ethyl alcohol, that is, absolute alcohol containing no water. See also **Ethyl Alcohol**. Gases in a mixture are commonly reported by volume percent, thus nitrogen in air 78.0% by volume (equivalent to 75.5% by weight).

The concentrations of substances in solution are expressed variously: percent by weight of the actual material stated; percent by weight of a material calculated chemically from the actual material; grams of the actual material (or a material calculated chemically from this) per 100 milliliters of solution; gram moles (the formula weight taken in grams) of the actual material per liter of solution (this is molar or formal concentration and the abbreviations, M or F, respectively, are used to express it); and gram equivalents–(the equivalent weight taken in grams of the actual material per liter of solution (this is normal concentration and the abbreviation, N, is used to express it).

Since the concentration is proportional in many individual cases to an easily determined physical constant, such as specific gravity (e.g., of solutions), the index of refraction, specific rotatory power (e.g., sugar solutions, terpenes), such constants are frequently used to ascertain and express concentration data.

See also **Demal Solution**; **Gram-Equivalent**; **Gram-Molecular Weight**; **Molal Concentration**; **Molar Concentration**; **Mole Fraction**; **Mole (Stoichiometry)**; **Mole Volume**; and **Normal Concentration**.

CONCENTRATION (Process). In the processing of various materials, it frequently is required to increase the proportion of one material in a mixture or solution by removing all or part of one or several other components. A simple example is the retrieval of impure sodium chloride from seawater by solar evaporation of the water. Concentration is a prime reason for several of the chemical engineering unit operations described elsewhere in this volume, such as: *solid–solid* separations, as by screening, jigging, tabling, flotation, sublimation, and freeze-drying; or *liquid–solid* separations, as by filtering, centrifuging, drying, evaporating.

crystallizing, leaching, expressing, and prilling; or *gas–solid* separations, as by gravity settling, electrical precipitation, cyclone and impingement settling; or *gas–gas* separations, as by absorption, adsorption, gaseous diffusion, chromatography, and electromagnetic methods; or *liquid–liquid* separations, as by distillation, dialysis, and extraction; or *liquid–gas* separations, as by drying, boiling, and condensing.

The process of concentration normally connotes an increase in the proportion of one material rather than a full separation of all other materials from the target material. Raw ores, for example, frequently will contain only a small percentage of the desired mineral. Thus, an ore may be concentrated from a fraction of 1% (wt) to 50% (wt) or more. The gaseous diffusion separation of $^{235}UF_6$ (required for nuclear fission reactors) from the natural occurring $^{238}UF_6$ (comprising 99.3%, wt) of the starting materials is an extreme example of concentration. Over 4,000 diffusion stages are required in a large atomic fuels plant to effect this concentration. Prior concentration of ores is known as *beneficiation*. This is described under **Iron**. See also **Classifying (Process)**.

CONCRETE. Concrete is a mixture of fine and coarse aggregates firmly bound into a monolithic mass by a cementing agent. The cement ordinarily employed for concrete is the standard Portland cement. The aggregates are usually sand and crushed stone or gravel. Crushed slag or cinders are used in special kinds of concrete. The formation of concrete can be thought of as a process in which the voids between the particles of coarse aggregate are filled by the fine aggregate, and the whole is cemented together by the binding action of the cement. The nature of Portland cement in this respect is described under **Cement**.

Due to its strength, permanency, and relatively low cost, concrete is one of the most important building materials employed in modern construction. It is widely used for foundations of all types, buildings, bridges, dams, retaining walls, highways, and other purposes too numerous to mention. However, the success of concrete in meeting any particular set of conditions, depends upon the proper correlation of many factors bearing on the selection and mixing of the materials, the placing of the concrete, and the original design. Concrete is strong in compression, but relatively weak in tension. Therefore structures in which the concrete is likely to be in tension must be reinforced with steel rods, which carry the tension. For strong permanent concrete, the aggregates should be clean, coarse, and well graded. River or coarse sand is better than pit sand, and should always be used where possible. Table 1 gives typical concrete mixes, with the characteristics of each.

This table is suitable for preliminary estimates only, or for small amounts of concrete. It should be remembered that research and development in the science of concrete proportioning have advanced to the point where little short of a laboratory analysis can establish the best and most economical mix for a given condition. The strength of the cementing agent is a function of the water-cement ratio, and therefore strength will vary widely depending upon the amount of water used. To obtain maximum strength, the water-cement ratio should be kept as low as possible. Type and gradation of aggregate, moisture content of the sand, and water-cement ratio are typical factors taken into account in a complete analysis for the specification of large amounts of concrete work.

TABLE 1. DATA ON CONCRETE MIXES TO YIELD 1 CUBIC YARD OF CONCRETE

Mixture	Cement, Sacks	Sand, Cu. Yd.	Stone, Cu. Yd.	Application	Weight, Tons per Cu. Yd.
1:2:3	7	0.51	0.77	Roofs, sills, tanks, Tunnels	2
1:2:4	6	0.44	0.88	R. C. floors, beams, and columns	2
$1:2\frac{1}{2}:4$	5.6	0.52	0.83	Building walls	2
1:3:5	4.7	0.52	0.86	Foundations and footings	2
			CINDERS, Cu. Yd.		
1:2:4	6.6	0.49	0.98	R. C. floors	1.5
			SLAG, Cu. Yd.		
1:2:4	6.6	0.49	0.98	R. C. floors	1.6

Concrete should be transported rapidly from the mixer to the forms, so that no initial set will have occurred before the concrete is placed in its final position. It is necessary to place concrete in the forms with care to prevent segregation of the lighter and heavier parts. This precludes dropping the concrete into place from any height. After the "green" concrete has been poured, it should be cured, or hardened, slowly over a period of about a week, during which time it should be protected from vibration, freezing, and a too-rapid rate of drying out. Strengths of concrete are usually classified on the basis of 28-day strength. Most of its strength will be acquired in this time but there is a slow increase in strength for a much longer period thereafter.

For small projects, particularly around the home, a variety of premixed dry cements and concretes are available. These simply require the addition of the requisite amount of water and adequate mixing.

Prestressed concrete elements for use in construction has increased severalfold since World War I. The concrete block industry also has expanded greatly during the same period, replacing brickwork and stonework for many applications because of economy and speed. In addition to the usual cement, sand, and gravel, concrete blocks are also available with several other ingredients to lower the weight and density of the blocks, increase thermal insulative qualities, and to add color. See also **Ceramics**.

CONDENSATE. A vapor may be reduced to liquid by removal of such portion of the latent heat of evaporation as it may contain. The act is called condensation, and the liquid is condensate. It is the property of vapors that the condensate is dense as compared to the vapor, which, in condensing, formed it; that is, there is considerable shrinkage of volume upon a reversion to the liquid state. The thermal condition of the condensate immediately upon formation is that of saturated liquid at the temperature of vapor. See also **Distillation**.

CONDUCTION (Heat). See **Heat Transfer**.

CONNATE WATER. Water that is trapped in marine sediments at the time they are laid down in the sea is commonly called *connate water*. As the term implies, connate water is produced at the same time as the rock and constitutes a sort of fossil seawater.

When marine sediments are raised above sea level and subjected to the action of circulating meteoric water, their connate water and solutes are removed by leaching and flushing and carried back to the ocean. The flushing process however is slow in fine-grained and deeply buried sediments, and water that almost certainly owes its high content of dissolved ions to remnants of marine solutions is common in such environments. The water associated with petroleum commonly is saline and occurs in formations whose porosity and structure are generally unfavorable for extensive water circulation and coincident removal of solutes. Usually the salt dissolved in brines that occur in deeply buried rocks is considered to be of connate origin. See also **Petroleum**.

Many geological processes may have modified the composition of connate brines to produce their wide range. Obviously these alterations have been extensive. Some connate waters are essentially saturated

or nearly saturated solutions of sodium chloride. Others contain large proportions of calcium as well as sodium and chloride. Although the composition of connate water gives few useful clues as to the composition of the ocean in past geologic periods, the ocean has evidently been rich in chloride for a very long time, and brines in which anions other than chloride are predominant cannot logically be ascribed entirely to a connate origin.

Among the processes which might be expected to alter the concentrations of ions in connate water are: the precipitation of solids such as calcite on mineral surfaces, the solution of rock minerals and evaporites, sorption and desorption of ions on solids, and the differential movement of water molecules and ions through clay and shale strata. The latter effect is equivalent to the ultrafiltration effect of certain types of membranes used in the reverse osmosis method of removing solutes from water. Under the high pressures encountered at great depths, water and ion movements may be very different from the ones expected at low pressure. These effects may possibly explain the high concentrations of solutes in some connate brines and the difference in ion content between such brines and ordinary seawater. Another factor of considerable importance in many places appears to be the biochemical reduction of sulfur from S^{6+} as found in sulfate ions to sulfur in the more reduced forms of free sulfur, polysulfides, or sulfide ions. The brines encountered in oil and gas fields, and the gases themselves, are often high in hydrogen sulfide content as a result of sulfate reduction.

Analyses of a variety of connate brines have been published by White, Hem, and Waring (1963). White (1957) has suggested criteria for distinguishing connate water by means of ratios of concentrations of certain of the dissolved ions to one another. In most connate water the ratios of bromide and iodide to chlorine are relatively high and ratios of potassium and lithium to sodium are low.

CONSERVATION LAWS AND SYMMETRY. Basic among the natural laws are the so-called conservation laws which, in essence, state that in a given physical system under specified conditions there is a certain measurable quantity that remains changeless regardless of what actions may occur within the system. Three classical laws of this type are: (1) the law of the conservation of energy; (2) the law of the conservation of momentum; and (3) the law of the conservation of angular momentum. The concept of the conservation laws dates back to the early days of science and modifications have occurred and will continue to occur as new knowledge is gained. One of the tasks of physics is to explain the detailed rationale for laws that, on the surface, have a quality of being "self-evident."

An outstanding example of how these laws are subject to modification was Einstein's elucidation of the mass-energy equivalence ($E = mc^2$). Before that, the conservation of mass and the conservation of energy were considered to be independently valid.

General Functions of Laws of Conservation

An important function of the conservation laws is that they allow predictions about the behavior of a system without going into mechanical details of what happens during the course of a reaction. The laws provide a direct connection between the state of the system before the reaction and the state after the reaction. Also, one may conclude that any action that violates one of the conservation laws must be forbidden.

Laws of this nature are postulated as a result of many measurements of the energies and momenta involved in reactions of all kinds. It is always found that within the limit of accuracy of the experiment, for example, the amount of energy in the system after the reaction is the same as the amount of energy before the reaction. Prior to the development of elementary particle physics, there was much emphasis on transformation of energy between its various "forms," such as mechanical, electrical, and thermal energy. The present viewpoint is that the macroscopic behavior of matter is the result of interactions between elementary particles and that these elementary interactions individually obey the various conservation laws. In its elementary form, the law of conservation of energy states that when two or more particles interact, the total energy (kinetic plus potential) is always a constant. When it is said, for example, that the kinetic energy of a moving object has been transformed into the potential energy of a compressed spring, what is really meant is that, on a microscopic level, the atoms of the spring have been pressed closer together, so that there is a greater amount of potential energy in the electric fields between the atoms of the spring. This increase of potential energy is associated with an equal decrease in the kinetic energy of the object that caused the spring to compress.

Concept of Symmetry

With the development of the Lagrangian and Hamiltonian methods of solving physical problems, and particularly with the growth of importance of quantum mechanics, it became clear that the conservation laws are closely connected with the concept of symmetry in space and time. This is based upon the ability to describe the interaction between two or more objects in terms of a potential energy function. If the potential energy of the system is known for any position of these objects in space and time, then the future motions of the objects can be predicted. Certain predictions can be made without going through a complete solution of the equations of motion. For example, it is found that if the potential energy does not depend explicitly on one of the space coordinates, then the momentum associated with that coordinate does not change, but is a constant of the motion.

Some examples of "geometrical symmetries" encountered in classical physics might include:

1. An object moves in a 3-dimensional space where its potential energy is the same at every point. The expression describing the potential does not explicitly contain the coordinates x, y, or z. That is, the system is invariant with respect to translation of the origin of the coordinate system in any direction. This symmetry is associated with conservation of linear momentum; the momentum in all three dimensions is a constant.
2. An object moves in a world that is flat so that the force of gravity is in the vertical (z) direction. The potential depends only on the height of the object above the ground, but does not depend on its location in the horizontal plane; i.e., the potential is invariant to a translation of the coordinate system in the x-y plane. There is now symmetry in two dimensions, and momentum in the x-y plane is conserved.
3. In the interaction between two spherical bodies, if the potential depends only on the distance between the bodies, then there is spherical symmetry. The system is invariant to a rotation of the coordinate system about any axis. In this case, two components of angular momentum are conserved; as the two bodies orbit around their common center of mass, the magnitude of their angular momentum is constant, while the plane of the orbit in space does not change.
4. If the interaction between two objects does not depend explicitly on the time coordinate, then the actions that take place do not depend on when one starts to measure time; i.e., the properties of the system are invariant with respect to a translation of the origin of coordinates along the time axis. This symmetry is associated with conservation of energy. Use of a 4-dimensional coordinate system allows one to associate conservation of momentum and energy in a unified manner with the geometrical symmetry of space-time.

The conservation laws and the concept of symmetry acquired importance in the area of elementary particle physics. The conservation laws act as "selection rules" to determine which reactions may take place between the many existing particles out of the very large number of otherwise conceivable reactions.

An important property of elementary particles is *parity*. Each particle has a parity number associated with it; either +1 or −1, depending on the type of particle. In an assembly of particles, there is a total parity, which is the sum of the individual parities. If parity is conserved, then this total parity does not change during the course of the reaction. This property of matter is associated with the so-called mirror symmetry. All the laws of nature which possess this type of symmetry are such that if the words "right" and "left" are interchanged in the statement of the law, then the behavior of the system obeying these laws is unchanged. At one time, it was thought that every natural law was of this type. As a result of conservation of parity, it was believed that it would be impossible to describe the difference between "right" and "left" by the use of words alone. Yang and Lee (1956) pointed out that in a special class of reactions involving the "weak nuclear" interaction, parity need not be conserved. As a result of this finding, it was seen that the universe does possess an

asymmetry between right and left and that it is possible to describe an experiment which will definitely distinguish between the directions "right" and "left" in the universe.

Another type of symmetry of importance in elementary particle physics is that entitled *charge conjugation*. This principle states that if each particle in a given isolated system is replaced by its corresponding antiparticle, then no difference can be observed. For example, if, in a hydrogen atom, the proton is replaced by an anti-proton and the electron is replaced by a positron, then this antimatter atom will behave exactly like an ordinary atom, so long as it does not come into contact with ordinary atoms.

However, it is found that there are certain types of reactions where this rule does not hold. These are the types of reactions where conservation of parity breaks down. If one considers a piece of radioactive material emitting electrons by beta decay, the radioactive nuclei are lined up in a magnetic field which is produced by electrons traveling clockwise in a coil of wire (as seen by an observer looking down on the coil). Because of the asymmetry of the radioactive nuclei, most of the emitted electrons travel in the downward direction. If the same experiment were done with similar nuclei composed of antiparticles and the current in the magnet coil consisted of positrons instead of electrons, then the emitted positrons would be found to travel in the upward rather than in the downward direction. Thus, interchanging each particle with an antiparticle has produced a change in the experiment.

In the foregoing situation, however, the symmetry can be restored if the words "right" and "left" are interchanged in the description of the experiment at the same time each particle is exchanged with its antiparticle. In this example, this is equivalent to replacing the word "clockwise" by "counterclockwise." When this is done, the positrons are emitted in the downward direction, just like the electrons in the original experiment. The laws of nature thus have been found to be invariant to the simultaneous application of charge conjugation and mirror inversion.

Other more technical conservation laws play a role in elementary particle physics. Conservation of *baryon number* and *conservation of strangeness* are rules required to account for the fact that certain reactions involving heavy particles are forbidden. *Time reversal invariance* describes the situation that, in reactions between elementary particles, it does not make any difference if the direction of the time coordinate is reversed.

Although a symmetry idea may first suggest a conservation law, the conservation law must be tested by experiment to see if the symmetry is valid.

Conservation of Energy in Thermodynamics

The principle of conservation of energy plays a fundamental role in thermodynamics and is, therefore, also called the first law of thermodynamics. In its most general form it postulates the existence of a function of state, called the internal energy of the system U, such that its change per unit time is equal to some flow, called the energy flow from the surroundings.

This statement can be expressed symbolically by the formula

$$dU = d_eU \text{ or } d_iU = 0 \tag{1}$$

in which d_eU is the energy received during the time dt from the outside, and d_iU is the energy "creation" inside the system.

The explicit form of the energy flow depends on the nature of the system considered.

In closed systems and in the absence of an external field, the energy U supplied from the outside during the time interval dt is equal to the sum of the heat flow dQ expressed in units of energy and the mechanical work dW performed at the boundaries of the system. If the pressure is normal to the surface, the mechanical work is simply $-p\,dV$ and the expression of the energy conservation becomes

$$dU = dQ - p\,dV \tag{2}$$

From a purely phenomenological point of view, this expression of the conservation of energy may be considered the definition of the heat received by the system. The extension of the mechanical principle of conservation of energy to include the flow of heat is due mainly to Carnot, Joule, Helmholtz, and Clausius.

In order to express the energy conservation in continuous systems, it is useful to introduce the energy density per unit volume

$$u_v = \frac{\Delta U}{\Delta V} \tag{3}$$

In agreement with the general formulation of the principle of energy conservation

$$\frac{\partial u_v}{\partial t} = \text{div } \Phi[U] \tag{4}$$

where $\Phi[U]$ is the energy flow. This flow contains in general different contributions, among which are:

1. The convection flow corresponding to a center of mass motion ω, amounting to $u_v\omega$.
2. heat flow Q.
3. flow of energy corresponding to the pressure tensor p_{ij} in the fluid, its i component being
$$\sum_j p_{ij}\omega \tag{5}$$
4. flow of potential energy (e.g., the outward flow of electromagnetic energy).
5. flow of energy related to diffusion.

The total energy U may be split into an internal energy, a potential energy, and a macroscopic kinetic energy. Each contribution taken separately does not satisfy an equation of the simple form of Equation (4) because of possible transformation of one form of energy to another.

Conservation of Mass

This law has been put in the form that matter can be neither created nor destroyed. More accurately, the total mass of any system remains constant under all transformations. The statement, however, is subordinate to mass-energy equivalence.

Consider a homogeneous closed system containing c components ($\gamma = 1 \ldots c$) among which a single chemical reaction is possible. In such a system any variation in the masses will result only from the chemical reaction. Thus, the change of the masses m_γ of component γ during the time interval dt can be written as

$$dm\gamma = \nu_\gamma M_\gamma d\xi \tag{6}$$

where M_γ is the molar mass of component γ and ν_γ its stoichiometric coefficient in the chemical reactions.

This coefficient is generally counted positive when ν appears in the right-hand member of the reaction equation, negative when it appears in the left-hand member; ξ is the degree of advancement or extent of reaction.

The total mass of the system is given by $m = \Sigma_\gamma m_\gamma$. Summing over γ, the conservation of mass for a closed system is expressed by

$$dm = \left(\sum_\gamma \nu_\gamma M_\gamma\right) d\xi = 0 \tag{7}$$

The equation

$$\sum_\gamma \nu_\gamma M_\gamma = 0 \tag{8}$$

is called the equation of the chemical reaction or, more briefly, the stoichiometric equation.

Instead of the mass of the components it is often useful to consider the mole numbers $n_1 \ldots n_c$. Instead of Equation (6), this becomes

$$dn_\gamma = \nu_\gamma d\xi \tag{9}$$

Equations (6) and (9) are extended easily to r simultaneous reactions. The different reactions are designated by indices ($\rho = 1 \ldots 3r$). Instead of Equations (6) and (9), there are

$$dm_\gamma = M_\gamma \sum_{\rho=1}^{r} \nu_{\gamma\rho} d\xi_\rho \tag{10}$$

$$dn_\gamma = \sum_{\rho=1}^{r} \nu_{\gamma\rho} d\xi_\rho \tag{11}$$

where $\nu_{\gamma\rho}$ denotes the stoichiometric coefficient of γ in the reaction.

The conservation of mass in a continuous system is expressed by the equation of continuity for the density, ρ,

$$\frac{\partial \rho}{\partial t} = -\text{div } \rho\omega \tag{12}$$

where ω is the macroscopic velocity. This equation expresses the fact that the local change of the density is equal to the negative divergence of the flow of matter.

Equation (12) holds also for a mixture; ω is then related to the macroscopic velocities of the different components by

$$\omega = \left(\sum_{\gamma} \rho_\gamma \omega_\gamma\right) / \rho \qquad (13)$$

Thus ω is simply the velocity of the center of gravity in an element of volume.

In general, the local change of a physical quantity is due not only to the divergence of the current which is associated with it, but a "source" term has also to be taken into account. For instance, the equation of continuity for the density ρ_γ of a component γ participating in a chemical reaction is

$$\frac{\partial \rho_\gamma}{\partial t} = -\text{div}\ \rho_\gamma \omega_\gamma + v_\gamma M_\gamma V_\gamma \qquad (14)$$

where V_γ is the rate of the chemical reaction per unit volume.

In an open system, it is possible to split the change of mass of component γ into an external part, $d_e m_\gamma$ supplied from the exterior, and an internal part, $d_i m_\gamma$ due to changes inside the system

$$dm_\gamma = d_e m_\gamma + d_i m_\gamma \qquad (15)$$

Taking into account the equations on conservation of mass in closed systems, this becomes

$$dm_\gamma = d_e m_\gamma + M_\gamma \sum_{\rho=1}^{r} v_{\gamma\rho} d\xi_\rho \qquad (16)$$

$$dn_\gamma = d_e n_\gamma + \sum_{\gamma=1}^{r} v_{\gamma\rho} d\xi_\rho \qquad (17)$$

Summing Equation (16) over γ and taking into account the stoichiometric equations $\Sigma_\gamma v_{\gamma\rho} M_\gamma = 0$, the total change of mass is

$$dm = d_e m \qquad (18)$$

This relation expresses the conservation of mass in open systems and indicates that the change of the total mass is equal to the mass exchanged with the outside world.

Conservation of Momentum

The principle of conservation of momentum states that for a dynamical system consisting of n material particles of masses $m_1, m_2, \ldots, m_n$, respectively, and position vectors $r_1, r_2, \ldots, r_n$, respectively, if the only forces acting are the mutual interaction forces of the particles the total momentum of the system remains constant; for example

$$\sum m_i \frac{d\mathbf{r}}{dt} = \text{constant} \qquad (19)$$

The law of conservation of momentum is as fundamental to physics as the law of conservation of mass energy. Like that law, it holds in quantum mechanics and relativistic mechanics as well as in classical mechanics.

Conservation of Electric Charge

Since electric charge comes in discrete quantities (there is no known way of breaking an electric charge down into bundles smaller than that contained in an electron), this law deals with the counting of objects, rather than with the measurement of continuous variables, such as momentum or energy. Conservation of electric charge means that the total number of electric charges (taking positive and negative signs into account) in a closed system does not change. This, in earlier times, meant that electric charge could not be created or destroyed. The creation of charged particles is now spoken of, but the creation of a positive charge must always be accompanied by formation of an equal negative charge (e.g., an electron-positron pair is created by a photon). Conservation of electric charge is associated with a symmetry property of Maxwell's equations known as gage invariance which states that the absolute value of the electric potential (as opposed to the relative value) plays no part in physical processes. Further developments in quantum mechanics indicate that conservation of electric charge is connected with the observation that the properties of a system of particles do not depend on the phase of the wave function describing the system.

The following conservation principles apply particularly to interactions of elementary particles:

1. *The Total Baryon Number Remains Constant.* A baryon is a nucleon (proton or neutron) or any particle heavier than those that can be considered to have an atomic mass number $A = 1$. Some mesons have a mass greater than the proton, but they have a mass number $A = 0$, so they are not baryons. In computing the number of baryons present in a system, each baryon counts 1; each antibaryon counts −1; and leptons and mesons count 0.
2. *The Total Lepton Number Remains Constant.* Leptons consist of the neutrinos, electrons, muons, and their antiparticles. Here again, the basic principles applied are analogous to those for baryon number; particles count 1; antiparticles count −1; and baryons and mesons 0.
3. *Total Strangeness Quantum Number.* This remains constant except as previously mentioned in connection with weak interactions.

CONSISTENCY. See **Rheology**.

CONSOLUTE LIQUIDS. This term is applied to liquids when they are miscible in all proportions, i.e., mutually completely soluble, under some given conditions. It is not usually applied to gases because they are all miscible.

CONSOLUTE TEMPERATURE. The upper consolute temperature for two partially miscible liquids is the critical temperature above which the two liquids are miscible in all proportions. In some systems where the mutual solubility decreases with increasing temperature over a certain temperature range, the lower consolute temperature corresponds to the critical temperature below which the two liquids are miscible in all proportions. Some systems such as methylethyl ketone and water have both upper and lower consolute temperatures.

CONSTITUENT. 1. In general, one of the elements or parts of a compound. 2. An identifiable component in the microstructure of an alloy. It may be a phase or a characteristic configuration of several phases.

CONTRACTILITY AND CONTRACTILE PROTEINS. The fundamental property of living matter on which its power of movement depends is termed contractility. In the simplest forms of living things, it is evident in the flowing movement of the material of the cell. In more complex forms, the property is centralized in muscle tissues. Muscle cells are elongate and are so arranged that necessary movements result from their shortening when stimulated.

The study of the fibrillar proteins of muscle invites interest for two reasons. On the one hand, they form the prime ingredients of the mechanism that performs a typical vital activity, movement, in its most specialized form; thus, the elucidation of their functions, and of the physical and chemical properties basic to it, represents one of the cardinal parts of molecular biology. On the other hand, the isolated proteins display such striking physical behavior that to the macromolecular physicist they are among the most fascinating materials. Unfortunately, they are difficult to obtain and exceedingly changeable and labile; thus, working with them is somewhat difficult.

The major fibrous proteins are myosin and actin. Other proteins that may be involved in myofibrillar structure are tropomyosin and paramyosin. All four proteins share certain chemical properties; among others, they are all exceptionally rich in ionizing amino acids, thus they are highly charged molecules. Myosin is an adenosine triphosphatase. The molecular weight is

not accurately known; a number of determinations cluster around 500,000. Light scattering dissymmetry suggests a mean molecular length of about 1600 micrometers, and electron microscopy suggests similar lengths.

CONTACT POTENTIAL DIFFERENCE. In his experiments with electroscopes, Volta found that when pieces of two different metals, otherwise insulated, are brought into contact, they acquire opposite charges and maintain a difference of electrical potential even while still touching. This potential difference he found to be characteristic of the given pair of metals. Thus when the metals are iron and copper, the iron has a potential about 0.15 volt higher than the copper, while for tin and iron the difference is 0.31 volt, tin being the higher. Volta listed a series of several metals, viz., zinc, lead, tin, iron, copper, silver, gold, such that when any two are put in contact, the one first named is at the higher potential. "Volta's law," which he was not in a position to demonstrate but which was established much later, states that the potential difference between any two metals in direct contact is the sum of the potential differences between intervening metals of the series. Thus for tin and copper (above) it is 0.31 volt + 0.15 volt = 0.46 volt; and it makes no difference whether the tin and copper are in direct contact or have other metals intervening between them.

The contact potential difference depends on the relative Fermi levels of the two solids. On contact, electron flow will take place until the Fermi levels of the two solids are equal. This will result in a potential difference between the two solids, called the contact potential.

A distinction must be made between the contact potentials in air and the so-called "intrinsic" contact potentials in a vacuum with all adsorbed gases removed. According to Millikan, the intrinsic potential difference between two metals A and B is expressed by $V_{AB} = h(\nu_A - \nu_B)/e$, in which h is Planck's constant, ν_A and ν_B are the critical frequencies of photoelectric emission for the two metals (see **Photoelectric Effect**), and e is the electronic charge. In any case, if the electronic work functions of the metals are p_A and p_B, the contact potential difference is $V_{AB} = (p_A - p_B)/e$. The work functions, and hence V_{AB}, are in general dependent upon the medium surrounding the metals. Accurate measurements of these potentials are, unfortunately, very difficult.

CONVECTION. In general, mass motions within a fluid resulting in transport and mixing of the properties of that fluid. Natural convection results from differences in density caused by temperature differences. Warn air is less dense than cool aid; the warm air rises relative to the cool air, and the cool air sinks. Forced convection involves motion caused by pumps, blowers, or other mechanical devices. See also **Heat Transfer**.

CONVERSION. (1) In its most general usage, this term denotes a change, often with the force of a directed or induced change. One specific use is a change in numerical value of a quantity resulting from the use of a different unit in the same or a different system of measurement. (2) An intramolecular rearrangement of organic substances in which the relative positions of the radicals are modified. The Beckmann rearrangement is a case in point. Radicals may be transferred from carbon, oxygen, or nitrogen to carbon; from carbon or oxygen to nitrogen; from side chains to nucleus, etc.

CONVERSION COATINGS. The industrial application of organic finishes to metals almost always requires the use of an intermediate conversion coating, particularly when the performance demands are high. Conversion coatings are formed chemically by causing the surface of the metal to be "converted" into a tightly adherent amorphous or crystalline coating, part or all of which consists of an oxidized form of the substrate metal. Conversion coatings can provide high corrosion resistance as well as strong affinity for organic coatings. They are also useful as lubricants for the drawing and forming of metals and sometimes are used for decorative purposes. The most important and widespread use of conversion coatings is on steel, zinc or galvanized steel, and aluminum alloys. The most widely used classes of conversion coatings for use on these metals are the phosphates and chromates. Depending on size, shape, volume of production, and other factors, the coating may be applied by spray, immersion, roll coat, or brush. A typical metal pretreatment sequence is: (1) cleaning; (2) rinsing; (3) conversion coating; (4) rinsing; and (5) final rinsing.

Phosphating of Steel

When a ferrous alloy is immersed in phosphoric acid, it initially forms a soluble phosphate. As the pH rises at the metal/solution interface, the phosphate becomes insoluble and crystallizes epitaxially on the substrate metal. The phosphate coating thus produced consists of a nonconductive layer of crystals that insulates the metal from any subsequently applied film and provides a topography with enhanced "tooth" for increased adhesion. The crystals insulate microanode and microcathode centers caused by stress or imperfections in the metal surface. This greatly reduces the severity of electrochemical corrosion.

Practically all phosphating processes involve patented proprietary solutions which produce superior coatings in shorter times and at lower temperatures than are obtainable with phosphoric acid alone. Treating times have been reduced from the earlier 1–2-hour to 1–5-minute periods, while temperatures have been reduced from 98 to 20–30°C.

Increasing energy costs have led to more widespread use of low-temperature phosphatizing baths. These comprise a lower free acid content which results in higher saturation of the primary zinc phosphate and thus provides a greater tendency to deposit at temperatures at or close to ambient temperature. In many cases, depending on the type of soil, it is difficult to reduce the cleaner temperature and, as a result, the cleaned parts tend to heat the phosphatizing stage to approximately 50°C even when no external heat is used.

Iron Phosphate Coatings

These coatings, weighing about 40–60 milligrams per square foot (430–646 milligrams per square meter), provide good paint adhesion, but inferior heat and corrosion resistance. They are used when coating performance is not very demanding. Iron phosphate coatings appear as a very thin blue or brown film to the naked eye.

Crystalline Zinc Phosphate Coatings

These coatings, weighing about 200 milligrams per square foot (2152 milligrams per square meter) when applied by spray, or as much as 3000 milligrams per square foot (32,280 milligrams per square meter) when applied by immersion, are of a medium-gray color and are used when higher quality is mandatory. For even greater corrosion resistance and paint adhesion, *microcrystalline zinc phosphate* coatings are used. They are dark in color and give coating weights of about 150–200 milligrams per square foot (1614–2152 milligrams per square meter) when sprayed and up to 1000 milligrams per square foot (10,760 milligrams per square meter) when applied by immersion. They are used as a paint base for products which are expected to last for years under varying environmental conditions.

Phosphating Chemistry

Iron and iron oxide react with phosphoric acid to form soluble primary iron phosphate, $Fe(H_2PO_4)_2$, liberating H_2 and H_2O, respectively. Due to the consumption of acid at the metal interface, there is a local rise in pH, which causes insoluble secondary iron phosphate, $FeHPO_4$, to coat the metal. The iron in the coating is supplied by the substrate.

In zinc phosphating, a small amount of iron phosphate is formed initially, but the bath contains primary zinc phosphate, $Zn(H_2PO_4)_2$, which crystallizes on the metal surface as secondary and tertiary zinc phosphates, $ZnHPO_4$ and $Zn_3(PO_4)_2$, respectively, when the pH rises at the metal/solution interface. The most frequently used baths contain accelerators, preferably nitrates and nitrites, which oxidize the hydrogen formed by the pickling reactions. The fundamental zinc phosphate reactions occur in three steps, all in the same bath:

(Pickling)

$$Fe^0 + 2H^+ \longrightarrow Fe^{++} + H_2$$

$$3Fe^0 + 2NO_3^- + 8H^+ \longrightarrow 3Fe^{++} + 2NO + 4H_2O$$

(Coating)

$$3Fe^{++} + 2H_2PO_4^- \longrightarrow 4H^+ + Fe_3(PO_4)_2$$

$$3Zn^{++} + 2H_2PO_4^- \longrightarrow 4H^+ + Zn_3(PO_4)_2$$

(Iron Removal)

$$4Fe(H_2PO_4)_2 + O_2 \longrightarrow 4FePO_4 + 4H_3PO_4 + 2H_2O$$

(sludge)

$$Fe(H_2PO_4)_2 + NaNO_2 \longrightarrow FePO_4 + NO + H_2O + NaH_2PO_4$$

(sludge)

In the coating reaction, each 3 moles of iron or zinc liberates 4 moles of hydrogen ion. However, in the pickling reaction, 8 moles of hydrogen ion are consumed. Thus, the pH at the metal interface rises, and insoluble tertiary ferrous phosphate and zinc phosphate crystallize on the iron surface. The coating closest to the metal interface is largely iron phosphate, while that farther away is rich in zinc phosphate.

Iron buildup in the bath is objectionable; in the iron-removal equations above, it is seen that dissolved Fe^{++} can be removed by oxidation, slowly in air or more rapidly by peroxides or nitrite, as shown in the final equation. The iron removed becomes ferric phosphate, while iron in the coating is ferrous phosphate.

Accelerators speed phosphating reactions by reacting with hydrogen liberated at the metal. Were hydrogen not removed, it would form gas bubbles which would interfere with metal/solution contact. Strong oxidizer accelerators also serve to precipitate dissolved iron and, to a degree, act as metal cleaners by oxidizing residual organic soils. In spray application, mild accelerators are usually adequate for maintaining dissolved iron at safe levels because atomization of the solution permits it to absorb from air the oxygen needed for precipitation of iron.

Zinc phosphate coatings consist of varying ratios of hopeite, $Zn_3(PO_4)_2 \cdot 2H_2O$, and phosphophyllite, $Zn_2Fe(PO_4)_2 \cdot 4H_2O$, with hopeite usually predominant. Hopeite and phosphophyllite grow epitaxially on alpha-iron crystallites. Only a slight adaptation deformation is necessary for the lattice planes of both foreign phases compared with the alpha-iron lattice of the substrate. Good adhesive strength can be expected from such a bond.

The smaller the crystals, the better the adhesion: crystal-to-metal, crystal-to-crystal, and crystal-to-final finish. Also, the smaller the crystals, the tighter the packing, the denser the coating, the less total porosity area for corrosive reactions to take place.

Crystal size depends upon such factors as growth rate, agitation, and the effects of nucleating agents and foreign atoms in the crystal lattice. Spray application provides agitation which reduces crystal size. Accelerators increase the number of nucleation sites on the substrate and result in smaller crystals. The most refined technique for producing very small crystals is the introduction of foreign elements of different atomic radii into the crystal lattice. A calcium additive in a zinc phosphating solution produces scholzite, $CaZn_2(PO_4)_2 \cdot 2H_2O$, in which the crystals may average one-twentieth the size of the finest crystals produced by other methods. It is believed that the foreign elements cause uneven growth along one crystal face, creating stresses that either stunt growth at an early stage, or rupture the crystal.

The relatively recent surge into the use of cathodic electrodeposition, especially in the automotive industry, has necessitated change in the metal pretreatment. The generation of hydroxyl ions at the cathode where the organic coating is deposited tends to dissolve zinc from the conventional zinc phosphate conversion coating with consequent deleterious coating performance. By increasing the concentration of phosphoric acid in the zinc phosphatizing stage, the ratio of iron to zinc in the conversion coating is increased. Such conversion coatings show superior performance under cathodically electrodeposited coatings.

The following sequence is typical of a production spray phosphate system: (1) cleaning for 60 seconds at 71–77°C; (2) rinsing for 15 to 30 seconds (hot or cold); (3) phosphating for 60 seconds at 54–60°C; (4) rinsing for 15–30 seconds (cold); and (5) chromate-rinsing for 30–45 seconds at 27–60°C. The final stage, an acid chromate rinse, is extremely important to the overall adhesion and corrosion resistance of the finish. One of its functions is to seal the pores in the phosphate coating. The effect can be demonstrated by placing a drop of chromic acid in the center of a phosphatized panel and subjecting it to corrosive exposure. Corrosion in the chromated area will be strongly inhibited.

Phosphating of Zinc

The chemistry in the phosphating of zinc alloys is similar, with the exception that iron does not play an important role in the coating or in the bath. The only cation involved is Zn. Zinc phosphate coatings are used widely in the treatment of galvanized steel for refrigerators, air conditioners, kitchen cabinets, and house and building siding.

Aluminum Pretreatment

Although Al protects itself against corrosion by forming a natural oxide, the protection is not complete. In the presence of moisture and electrolytes, Al alloys, particularly the high-copper alloys, corrode much more rapidly than pure Al.

Chemically produced oxides can be formed by treatment in 2–3% sodium carbonate containing 0.1% sodium dichromate for 10–20 minutes at 66°C, followed by "sealing" in 5% sodium dichromate at 82–88°C for 10 minutes. Such coatings are softer, more porous, and not as effective as those produced by chromic acid anodizing.

Electrically produced anodic coatings from chromic, sulfuric, or oxalic acid electrolytes are more dense and less porous. Their corrosion resistance is improved by hot-water sealing, which is even more effective with the inclusion of dichromate.

Generally, the higher the alloy content of the base aluminum, the heavier the oxide present and the more difficult it is to remove prior to effective chemical pretreatment. A properly formulated deoxidizer will remove the oxide only to the desired degree, with minimum attack on the base metal. The baths usually consist of fairly high concentrations (5–10%) of either nitric or sulfuric acid, along with chromates and either free or complex fluorides. A deoxidizer will also remove the smut that forms on etching in strong alkali. Smut consists of the alkali-insoluble alloying elements and their oxides.

Amorphous Phosphate Coatings for Aluminium

These coatings were introduced in 1945. Their simplicity of operation, speed, and economy have resulted in wide commercial acceptance. They provide a continuous uniform green coating with excellent paint-bonding properties and underfilm corrosion protection. The coatings consist of varying ratios of chromic phosphate and hydrated aluminum oxide. The bath contains hydrofluoric acid, which removes the natural oxide to permit contact of the coating-forming chemicals with the metal. The complexity of the reactions involved makes it difficult to present a simplified chemistry, but the results of many tests and analyses give the following coating composition: $xCrPO_4 \cdot yAl_2O_3 \cdot zH_2O$. The phosphate coatings vary from 10 to 300 milligrams per square foot (108 to 3228 milligrams per square meter), depending on the end use. The lower coating weights are used for paint bonding; the higher range is used for decorative purposes.

Gold-colored conversion coatings are formed in baths containing hydrofluoric acid to remove the natural oxide, and chromic acid. The coating composition is chromic chromate plus varying amounts of hydrated aluminum oxide. Some baths also contain ferricyanide iron, which greatly accelerates the coating action and forms some chromic ferricyanide in the coating. This constitutes one of the most widely used conversion coatings on aluminum because of its high speed, excellent corrosion resistance, and high affinity for organic finishes. The hexavalent chromium content permits these coatings to withstand somewhat more severe corrosive environments than do the amorphous phosphate coatings. The baths have a pH of about 1.2–1.9 and can be applied by dip, brush, spray, or reverse roll coater.

Proprietary chromate rinses are frequently used over conversion coatings on aluminum for increased corrosion resistance. See also **Autodeposition**.

Amchem Products, Inc.
Ambler, Pennsylvania

CONVERSION RATIO. 1. The ratio of the number of internal conversion electrons to the number of gamma rays emitted in a given time interval by a single nuclidic species during the de-excitation of one of its excited energy states. Sometimes known as the *internal-conversion coefficient*. 2. In a nuclear reactor, the number of fissionable atoms produced per fissionable atom destroyed. See also **Nuclear Power Technology**.

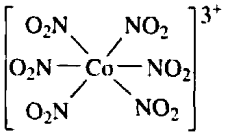
COOLANT. Any liquid or gas having the property of absorbing heat from its environment and transferring it effectively away from its source. Coolants are used in all types of automobiles, as well as in chemical processing and nuclear engineering equipment. One of the most effective and cheapest coolants is water, which is almost universally used in automotive and ordinary reaction equipment. Air is also used. Where intense heating requires a more efficient medium, special coolants are used; liquid sodium in nuclear reactors, liquid hydrogen in high-thrust nuclear rocket engines; carbon dioxide, propylene glycol, and "Dowtherm" in chemical-processing reactors. Methoxy propanol has been introduced for diesel engines. Some coolants provide antifreeze protection.

See also **Antifreeze Agents**.

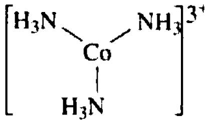
COOLER (Thermoelectric). See **Thermoelectric Cooling**.

COORDINATION COMPOUNDS. One of a number of types of complex compounds, usually derived by addition from simpler inorganic substances. Coordination compounds are essentially compounds to which atoms or groups have been added beyond the number possible on the basis of electrovalent linkages, or the usual covalent linkages, to which each of the two atoms linked donates one electron to form the duplet. The coordinate groups are linked to the atoms of the compound usually by coordinate valences, in which both the electrons in the bond are furnished by the linked atom of the coordinated group. The amines and complex cyanides are representative of coordination compounds.

In attempting to classify coordination compounds, Sidgwick noted that the number of molecules or atoms coordinated with a metallic atom (which he called *coordination number*) is 2, 3, 4, 5, 6, or 8, and that 2, 4, and 6 are the most common. In forming such compounds, each molecule or atom donates a pair of electrons to the metallic atom, forming a semi-covalent type of bond. Thus, in the nitrocobaltates, six nitro groups each donate a pair of electrons to a cobalt(III) ion, forming the complex ion.



In the positive triammine cobalt(III) ion, three ammonia molecules donate one pair of electrons each to the cobalt(III) ion, to form the complex ion.



The covalent character of the coordination bond is evident from the fact that both the ions and the molecules that form it fail to exhibit their characteristic reactions after coordination.

Included in the coordination compounds are the double salts, the complex salts, the oxysalts, and the hydrates.

See also **Chelates and Chelation**; **Cobalt**; **Copper**; **Gold**; **Hydrate**; **Iron**; **Manganese**; and **Molybdenum (In Biological Systems)**.

COORDINATION NUMBER. The number of nearest neighbors of a given atom in a crystal structure. In covalent crystals, only those neighbors to which the atom is directly bonded are counted, and this number is usually 4 or less. In metals, the coordination number may be as high as 12, as in the close-packed structures.

COORDINATION POLYHEDRA. The arrangement of oxygen ions about the cation to which they are closely bonded in an ionic crystal, as, for example, the group SiO_4 which forms a tetrahedron. Such polyhedra pack as units in the crystal structure.

COPALITE (or Copaline). The mineral copalite or "Highgate resin" is a fossil resin found in irregular fragments in the blue clay of London, England. It resembles copal, the resin of certain modern tropical trees. Copalite is pale yellow to greenish or brownish, and emits an aromatic odor when broken. It has a hardness of 1.5; a specific gravity of 1.046; burns with a very smoky yellow flame.

COPOLYMER. See **Elastomers**; **Polymerization**.

COPPER. [CAS: 7440-50-8]. Chemical element, symbol Cu, at. no. 29, at. wt. 63.546, periodic table group 11, mp 1083°C, bp 2567°C, density 8.92 g/cm^3. Elemental copper has a face-centered cubic crystal structure. The metal is yellowish-red, soft, very malleable and ductile. Very thin sheet copper is translucent and transmits greenish-blue light. The element is unattacked by dry air, but in moist air containing CO_2, a protective greenish film of basic carbonate is formed. There are two natural isotopes, ^{63}Cu and ^{65}Cu. Seven radioactive isotopes have been identified, all with comparatively short half-lives: ^{58}Cu through ^{62}Cu, ^{64}Cu, ^{66}Cu, and ^{67}Cu. Copper may have been the first metal used by humans and today ranks second, exceeded only by iron, in annual consumption.

First ionization potential 7.723 eV; second, 20.29 eV; third, 29.5 eV. Oxidation potentials: $2Cu + 2OH^- \longrightarrow Cu_2O + H_2O + 2e^-$, 0.361 V; $Cu + 2OH^- \longrightarrow Cu(OH)_2 + 2e^-$, 0.224 V; $Cu^+ \longrightarrow Cu^{2+} + e^-$, −0.153 V; $Cu \longrightarrow Cu^{2+} + 2e^-$, −0.344 V; $Cu \longrightarrow Cu^+ + e^-$, −0.522 V. Other important physical properties of copper are given under **Chemical Elements**.

Ancient Copper Metallurgy

Efforts by scientists to locate the sources of copper used in ancient Mediterranean and Near Eastern cultures through comparative chemical analyses of copper ores and archeological artifacts have largely failed for various mineralogical and metallurgical reasons. The isotopic composition of lead, an element present in a minor amount in many copper ores and bronze objects, is unchanged through metallurgical processes and may, in principle, be used to determine the sources of the copper used in Bronze Age artifacts. Results of work during the early 1980s suggest that for Late Bronze Age Crete the Laurion region in Attica, Greece, may have been a more important copper source than Cyprus.

In 1984, Lechtman (Massachusetts Institute of Technology Laboratory for Research on Archaeological Materials) reported that the metalsmiths of Andean cultures knew how to plate copper with gold or silver and how to treat alloys of copper, gold, and silver so that the surface of the metal consisted only of gold. The Spanish conquistadors, when melting gold and silver objects which had been looted from the Incas, found that the bullion was quite impure. Although appearing as pure gold or silver objects, the materials actually were alloys of those elements with copper. Andean metalsmiths had developed the alloys along with procedures for treating them so that the finished objects presented a surface of pure silver or pure gold. As further reported, the smiths also knew how to plate objects made entirely out of copper with a thin coating of gold or silver.

Readers interested in the archeology of copper will find several of the references listed at the end of this article of value. To assess the authenticity of ancient copper and bronze objects, museums such as the Cincinnati Art Museum have turned to modern scientific examination. For example, ultrahigh-voltage industrial computed tomography, coupled with x-ray inspection, has been used.

Copper Ores

Copper occurs as native copper, particularly in the region south of Lake Superior (often 99.9% Cu), as sulfides (chalcocite, copper glance, cuprous sulfide, Cu_2S; chalcopyrite, $CuFeS_2$), as oxide (cuprite, cuprous oxide, Cu_2O, red); as basic carbonates (malachite, $CuCO_3{\bullet}Cu(OH)_2$, green; azurite, $2CuCO_3{\bullet}Cu(OH)_2$, blue). The copper content of its ores varies from 0.3 to 8% Cu and the average is on the order of 2.5%. The value depends largely upon the content of silver and gold. The area of production is widely distributed; in the United States, Montana, Utah, New Mexico, Arizona, Michigan, and Tennessee.

Native copper ore is crushed, concentrated by washing with water, smelted, and cast into bars. Oxide and carbonate ores are treated with carbon in a smelter. Sulfide ore treatment is complex, but, in brief, consists of smelting to a matte of cuprous sulfide, ferrous sulfide, and silica, which molten matte is treated in a converter by the addition of lime and air is forced under pressure through the mass. The products are blister copper, ferrous calcium silicate slag, and SO_2. Refining is conducted by electrolysis, and the anode mud is treated to obtain the gold and silver. See Fig. 1.

Leading world producers of copper include: United States, Chile, Canada, Zambia, Russia, Zaire, Peru, Philippines, South Africa, Australia, Japan, and China.

Copper is frequently detected in atmospheric particles, even in those collected at locations far removed from anthropogenic sources. Cattell and Scott (1978) reported similar enrichments found over the north Atlantic and the South Pole. It had been proposed that measured atmospheric concentrations are larger than those predicted for unenriched crustal weathering or oceanic production. It was proposed that the enrichment may result from natural processes of anomalously enriched elements in aerosol particles. These may derive from low- temperature volatilization processes, such as biological methylation, or volcanism, or direct sublimation from the earth's crust, or emissions from plants, or fractionating at the air-sea interface which enriches elements in particles produced from the oceans. Atmospheric studies conducted by Cattell and Scott near the island of Tasmania in 1977 led to the conclusion that a biogenic agent may be

Fig. 1. Beneficiation of basic minerals involves wet operations requiring large volumes of water. Here copper tailings from a mining operation are settled in a 275-foot (84-meter) diameter thickener which handles over 2000 gallons (76 hectoliters) per minute and some 13,000 tons (11,795 metric tons) of ore per day. Underflow solids are disposed of by pumping to tailing ponds. Clarified water is returned to the mill process, thus avoiding waste of water

responsible for the approximately 20,000-fold enrichment of copper during aerosol production from the ocean.

Proposed Acid Injection Mining

In the early 1990s a new copper extraction technology, known as *in situ* leach mining, was under investigation. This methodology was proposed, and demonstration plants were to be constructed to test the proposal. These were jointly sponsored projects by the U.S. Bureau of Mines and two mining companies. If successful, leaching would cut the costs and hazards of the traditional open-pit methods currently used.

In this method a known copper deposit would be injected in several locations with a solution of dilute sulfuric acid. This acid would percolate through the veins of the ore-bearing rock (usually copper oxide). The copper would go into solution as copper sulfide and be pumped to the surface by way of several recovery wells. At the surface the copper would be plated onto cathodes (electrowinning process). It is proposed that the dilute solution, when free of copper, could be returned and circulated up to several times. An automatic analytical system would maintain the required strength of the acid solution. Proponents claim that the cost of the system would be less per ton of copper produced and would increase miner safety. One factor that must be carefully tested is the possible percolation of acid solution into nearby groundwater.

Special Properties

Copper is distinguished by several properties that contribute to its extensive use: (1) a combination of mechanical workability with corrosion resistance to many substances; (2) excellent electrical conductivity, (3) superior thermal conductivity; (4) effect as an ingredient of alloys to improve their physical and chemical properties; (5) efficiency of copper and some of its compounds as catalysts for several kinds of chemical reaction; (6) nonmagnetic characteristics, advantageous in electrical and magnetic apparatus; and (7) nonsparking characteristics, mandatory for tools for use in explosive atmospheres. There are additional attractions of copper for many other applications. The metal would be used even more widely, but for some uses, even though superior, copper cannot compete with substitute materials because of cost.

Unalloyed Copper

In the United States, the term *copper* signifies copper that contains less than 0.5% impurities or alloying elements. Copper-base alloys are those that contain no less than 40% copper. Additionally, copper appears as a minor, but important ingredient of several alloys. There are six major types of commercial, unalloyed copper. These are described briefly in Table 1.

Very-High-Copper Alloys

Although not meeting the foregoing definition of copper precisely, there is a group of copper alloys which contain only a few percent of other ingredients and commonly these are also referred to as coppers, usually with the name of the other element preceding copper in the name—as *chromium copper* or *beryllium copper*. These very-high-copper alloys are described briefly in Table 2.

Because of major changes made in the production of electronic circuits, including surface-mount technology and the use of smaller, lighter, higher-density components, interconnection design requirements have become more stringent. Higher-density electronic packaging increases the demands for improved electrical, mechanical, and thermal characteristics of connector materials. To meet some of these needs, there has been increasing demand for beryllium-copper strips in many instances to replace brass alloys and phosphor bronzes.

TABLE 1. COMMERCIAL UNALLOYED COPPERS

Electrolytic Tough-Pitch Copper

Cu, 99.90%; O, 0.04% nominal; density 8.89–8.94 g/cm^3, EC, 101%
Architecture: downspouts, flashing, building fronts, gutters, screening, roofing
Automotive: radiators and gaskets
Electrical: conductive-wire contacts, terminals, switch parts, bus bars
Hardware: cotter pins, nails, rivets, soldering copper, ball floats
Other: anodes, chemical process equipment, kettles, pans, printing rolls, expansion plates, rotation bands, die-pressed forgings

Deoxidized Copper

Cu, 99.90% minimum; P, 0.025% nominal; density 8.94 g/cm^3, EC, 80–90%
Industrial: condensers, evaporators, heat-exchangers, dairy tubes, fraction-ating columns, kettles, pulp and paper piping, steam and water piping, tanks
Transportation: gasoline, oil, air, and hydraulic fluid lines, oil coolers
Other: shell rotation bands, die-pressed forgings, gauge lines

Oxygen-free Copper

Cu, 99.92% minimum; no residual oxidants; density 8.89–8.94 g/cm^3, EC, 101%
Electrical: conductors, electron tubes, bus bars, waveguides (for operation at high temperatures in presence of reducing gases)
Industrial: heaters, oil coolers, gasoline supply lines, radiators, refrigeration lines, water piping

Silver-bearing Copper

Cu, 99.90% minimum; 8–25 ounce (226–708 grams) Ag/ton; density 8.91 g/cm^3, EC, 100–101%
Electrical: commutator bars, heavy-duty motor windings (particularly for retention of strength at elevated temperatures)
Other: brazing solders, die-pressed forgings

Arsenical Copper

Cu, 99.68%, nominal; P, 0.025% nominal; As, 0.30% nominal; density 8.94 g/cm^3, EC, 90%
Industrial: heat-exchangers, boilers, radiators, condenser tubes

Free-cutting Copper

Cu, 99.4–99.5%; Te, 0.5–0.6%; density 8.94 g/cm^3, EC, 90%
Industrial: electrical connectors, motor and switch parts, soldering coppers, screw-machine parts, forgings, welding-torch tips

EC, electrical conductivity (International Annealed Copper Standard)

TABLE 2. VERY-HIGH-COPPER ALLOYS

Cadmium Copper

Cu, 99.00-plus %; Cd, 0.6–1.0%
Cadmium toughens copper and increases resistance to fatigue: also increases softening temperature.
Electrical conductivity (fully annealed) is about 95% (IACS).
Essentially free of oxygen: not susceptible to gassing.
Uses: contact wires used in electrical transportation, notably long-span overhead electric transmission lines.

Chromium Copper

Cu, 99.50%; Cr, 0.5%
Chromium improves mechanical properties while retaining high thermal and electrical conductivities.
Strength and hardness depend on heat treatment and not cold working—hence alloy can be used up to temperature of about 450°C without danger of softening.

Tellurium Copper

Cu, 99.50%; Te, 0.5%
Tellurium increases softening temperature of work-hardened copper.
Alloy is excellent where combination of good machinability and electrical conductivity is required.
Uses: motor and switch parts, electrical connectors, screw-machine parts, electrical instrument parts.

Beryllium Copper

Type 1: Cu, 98%; Be, 2%
Type 2: Cu, 97%; Be, 0.4%; Co, 2.6%
Cobalt is added as a lower-cost substitute for beryllium.
Uses: instrument springs, bellows, diaphragms, bourdon tubes, nonsparking sparking tools for hazardous locations.
Alloy permits springs to be shaped while soft, followed by hardening.
Selenium copper also available for combining high electrical conductivity with free-machining and hot-working properties. Alloy makes excellent copper-to-glass seals.

Copper also is finding increased applications in composite materials, notably graphite/Cu. These composites provide both weight savings and greater strength and stiffness in advanced aerospace applications.

Growing interest also is being shown in copper-nickel-tin alloys that can be aged hardened after forming. These alloys have improved tensile strength and greater resistance to oxidation, stress relaxation, fatigue, and stress-corrosion cracking. They are finding increased usage in electronic leads, contact pins, and sockets, as well as for eyeglass frames, circuit boards, and electronic-contact clips.

In an effort to avoid penalties pertaining to lead in potable-water plumbing systems, pipe fitting and fixture manufacturers are turning away from the free-cutting copper alloys that contain lead. Copper alloyed with nontoxic bismuth and a ductility enhancer, such as phosphorus, indium, and tin, which machine as well as leaded material, are now being considered. Most possible copper alloying combinations are now under study. This program is carefully detailed in the Plewes-Loiacono reference cited.

The Brasses

There are eight principal categories of brasses, not including the leaded and alloy brasses. Brass essentially is an alloy of copper and zinc. Several of the brasses contain other ingredients, such as lead and iron. When zinc is added to copper, there is a progressive alteration of color and lowering of melting point. When the zinc content is about 10%, the metal is a bronze color; with 15% zinc, the color may be described as golden; from 20–40% zinc, there is a range of yellow colors; over 45% zinc, the color is silver-white. The melting point of a 95% copper-5% zinc brass is about 1,065°C, whereas the melting point of 50% copper-50% zinc brazing metal drops to about 880°C. The ratio of copper to zinc also progressively affects mechanical and corrosion-resistance properties. Maximum tensile strength, for example, is attained with a 55% copper content, whereas maximum ductility is attained with a 70% copper content. This exceptional range of properties accounts for the availability and demand for a wide variety of brasses. Metallurgically, brasses may be classified as (1) *alpha brass*, in which the content of zinc is less than 36% and in which the zinc is dissolved in the copper, imparting to the alloy the basic structure of copper; (2) *beta brass*, in which the content of zinc ranges between 36% and 45%. This alloy contains the CuZn as a compound and enhances the hot workability of the alloy; and (3) *gamma brass*, in which the zinc content exceeds 45% and where there are crystals in the alloy. This combination does not lend itself to either hot or cold workability. Some of the important commercial brasses are described briefly in Table 3.

The Bronzes

Classically, a bronze is defined as an alloy of copper and tin, but over the years the term has taken on a much broader meaning. The term may apply to numerous copper alloys that possess a crystalline, bronze-like structure, are of a bronze color, or may contain some tin. Further, bronze generally is considered a casting metal. In contrast, brass is generally wrought. Some alloys are commercially named bronze even though they contain no tin whatsoever.

Copper Wire and Cable

The International Annealed Copper Standard (IACS), which sets annealed copper as having 100% electrical conductivity as a basis against which to compare other metals, alloys, and materials, is accepted internationally. Using this standard for comparison, the conductivity of copper is exceeded only by silver for which the IACS figure is 108.4%. This comparison is on the basis of conductivity per gram, pound, or other mass unit. Aluminum, although widely used as an electrical conductor for selected applications, has a rating on this schedule of approximately 61%, steel a rating of 11%, and nickel-chromium alloy (valued because of its high electrical resistance rather than conductivity) has a rating of 1.5%. Thus, the value of copper for electrical conductors, considering its availability and economics, is self-evident.

Processing Equipment

In terms of thermal conductivity, assigning a value of 100 to copper, the metal is exceeded only by silver which has a value of 108. Copper is followed by gold (76), aluminum (56), magnesium (41), zinc (29), nickel (15), iron (15), steel (13–17), lead (9), and antimony (5). Thermal conductivity means good heat transfer and this is extremely important in most industrial processing equipment where heating and cooling cycles are involved. This property, when combined with corrosion resistance, makes copper attractive for the construction and lining of process vessels. Deoxidized copper, admiralty brass, and arsenical copper are effective in condenser tubes operating with fresh water. Copper is less suitable for seawater because of its inability to form a protective film. Aluminum brass and 70–30 cupronickel alloy are favored for severe seawater service. Copper and copper alloys are not suited for use in oxidizing acidic solutions, in mercury, or in the presence of free NH_3. Copper vessels are used extensively in food processing and for numerous organic materials, particularly distillation columns and hardware. The relatively high cost of copper as compared with other metals, however, is always an important factor.

Piping

Copper and copper alloys are used in a wide variety of pipes and tubes, both for industrial and domestic systems. In many areas, galvanized water pipe has been almost completely replaced by copper piping in new construction. Advantages include corrosion resistance and ease of installation, which offset higher costs. Because of excellent thermal conductivity, copper and brass fittings are used widely in hot water and steam-heating systems. However, the greater conductivity of bare copper pipe in long runs requires more attention to insulation covering.

Chemistry and Compounds

Copper is dissolved best by HNO_3; not attacked by cold dilute HCl or H_2SO_4, but in hot HCl dissolves to yield cuprous chloride, in hot concentrated H_2SO_4 to yield copper sulfate; attacked by chlorine, especially when heated, to form cuprous and cupric chlorides; only slight action by H_2S or SO_2 at ordinary temperatures in the absence of air.

In view of its $3d^{10}4s^1$ electron configuration and the relatively small energy difference between the two levels, copper forms dipositive ions as well as monopositive ones. In fact, the former are the more stable in

TABLE 3. REPRESENTATIVE BRASSES AND BRONZES

Gilding Brass

Cu, 95%; Zn, 5%; Pb, 0.03% maximum; Fe, 0.05% maximum; density 8.86 g/cm³; mp 1066°C; AT, 427–788°C; HWT, 760–871°C
Coinage: coins, metals, tokens
Munitions: firing-pin support shells, bullet jackets, fuse caps, primers
Novelties: emblems, plaques, jewelry
Other: base for gold plate and for vitreous enamel

Commercial Bronze

Cu, 90%; Zn, 10%; Pb, 0.05% maximum; Fe, 0.05% maximum; density 8.80 g/cm³; mp 1043°C; AT, 427–788°C; HWT, 760–871°C
Architectural: grillwork, etching bronze, screen cloth, weather stripping
Cosmetics: lipstick cases, compacts
Hardware: kickplates, line clamps, marine hardware, escutcheons, rivets, screws
Munitions: rotating bands, primer caps
Other: costume jewelry, screen wire, ornamental trim, vitreous enamel base

Red Brass

Cu, 85%; Zn, 15%; Pb, 0.06% maximum, Fe, 0.05% maximum; density 8.75 g/cm³; mp 1027°C; AT, 427–732°C; HWT, 788–900°C
Architectural: trim, etching parts, weather stripping
Electrical: screw shells, sockets, conduit
Hardware: fasteners, fire extinguishers, eyelets
Industrial: heat-exchanger tubes, condensers, flexible hose, piping, pumps, radiator cores, pickling crates
Other: compacts, costume jewelry, dials, badges, etched articles, lipstick cases

Jewelry Bronze

Cu, 87.5%; Zn, 12.5%; Pb, 0.05% maximum; Fe, 0.10% maximum; density 8.78 g/cm³; mp 1035°C; AT, 427–760°C; HWT, 760–900°C
Architectural: angles, channels
Hardware: chains, fasteners, slide fasteners, eyelets
Novelties: costume jewelry, emblems, compacts, etched articles, lipstick cases, plaques
Other: base for gold plate

Low Brass

Cu, 80%; Zn, 20%; Pb, 0.05% maximum; Fe, 0.05% maximum; density 8.67 g/cm³; mp 999°C; AT, 427–704°C; HWT, 816–900°C
Architectural: medallions, spandrels, ornamental metalwork
Electrical: battery caps
Instruments: bellows and musical instruments
Hardware: flexible hose, pump lines, tokens, clock dials

Cartridge Brass

Cu, 70%; Zn, 29-plus %; P, 0.07% maximum; Fe, 0.05% maximum; density 8.53 g/cm³; mp 954°C; AT, 427–760°C; HWT, 732–843°C
Automotive: radiator cores and tanks, reflectors
Electrical: flashlight shells, lamp fixtures, socket shells, screw shells, bead chain
Hardware: fasteners, pins, rivets, eyelets, springs, tubes, stampings
Munitions: various components. Note: Admiralty brass is similar: Cu, 71%; Zn, 28%; Sn, 1%

Yellow Brass

Cu, 65%; Zn, 34-plus %; Pb, 0.15% maximum; Fe, 0.05% maximum; density 8.47 g/cm³; mp 932°C; AT, 427–704°C

Architectural: grillwork

Automotive: reflectors, radiator cores and tanks
Electrical: lamp fixtures, flashlight shells, screw shells, socket shells, bead chain
Hardware: kickplates, push plates, locks, hinges, grummets, fasteners, eyelets, stencils, plumbing accessories, pins, rivets, screws, springs

Muntz Metal

Cu, 60%; Zn, 39-plus %; Pb, 0.30% maximum; Fe, 0.07% maximum; density 8.39 g/cm³; mp 904°C; AT, 427–593°C; HWT, 621–788°C
Hardware: large nuts and bolts, brazing rod, condenser plates, valve stems, hot forgings

Leaded Brasses

When lead is added to brass up to about 4%, improved machinability results. The lead has practically no effect on tensile strength or hardness. However, for cold-worked materials, lead does lower ductility and shear strength.

Phosphor Bronzes

Although tin is the primary alloying element in these alloys, their name derives from the addition of small quantities of phosphorus used as a deoxidizing agent in casting the alloys. Tensile strength ranges from moderate to very high, decreasing with amount of tin added. Tin percentage will range from 1.25 to 10%. Of the copper alloys, the phosphor bronzes are best suited for sea duty and where acid reagents may be present.

Silicon Bronzes

Most of these alloys are of proprietary compositions and are known by a variety of trade names. Silicon content ranges from 1.5 to 3.5%; usually less than 1.5% zinc content. Tin, manganese, and iron also may be added in small quantities. Because of their excellent strength, ease of welding, and corrosion resistance, the alloys have become important construction materials. As the silicon content increases, the alloys become more subject to fire cracking.

Aluminum Bronzes

The aluminum content of these alloys ranges from 4 to 10%. They are moderately hard, very ductile, and tough. The alloys resist scaling and oxidation at high temperatures because of the aluminum content. They perform well in both acids and alkalis. The alloys are good for sea duty, particularly in contact with turbulent seawater.

Nickel Silvers

Nickel essentially is added to copper-zinc alloys to enhance color. With a nickel content of about 18%, the alloy is silver-white. Also, most of the mechanical properties and corrosion resistance are improved. The alloys find wide application for operations that require ductility in the cold condition, as in stamping, spinning, deep drawing, and for articles to be plated. An alloy widely used as a spring material because of its high tensile and fatigue properties has the composition: Cu, 55%; Zn, 27%; Ni, 18%. German silver contains: Cu, 50%; Ni, 30%; Zn, 20%. It is interesting to note that the nickel silvers do not contain silver.

Cupronickels

The nickel silvers generally are classified as brasses. Cupronickels fall more into basic copper-nickel alloys. Possible minor ingredients are manganese, iron, and zinc. These alloys can be used for severe drawing, spinning, and stamping operations because they do not harden readily. They also are extensively used for condenser tubes and plates, heat exchangers, and other process equipment.

AT, annealing temperature range.
HWT, hot-working temperature range.

aqueous solution, due primarily to the larger heat of hydration of Cu^{2+} than Cu^{+} Moreover, the d-electrons may participate in bonding, and tripositive copper, Cu(III), appears in complexes. In addition, copper forms a number of compounds essentially covalent in character, such as copper(I) oxide, Cu_2O.

This compound is less stable at room temperature than copper(II) oxide, CuO, although Cu_2O occurs in nature (as cuprite). It is the stable oxide above 1.026°C. It is prepared by fusion of copper(I) chloride, CuCl with sodium carbonate, Na_2CO_3. In its crystal, each copper atom has

two colinear bonds, and each oxygen atom four tetrahedral ones; two such interpenetrating lattices constitute the structure. Copper(I) hydroxide, CuOH, is relatively stable, and is produced by electrolysis of a sodium chloride solution between copper electrodes (by action of NaOH on the cathode). Copper(II) oxide, produced by heating copper in air, is also essentially covalent (CuO, 1.95 Å); it has tetrahedral bonding of the oxygen atoms, and coplanar bonding of the copper atoms. Copper(II) hydroxide, is precipitated by alkali hydroxides from Cu^{2+} solutions. It is gelatinous, and its composition and solubility vary somewhat with the alkali concentration. It is thermodynamically unstable even in contact with liquid water with respect to dehydration to CuO, but this occurs only very slowly, except upon heating or when catalyzed by hypochlorite, hydrogen peroxide, etc.

Copper(I) halides are formed with chlorine, bromine and iodine, the chloride and bromide by reduction of the copper(II) halides with copper powder, and the iodide by reduction of copper(II) sulfate, $CuSO_4$ solution with potassium iodide. The fluoride appears never to have been made, despite reports to the contrary. All are insoluble in H_2O. Copper(II) fluoride, CuF_2 may be made from CuO and hydrofluoric acid at 400°C, copper(II) chloride, $CuCl_2$ by dissolving the oxide or carbonate in HCl, and copper(II) bromide, $CuBr_2$ from copper and bromine water; copper(II) iodide, CuI_2, is unstable at room temperature with respect to decomposition into CuI and iodine. The chloride and bromide are water-soluble, and ionic. The fluoride is only slightly water-soluble. Anhydrous copper(II) chloride, $CuCl_2$, is monoclinic and its structure contains infinite-chain molecules formed by $CuCl_4$ groups that share opposite edges. $CuBr_2$ has a similar structure.

Complex halides of both monovalent and divalent copper are known. The monovalent complexes are primarily of the composition $MCuX_2$, where X is a halogen atom and M usually an alkali metal, although $CuCl_3^{2-}$ ions are also known, being found in infinite chain $(CuCl_3^{2-})_n$ structures, as in crystals of Cs_2CuCl_3. The ion $CuCl_4^{3-}$ is also known. The composition of the copper(II) complex halides is primarily in terms of $CuCl_3^-$, $CuCl_4^{2-}$, or $CuBr_4^{2-}$, ions, although the corresponding complex fluoride has trivalent copper, as in K_3CuF_6. Its paramagnetic moment indicates two unpaired electrons.

Copper oxyhalides of a number of different compositions have been reported, but the most definitely established compositions are Cu(OH)Cl, $Cu_2(OH)_2Cl_2$, and $CuBr_2 \cdot 2Cu(OH)_2$. The property of forming basic salts is not limited to the halides of copper. Basic sulfates, such as $CuSO_4 \cdot 2Cu(OH)_2$, $CuSO_4 \cdot 3Cu(OH)_2$, $CuSO_4 \cdot 4Cu(OH)_2$, and $CuSO_4 \cdot 5Cu(OH)_2$, have been prepared, more or less hydrated. In copper(II) carbonate, the stable forms are oxycarbonates, $xCuCO_3 \bullet yCu(OH_2)$, (where the $x : y$ ratios may be 2:1, 1:1, 2:3, 1:9, and still other values. Many of these compositions occur in minerals, such as malachite and azurite. Copper forms complexes with larger number of ions and molecules. The halogen complexes were discussed above. In general, copper tends to be 6-coordinate, as in the complex ion $[Cu(H_2O)_2ethylenediamine)_2]^{2+}$. With NH_3 and many amines, stable complexes are formed, both of Cu^+, such as $[Cu(NH_3)_2]^+$, and of Cu^{2+}, such as $[Cu(NH_3)_4]^{2+}$ which add halogen, pseudohalogen, and many other anions to form compounds of the composition $Cu(NH_3)_2X_2$ and $Cu(NH_3)_4X_2$.

Among the other copper compounds, copper(II) acetate is used as a pigment and fungicide; in its basic form it is the familiar verdigris that forms on copper surfaces in the presence of moisture and organic matter. The arsenic compounds of copper are used as insecticides and wood preservatives: copper(II) arsenite is called "Scheele's green" and copper(II) acetoarsenite, $Cu(AsO_2)_2 \bullet Cu(C_2H_3O_2)_2$, is "Paris green." Copper(II) hexacyanoferrate(II), brown, is precipitated from copper(II) solutions by soluble hexacyanoferrates(II), even from very dilute solutions, and copper(II) sulfide, black, by H_2S or other soluble sulfides. Copper(II) sulfate, when hydrated, forms its characteristic blue crystals (the hydrated Cu^{2+} ion is blue).

Copper(I) cyanide dissolves in alkali cyanide solution to form cyanocuprates(I) of the general formula $M_n[Cu(CN)_{n+1}]$ where M is an alkali metal, and n ranges in value from 1 to 5. Not all of the values, of course, are found for a particular alkali or in the presence of particular anions. With sodium cyanide, NaCN, most of the complex present has an n value of 2, but if the original solute was CuCl, more of the $n = 3$ cyanocuprate(I) is present. At low temperatures, values of n of 4 and 5 are found. Copper(II) appears to coordinate four cyanide ions to form the unstable tetracyanocuprate(II) ion which decomposes at once to the copper(I) complex and cyanogen. In fact, for Cu(II) the chelated complexes are more common than the simple ones, examples being those formed with ethylenediamine and its derivatives, oxalates, catechol, and the β-diketones.

A solution of CuCl in HCl absorbs carbon monoxide, forming copper(I) carbonyl chloride, $Cu(CO)Cl \cdot H_2O$. This reaction, which is used in gas analysis, is indicative of the ability of copper to combine with carbon monoxide. Evidence for a true carbonyl is limited to the observation that if hot carbon monoxide is passed over hot copper, a metallic mirror is produced in the hotter parts of the tube. Other organometallic compounds include the very unstable methyl copper, CH_3Cu, phenyl copper, C_6H_6Cu, and bischlorocopper acetylene $C_2H_2(CuCl)_2$.

Copper Industrial Chemicals

Copper oxides, salts, and organocopper compounds find extensive use in industry and commerce. Some of the more important compounds are summarized:

Cupric Acetate, $Cu(C_2H_3O_2)_2 \cdot H_2O$, sp gr 1.88, mp 115°C, decomposes at 240°C, dark-brown powder, slightly soluble in cold H_2O and alcohol; moderately soluble in hot H_2O and ether. Used as a fungicide, insecticide, as a catalyst, and in pigments.

Cupric Acetoarsenite (Paris Green), $(CuOAs_2O_3)_3 \cdot Cu(C_2H_3O_2)_2$, emerald-green powder, very slightly soluble in cold H_2O, soluble in alcohol and potassium cyanide. Used as a wood preservative.

Cupric Acid Orthoarsenite (Scheele's Green), $CuHAsO_2$, green powder, insoluble in H_2O, soluble in alcohol, acids, and NH_4OH. Used as a wood preservative.

Copper Carbonate (Basic), $CuCO_3 \cdot Cu(OH)_2$, dark-green monoclinic crystals, insoluble in cold H_2O decomposes in hot H_2O, soluble in potassium cyanide. Malachite, a copper ore, is of this composition. Refined compound is used as a pigment.

Cupric Hydroxide, $Cu(OH)_2$, blue, gelatinous compound, insoluble in cold H_2O decomposes in hot H_2O soluble in alcohol, NH_4OH, and potassium cyanide. Used as a pigment.

Cuprous Cyanide, $Cu_2(CN)_2$, white monoclinic crystals, insoluble in H_2O, soluble in HCl, NH_4OH, and potassium cyanide. Used in Sandmeyer's reaction to synthesize aryl cyanides.

Cuprous Iodide, Cu_2O, cubic white crystals, practically insoluble in H_2O or alcohol, soluble in NH_4OH, potassium iodide, or potassium cyanide. Used in Sandmeyer's reaction to synthesize aryl chlorides.

Cupric Oxide, CuO, black cubic crystals, insoluble in H_2O, soluble in HCl, NH_4OH, or ammonium chloride. Used as a green and blue colorant in ceramics.

Cuprous Oxide, Cu_2O, red cubic crystals, insoluble in H_2O soluble in HCl, NH_4OH, or ammonium chloride. Cuprite, a copper ore, is of this composition. Refined compound is used in electrical rectifiers.

Cupric Sulfate, $CuSO_4 \cdot 5H_2O$, blue triclinic crystals, moderately soluble in cold H_2O, quite soluble in hot H_2O, very slightly soluble in alcohol. Used in copper plating, dyestuff manufacture, water treatment, germicides, and coppering of steels.

Cupric Chloride, $CuCl_2$, brown-yellow powder, quite soluble in cold H_2O or alcohol, very soluble in hot H_2O. Catalyst for several organic syntheses, including production of vinyl chloride monomer.

COPPER (In Biological Systems). The activity of copper in plant metabolism manifests itself in two forms: (1) synthesis of chlorophyll, and (2) activity of enzymes. In leaves, most of the copper occurs in close association with chlorophyll, but little is known of its role in chlorophyll synthesis, other than the presence of copper is required. Copper is a definite constituent of several enzymes catalyzing oxidation-reduction reactions (oxidases), in which the activity is believed to be due to the shuttling of copper between the +1 and +2 oxidation states.

Traces of copper are required for the growth and reproduction of lower plant forms, such as algae and fungi, although larger amounts are toxic.

The effects of copper deficiency in plants are varied and include: dieback, inability to produce seed, chlorosis, and reduced photosynthetic activity. In contrast, excesses of copper in the soil are toxic, as in the application of soluble copper salts to foliage. For this reason, copper fungicides are formulated with a relatively insoluble copper compound. Their toxicity to fungi arises from the fact that the latter produce compounds, primarily hydroxy and amino acids, which can dissolve the copper compounds from the fungicide.

Copper is a necessary trace element in animal metabolism. The human adult requirement is 2 milligrams per day, and the adult human body contains 100–150 milligrams of copper, the greatest concentrations existing in the liver and bones. Blood contains a number of copper proteins, and copper is known to be necessary for the synthesis of hemoglobin, although there is no copper in the hemoglobin molecule.

Anemia can be induced in animals on a low copper diet, such as milk, and appears to be due to an impaired ability of the body to absorb iron. This anemia, however, is rare, because of the widespread occurrence of copper in foods. In locations, such as Australia and the Netherlands, diseases of cattle and sheep, involving diarrhea, anemia and nervous disorders, can be traced either to a lack of copper in the diet, or to excessive amounts of molybdenum, which inhibits the storage of copper in the liver.

Ingestion of copper sulfate by humans causes vomiting, cramps, convulsions, and as little as 27 grams of the compound may cause death. An important part of the toxicity of copper to both plants and animals is probably due to its combination with thiol groups of certain enzymes, thereby inactivating them. The effects of chronic exposure to copper in animals are cirrhosis of the liver, failure of growth, and jaundice.

Copper deficiency in plants is most frequent on organic soils, such as newly drained bogs, and on very sandy soils. The severe copper deficiency often found when bogs and marshes are first used for crop production is called *reclamation disease* in some parts of the world.

Ruminants are sensitive to copper deficiency. The symptoms of copper deficiency in animals vary with the species and age, but often the fading of brown or black hair is evident. On some acidic soils, the use of copper in fertilizers increases crop and pasture production, and the increases in level of copper in the plants help to prevent copper deficiency in the cattle and sheep. In parts of Australia, livestock production was impossible until copper fertilizers were used on the pastures. Application of copper fertilizers to alkaline soils generally does not increase the copper level in the crop. Farm animals are often supplied with copper in the form of dietary mineral supplements. Compounds used include copper gluconate, copper oxide, and copper sulfate.

Although copper fertilizers will sometimes increase crop yields and improve the nutritional quality of the crops, this practice must be used with caution and only on copper-deficient soils. Both plants and animals are subject to toxicity from excessive levels of copper. Ruminants, especially sheep, are sensitive to copper toxicity as well as to copper deficiency. Adding a copper fertilizer to a soil that naturally contains rather high levels of available copper may increase levels of the metal in the forage to the point of causing copper toxicity in grazing sheep. Copper toxicity from soils naturally high in copper occurs in Australia, but is uncommon in the United States. There are soils in the United States, however, that produce forage levels of copper close to toxicity limits, and if copper-bearing mineral supplements are inadvertently used with these forages, copper toxicity to sheep may result.

It is not easy to set a definite limit, in terms of the copper concentration in the diet, that will permit accurate predictions of the danger of copper deficiency or of copper toxicity in cattle and sheep. In particular, if the molybdenum concentration in the forage is high, extra amounts of copper are needed to prevent deficiency. Also, higher copper levels can be tolerated without danger of toxicity with molybdenum present.

Monogastric animals, including humans, are less sensitive than ruminants to either copper deficiency or toxicity. Copper deficiency in people has been found only when other complications, such as excessive bleeding, general starvation, and iron deficiency, are also present. Wilson's disease, an inherited disease of humans, prevents the loss of excess copper from the body and brings on copper toxicity. No direct relationships have been found between levels of available copper in the soil and the copper status of humans.

A number of copper-containing protein compounds are enzymes with an oxidase function (ascorbic acid oxidase, urease, etc.) and these play an important role in the biological oxidation-reduction system. There is a definite relationship of copper with iron in connection with utilization of iron in hemoglobin function.

Copper absorption is depressed by ascorbic acid, dietary phytates, cadmium, mercury, silver, and zinc. It appears that metals impede copper absorption through competition for metal-binding sites. Dietary copper, molybdenum, and sulfur are closely interrelated in optimum copper and molybdenum nutrition of ruminants. Increase pasture molybdenum content and low-pasture copper result in a condition known as "peat scours."

Copper toxicity tends to accumulate in the liver. The capacity to tolerate copper varies considerably with the species. Sheep are most susceptible. Swine have a much greater tolerance and copper may be added to the swine diet for pharmacological reasons (for example, use as an anthelminthic to control internal parasites).

Continuing research is providing a better understanding of the biological role of copper. The prooxidant and antioxidant effects of ascorbic acid and metal salts, including copper, in a beta-carotene-linoleate model system were studied by Israeli scientists. The interacting effects of ascorbic acid and metal ions on carotene oxidation were studied in an aqueous carotene-linoleate solution at pH of 7. Ascorbic acid at concentrations up to $10^{-3}M$ was a prooxidant. Fe^{3+} and, to a lesser extent, Co^{2+} acted synergistically with ascorbic acid, the prooxidant effect increasing with metal concentration. Cu^{2+} formed a prooxidant system with ascorbic acid only at low metal concentration, but as the copper concentration was raised, inversion of activity occurred and the copper-ascorbic acid system exerted a stabilizing action on carotene. Prooxidant effects were enhanced and antioxidant effects weakened in the presence of added linoleate hydroperoxides. The latter were unstable in the presence of ascorbic acid and especially ascorbic acid plus Cu^{2+}. Ascorbic acid itself became unstable in the presence of Cu^{2+}. Oxygen depletion, brought about by the rapid oxidation of ascorbic acid, may be partly responsible for the carotene-stabilizing effect of the Cu^{2+} couple. The investigators postulated that additional stabilization results from the radical-scavenging properties of copper or of a copper chelate formed by ascorbic and/or dehydroascorbic acid.

A team of investigators at the Department of Food Science and Human Nutrition, Michigan State University, studied the kinetics of ascorbic acid

stability of tomato juice as a function of temperature, pH, and metal catalyst, including copper. The rate of copper-catalyzed destruction of ascorbic acid increased as copper concentration in tomato juice increased, and was affected by pH.

Relatively recent hypotheses concerning the effect of zinc-to-copper ratios in the diet as a determining factor of plasma cholesterol levels have been made.

A study by the Department of Foods and Nutrition, Kansas State University is exemplary of the much needed further research in determining the properties of certain elements, including copper, when contained in various food substances. Part of the study was directed at determining the effects of cooking on copper content of turkey muscle. The researchers found that copper was significantly lower in cooked than in raw breast turkey muscle, but similar in raw and cooked thigh muscle.

CORDIERITE. The mineral cordierite, composition $(Mg, Fe)_2Al_4Si_5O_{18}$ is an orthorhombic mineral frequently seen, however, in pseudo-hexagonal forms, as well as massive. It is brittle, with a subconchoidal fracture; hardness, 7–7.5; specific gravity, 2.53–2.78; luster, vitreous; color, blue of varying shades; translucent to transparent. Cordierite exhibits pleochroism (or dichroism) being dark blue, light blue and light yellow when examined by transmitted light in different directions. Hence, it is frequently called *dichroite*, and less frequently, *iolite*. It is occasionally used as a gem.

Cordierite is found as a primary mineral in the igneous rocks. It is, however, found ordinarily in gneisses, schists and in areas of contact metamorphism. Localities for good specimens are numerous in Europe, including Bavaria, Finland, Norway. It is found in Greenland, Madagascar and Sri Lanka, from which latter place come the rolled pebbles of a rich blue color known as saphir d'eau, prized as a gem. In the United States, it is found principally in Connecticut.

Named for the French geologist, Pierre Louis Antoine Cordier, this mineral has also been called iolite from the Greek word meaning violet, and stone, as well as dichroite from the Greek meaning *two-colored*.

COREY, ELIAS JAMES (1928–). An American who won the Nobel prize for chemistry in 1990 for development of novel methods for the synthesis of complex natural compounds (retrosynthetic analysis). He specialized in synthesis of terpines. He was awarded is doctorate by M.I.T. in 1951.

CORK. Cork cells are found in the outer bark of most woody-stemmed plants, but in amounts too small and with too brittle walls to be of any use to man. But in *Quercus suber*, the Cork Oak, the cork cells become a very large part of the tissue of the bark, and have been used for centuries by man. The cork oak tree is a medium-sized tree, seldom much over 50 feet (15 meters) in height, growing in nearly all countries bordering the Mediterranean Sea. The evergreen leaves are small, $1\frac{1}{2}$–3 inches long, and about an inch wide, with slightly toothed margins. The bark of the tree soon becomes rough and deeply furrowed, but is of little value except as ground cork or as a source of tannin. When the tree is about 20 years old this first formed bark is removed, care being taken not to injure the phloem and cambium layers. Within 10 days a new cork layer has formed. This layer is the first of many layers which are removed once every 10 years or so throughout the life of the tree. Removal is generally done in the early summer at a time when hot dry winds will not cause injury to the unprotected phloem and cambium.

After removal, the cork is air-dried for a time, then boiled to soften it and to remove some of the tannin. The outer part of the bark is scraped off, and the rest pressed out flat and dried. It is then ready to ship.

The physical properties of cork account for its many uses. It is very light and buoyant, more than 50% of its volume being air, and hence is used in the manufacture of floats, life-preservers, and so forth. The living protoplasm of the cork cells dries up early in their development, leaving hollow cells, each containing a small mass of air which expands after compression. Therefore, cork is very resilient, and is frequently used as a core on which to wind yarn or string in the manufacture of baseballs. In the early stages of their formation, the walls of cork cells are cellulose, but this is soon impregnated by a waterproof and nonabsorbent lipoid substance, suberin. Therefore cork is used in making handles for fishing rods, shoe-soles, and cork stoppers. Since the hollow cork cells are poor conductors both of heat and sound, cork is much used as insulating material. For this use cork is ground up and then pressed into sheets with various binding materials, giving much larger sheets than can be obtained from the tree. Ground cork is also a constituent of linoleum, gaskets, and other products.

Cork is traversed by lenticels, loose masses of porous tissue, which appear as dark spots or holes in stoppers. Usually in making stoppers the bark is cut so that these will be transverse in the stopper. In making stoppers, the forms are first punched out as cylinders, and then trimmed down by machine to the required tapering shape.

CORNFORTH, JOHN (1917–). An Australian-born chemist who won the Nobel prize for chemistry in 1975 with Vladimir Prelog for work on the chemical synthesis of organic compounds. Although deaf since childhood, he attained his doctorate from Oxford and held prestigious posts all over the world, as well as authoring many papers on organic and biochemical subjects.

CORROSION. 1. The electrochemical degradation of metals or alloys due to reaction with their environment; it is accelerated by the presence of acids or bases. In general, the corrodability of a metal or alloy depends upon its position in the activity series (electromotive force series). Corrosion products often take the form of metallic oxides; in the case of aluminum and stainless steel, this is actually beneficial, for the oxide forms a strongly adherent coating, which effectively prevents further degradation. Hence, these metals are widely used for structural purposes. Probably the most familiar kind of corrosion is that of *rusting*. This is but a special case of a general classification known as atmospheric corrosion, wherein the oxygen of the atmosphere reacts with the material in question. Most metals, with exception of the noble metals, such as gold, can be oxidized by atmospheric oxygen. In the usual case, however, water vapor must be present before any appreciable oxidation can take place. With iron, for example, about 40% relative humidity is needed at ordinary temperatures before rusting will occur.

Acidic soils are highly corrosive. Sulfur is a corrosive agent in automative fuels and in the atmosphere (SO_2) as well, and is frequently mentioned in connection with so-called acid rains. Sodium chloride in the air at locations near the sea is strongly corrosive, especially at temperatures above 70°F (21.1°C). Copper, nickel, chromium, and zinc are among the more corrosion-resistant metals and are widely used as protective coatings for other metals.

2. The term *corrosion* is also sometimes used in connection with the destruction of body tissues by strong acids and bases.

In a restricted sense, corrosion is considered to consist of the slow chemical and electrochemical reactions between metals and their environments. From a broader point of view corrosion is the slow destruction of any material by chemical agents and electrochemical reactions. This contrasts with *erosion*, which is the slow destruction of materials by mechanical agents. The character of the atmospheres to which materials are exposed may be classified as: rural, urban, industrial, urban-marine, industrial-marine, marine, tropical, and tropical-marine. In addition to these general kinds of environments, corrosion is of particular concern in the environments of chemical, petrochemical, and other processing and manufacturing environments where extremely corrosive substances may be encountered.

Metals Corrosion

The relationships between metals and hydrogen in the activity series are important because in the electrochemical processes of corrosion the discharge of hydrogen ions and the evolution of hydrogen as a gas is one of the principal cathodic reactions. The facility with which this can occur is determined by such factors as the hydrogen ion concentration (pH) of the electrolyte, the electrical potential of the corrosion cell, and the overvoltage characteristics of the cathodic surface. In a situation sometimes called *concentration cell corrosion*, two solutions of different concentrations will set up an electrical potential between them similar to that produced by a battery. If oxygen is present in the liquid and is continually replenished by contact with the air, then the oxygen concentration in the liquid will remain substantially constant. Any liquid that is contained in small holes or cracks on a metal surface will not be able to obtain oxygen from the main bulk of the solution, so when the supply in the holes and cracks is exhausted, no more oxygen can get in to replace it. Therefore, the oxygen concentration in the cracks is different from that of the main bulk of the solution and a concentration cell is set up. This minute electrical effect is sufficient to make corrosion proceed quite rapidly. A similar cell type of corrosion is that called *galvanic* or *two-metal corrosion*. Two different

metals in contact will set up an electrical potential between them. If the two metals are surrounded by an electrolyte so that a closed circuit can be obtained, corrosion takes place. The magnitude of the electrical potential and, therefore, the speed and extent of the corrosion will depend upon the types of metals in each pair. In general, pairs farther apart in the activity series will corrode faster than those close together. See also **Electrochemistry**.

The electrochemical reactions in corrosion of a divalent metal may be written:

Anodic reaction:	$M^0 \rightarrow M^{++} + 2$ electrons
At the cathode:	(1) $2\ H^- + 2$ electrons $\rightarrow H_2$ gas
	(2) $\frac{1}{2}O_2 + 2\ H\ + 2$ electrons $\rightarrow H_2O$
	(3) $O_2 + 2\ H_2O + 2$ electrons $\rightarrow H_2O_2 + 2\ OH^-$
	(4) $\frac{1}{2}O_2 + H_2O + 2$ electrons $\rightarrow 2\ (OH)^-$

It is evident that oxygen as well as hydrogen plays an important part in metal corrosion. It can accelerate corrosion by participating in cathodic reactions, or it can retard corrosion by forming protective oxides or passive films. The dual effect of oxygen is one of the factors that complicates corrosion processes, including the interpretation of observations of the process and the steps to be taken to avoid corrosion damage.

Forms of Corrosion

(1) *Pitting* resulting from local action currents, as at discontinuities in protective or passive films or under or around deposits that set up concentration cells. (2) *Stress corrosion cracking* resulting from the combined effects of corrosion by a specific environment and either applied or internal static tensile stresses. Depending upon the metal and the environment, the cracks may be either intercrystalline or transcrystalline. (3) *Corrosion fatigue*, resulting from the combined effects of corrosion and cyclic stresses. Racks of this type are characteristically transcrystalline. (4) *Intergranular corrosion* resulting from preferential attack on, or around, a phase or compound that occupies grain boundaries. (5) *Corrosion-corrosion* resulting from the combined effects of corrosion and either abrasion or attrition. The mechanism usually involves local or general removal of otherwise protective corrosion product films. Particular forms are impingement attack due to the effects of high velocity or turbulence in flowing liquids, e.g., salt water in steam condensers, or other heat exchangers, in piping systems, valves, and pumps, among others. A particularly aggressive form is associated with the severe mechanical forces that are characteristic of *cavitation phenomena*. See also **Cavitation**. (6) Uniform attack or general wastage, such as may be caused by the action of strong acids as used for pickling (scale removal) or etching. This is also characteristic of the slow corrosion of durable materials in appropriate environments, such as copper roofing in suburban atmospheres, cupronickel tubes in ships, condensers, Monel-nickel copper alloy racks for pickling steel in sulfuric acid, or stainless steel columns for handling nitric acid.

Metal Corrosion Minimization

In the most recent official assessment of the economic costs of equipment damage arising from corrosion, prepared by the National Commission on Materials Policy (U.S.), it was stated that annual losses in the United States alone are on the order of many billions of dollars.

Some of the means used to combat corrosion losses include:

(1) Use of the right metal in the proper way and in the correct place. Planners tend to look too closely at first costs and not closely enough at maintenance costs; consequently, there are many applications of materials that are of lower first cost, but of severely limited life. For example, in some applications, inexpensive fasteners that will obviously corrode in a few years are used in place of stainless steel or hardened aluminum fasteners that would have cost only a few dollars more at the time of installation. When discussing applications of possible corrosion-resistant materials, it is important to define clearly the parameters of the environment of usage, such as temperature, pressure, humidity, presence of specific chemical agents, presence of living or dead organic materials, and the characteristics of associated electrical magnetic, light, and other radiation fields. Far more needs to be done on the microclimatology of environments and the specifics needed to ameliorate corrosion problems.

(2) Protective coatings—paints, enamels, other metals, oils, greases, among others. One of the more common methods used is zinc-coating, i.e., galvanizing. Galvanized iron wire with a thin layer of zinc applied to it by dipping in molten zinc or by electrical means usually will resist corrosion for an extended period. Cadmium, nickel, tin, and chromium are metals often used as protective coatings, generally applied by electroplating. See also **Electrochemistry**; **Electroplating**; **Galvanizing**; and **Paints and Coatings**.

(3) Inhibitors and neutralizers, i.e., compounds added to the environment in small concentration to form protective films which increase anodic or cathodic polarization or both, or to neutralize some corrosive constituents. For example, it is possible for corrosion to occur at many places in the piping leading to boilers or heaters, but usually it occurs in the boiler itself. The trouble is ordinarily found to be due to an acid condition of the boiler feedwater, or to dissolved oxygen contained in it. The raw water used may be acid from surface pollution or from subsurface drains. Usually this can be detected and readily remedied. A more serious factor is the oxygen dissolved in water. Under the high-temperature conditions existing in the boiler per se, this oxygen becomes extremely active in attacking metal surfaces. The operators of large, high-pressure boilers well know the necessity of removing oxygen from feedwater through the use of deactivators or de-aerators. Corrosion protection of boilers in power plants is effected by installation of ion exchange resin and other purifiers in the feedwater cycle, and by monitoring them by automatic analysis. In still other installations where acidity and oxygen are a problem, neutralizing chemicals with the dosage governed by automated pH and oxygen control systems are effective. Systems of this type are also effectively used to neutralize plant effluents to streams so that water users downstream have a reasonably neutral and clean supply of water. Clean water programs not only are desirable from an environmental standpoint, but also can help in reducing the costs of corrosion.

(4) Drying of air other gases to keep humidity below the level where corrosion becomes serious.

(5) Design of hydraulic systems to avoid excessive velocities or localized turbulence or to maintain a velocity high enough to prevent the accumulation of corrosion products or other deposits that will promote localized corrosion.

(6) Various features of design and operation of structures or equipment to favor rapid drainage and drying, prevent accumulation or concentration of corrosive chemicals in crevices or low spots, hold operating stresses and temperatures within desired limits, eliminate fabricating stresses by appropriate metallurgical treatment, avoid galvanically unfavorable combinations of different metals, and provide protection against stray electrical currents by appropriate insulation and electrical bonding.

(7) Heat-treating metals to leave them in optimum condition to resist corrosion.

(8) Applying protective electrical currents (*cathodic protection*) from sacrificial metals (galvanic anodes) such as zinc, magnesium, or aluminum or from some external source through a graphite, platinum, or other appropriate anode receiving current from a rectifier, generator, or battery. The location of the anodes, the magnitude of the current, and the applied voltage must be engineered so that without wasting current all surfaces that require protection will receive sufficient current to achieve this effect. Too much current may cause damage by the alkali generated by a cathodic reaction or by hydrogen evolved at the cathode, which can destroy protective films or embrittle metals. A current of 1 to 15 milliamperes per square foot (929 square centimeters) is usually required to protect bare steel area; for design purposes, the range is generally narrowed to 3 to 5 milliamperes. The potential required to produce this current flow depends, of course, on the resistivity of the electrolytic path between the electrodes.

Corrosion can also be suppressed by the controlled application of current to the metal as an anode. This is called *anodic protection*. Passivity is induced and preserved by maintaining the potential of the alloy at, or above, a critical potential in what is called the range of passivity in a potentiostatic diagram. Such diagrams are based on the relationship between applied anodic current density and the corresponding potential in the environment of interest.

When pipes and cables carrying an electric current are underground, they are commonly corroded by electrolytic action from unidirectional electric

currents in the ground. Stray current from electric traction equipment is retarded by increasing the resistance of the ground circuit and by reducing the electric resistance of the track. Also, cathodic protection is widely used. An external source of dc voltage is applied so that the protected equipment (pipeline or cable, for example) becomes lower in potential than the soil that surrounds it. Thus, the buried material is the cathode rather than the anode. Usual forms of corrosion can be prevented when the preventive system causes the pipe or metal structure to be 0.25 to 0.30 volt negative with reference to the soil or liquid that may be surrounding it. The negative lead from a small generator, battery, or rectifier is connected to the metal structure; the positive lead to the ground at some distance. Or sacrificial magnesium or zinc rods sunk in the ground may be externally connected to the structure.

Atmospheric Corrosion of Metals and Nonmetals

Taking into consideration the relative order of corrodibility, it is preferable to describe corrosive damage as attributable to certain agents rather than to the indefinite characterization "smoke." Corrosive agents can be placed into four major groups, namely, oxygen and oxidants, acidic materials, salts, and alkalis.

Corrosion attributable to oxygen is deemed to result from the solution of oxygen by a thin film of liquid adjacent to the metallic surface, the transportation of the oxygen through the film, and the subsequent reaction at the surface of the metal. This explains why there is corrosive action even in relatively arid land. In a very dry atmosphere corrosion is, however, markedly reduced.

There are three principal categories of oxidizing agents that occur as air pollutants. These are ozone, nitrogen oxides and nitric acid, and organic peroxide. Many materials that are relatively resistant to attack by the free oxygen of the air are far less resistant to attack by such oxidants and peroxides. These dissolve in the surface film and thus convert metals to their oxides which react readily even with such relatively weak acids as carbonic acid and sulfurous acid. For instance, copper tarnishes rapidly forming the oxide, which dissolves readily in dilute acids.

The acid components given off to the air by the various processes of combustion are sulfur dioxide and sulfurous acid, sulfuric acid, hydrogen sulfide, hydrochloric acid, carbon dioxide and carbonic acid, and tar acids. There is little doubt that the material of greatest importance in respect to atmospheric corrosion in this group is sulfur dioxide. Generally, the total acidity of the atmosphere is closely related to the sulfur dioxide content.

Other soluble acidic components such as sulfuric acid, hydrogen sulfide, hydrochloric acid, nitric acid and the like are all of minor importance. Carbon dioxide and carbonic acid play a significant role in acid decomposition.

One aspect of tar and tar acids should be noted, namely, that these are sticky and cling to the surfaces with which they come in contact. This enables the acids that such tar contains to have a prolonged corrosive action. It also increases the difficulty of removal by rain or wind or other action.

It is common to consider that certain salts have a very corrosive action. This is true in the respect that the corrodibility of marine atmospheres has been shown to be greater than rural, tropical, and urban atmospheres. For example, ammonium sulfate and ammonium chloride being salts of strong acids and a weak base, that is ammonium hydroxide, hydrolyze in water to yield the respective acids. These salts then have a corrosive action, which is due actually to the acid produced in hydrolysis.

Alkalis seldom occur as air pollutants except under industrial conditions. Nevertheless, the corrosive action of alkalis should not be completely ignored. While a number of metals are relatively resistant to acid attack, they have an amphoteric action and can react with alkalis. For instance, aluminum and zinc are in this category and they are subject to corrosive attack by relatively weak alkalis.

Metals exposed to air pollution can be placed into three groups:

1. Metals that corrode rapidly because they do not form completely protective corrosion products. The major metal in this group is iron. It should be noted, however, that iron oxide Fe_2O_3 does have some protective action.
2. Metals that are initially attacked somewhat readily but subsequently become resistant to attack because of the formation of a corrosion-resisting film, which hinders further attack. Among the metals in this group are aluminum, lead, zinc, brass, copper, nickel and magnesium.
3. Metals that are almost completely corrosion resistant, as for instance stainless steel of the 18/8 type, chromium plate products, monel, and gold.

Mention has already been made of the action of oxygen and oxidants on metal. It should be noted that metals react with sulfides, such as hydrogen sulfide, and are subsequently subject to additional slow attack by oxygen and oxidants. Thus, copper reacts to form sulfide and then the basic copper sulfate.

Generally, metals are resistant to attack in dry air; even in pure humid air, corrosion is slight; when, however, air pollutants are present the rate of corrosion will increase measurably, the increase being dependent upon the humidity and the character of the pollutant. Such action may be grouped as follows:

Relative Humidity		Degree of Corrosion
Less than	60	None
More than	60	Slow but definite
	80	Decided increase
Greater than	80	Very high

A factor of note is the settling and adherence of particles on metals. Particles of carbon, ammonium sulfate, and silica cause a marked increase in corrosion, and this is accentuated in atmospheres containing sulfur dioxide. The presence of such hygroscopic particles enhances the adherence of liquid and thus provides for electrochemical attack.

Stone building materials may be placed into relatively resistant and nonresistant categories. The acids of the air, such as sulfuric acid, attack carbonate-bearing stone, such as limestone, converting the calcium carbonate to calcium sulfate. The gypsum formed is dissolved by rainwater, causing pitting. Incrustations may be formed because of the crystallization of soluble salts. These break away in time and leave pitted surfaces. Other types of damage, such as porosity of the stone, are caused by analogous reactions.

Corrosion-Resistant Metals

Some concept of the economic importance of corrosion to the production and consumption of various metals can be gleaned from Table 1. Many mineral commodities are used in more or less direct proportion to steel production. In the case of the United States and many other countries, a large number of the mineral materials important to combating corrosion come from distant sources. That is why many countries maintain a stockpile of such materials, particularly those that are regarded as critical or strategic. In the United States, 93 materials are officially classified for defense purposes as basic stockpile commodities. Seventy-nine of these are metals and minerals, including nearly every one of the metals with important corrosion-resistant properties.

The possible use of low-grade, currently noncommercial, mineral deposits, requires constant consideration. For example, chromium has been recognized as an important strategic material ever since World War I. Over the years, the U.S. government, through the U.S. Geological Survey and the Bureau of Mines, has discovered and carefully defined numerous domestic chromium deposits. The Bureau of Mines in its metallurgical laboratories has produced acceptable chrome concentrates from these deposits as well as acceptable ferrochromium chemicals. Current Bureau of Mines research includes recovering chromium, nickel, and cobalt from laterite deposits, both domestic and from other countries, and also from flue dusts, plating wastes, and other residues.

Corrosion Monitoring

Combatting corrosion in continuous processing plants, which may be scheduled for quite infrequent but thorough equipment checking and maintenance, is particularly difficult. Process downtime costs for a large unit may be several hundred thousand dollars per day in terms of lost production. To avoid excessive downtime for checking and still control the effects of corrosion (personnel and equipment safety, product quality and throughput rates, etc.) requires means to measure the status and rate of corrosion that may be taking place within the equipment. The design

TABLE 1. APPLICATIONS OF CORROSION-RESISTANT METALS

Metal	Corrosion resistance use	Consumption: For corrosion applications	Consumption: Percent of all uses of metal
Nickel	Alloying, 34%; high-temperature oxidation resistance, 26%; plating, 13%	144,000 MT	73
Chromium	Alloying, 57%; coatings and plating, 7%	306,000 MT	64
Titanium	Coatings, 51%; alloying, 1%	243,000 MT	52
Cadmium	Plating	2,520 MT	45
Gold	Plating and alloying	50,000 kg	35
Zinc	Galvanizing, 32%; coatings and sacrificial anodes, 3%	432,000 MT	35
Tin	Plating, tinning	19,800 MT	34
Tantalum	Alloying, 16%; cladding, 12%; high-temperature oxidation resistance, 5%	1,935 MT	33
Rare earths	Alloying	3,600 MT	30
Platinum	Resistance to chemical attack	13,375 kg	27
Silver	Alloying	1,370 kg	26
Columbium (Niobium)	Alloying; high-temperature oxidation resistance	630 MT	25
Iron oxide pigments	Coatings	30,600 MT	25
Copper	Alloying and plumbing	370,000 MT	18
Molybdenum	Alloying; coating	4,860 MT	18
Cobalt	Alloying; high-temperature oxidation resistance	1,530 MT	17
Magnesium	Alloying; sacrificial anodes	14,400 MT	15
Zirconium	Alloying; chemical resistance	340 MT	15
Thorium	Alloying	31 MT	12
Hafnium	Alloying	3 MT	11
Beryllium	Alloying	4 MT	10
Lead	Pigments and plating, 8%; cable covering, 1%	108,000 MT	9
Indium	Coatings	1,555 kg	8
Aluminum	Alloying; coatings; cladding	225,000 MT	5
Manganese	Alloying; cladding	45,000 MT	4

MT = metric ton; kg = kilogram

of corrosion monitors is among the most recent developments in overall process instrumentation. For obvious reasons, such on-line corrosion testing must be of a nondestructive nature.

In one type of monitor, changes in electrical resistance of a measuring element or probe relate to corrosion rate. The measuring element may be a wire, tube, or strip that can be inserted in a tee or an elbow in the process piping. As the measuring element corrodes, the cross-sectional area reduces and the electrical resistance increases. The thickness of the measuring element is directly proportional to a corrosion dial reading. The difference in dial readings is plotted over a period of time and from these data, corrosion rate can be determined. Probes are available in a number of different metals for different temperature ranges and corrosion conditions. In another variation, three electrode probes are used. The corrosion rate is determined by measuring electrical current flow between the test and auxiliary electrodes. That current either cathodically protects or anodically accelerates the corrosion rate of the test electrode, depending upon the flow. The current is measured on a microammeter that has been converted to read directly the corrosion rate in mils (1 mil = 0.001 inch = 25.4 micrometers) per year of the test electrode.

In another instrumental approach, a hydrogen test probe operates on the principle that hydrogen will diffuse through the thin wall of a test probe and set up a pressure within the tube. The rate at which the pressure increases is measured by a pressure gage. The rate at which hydrogen is penetrating per unit area can then be determined, using the exposed surface area and the internal volume of the probe. Beyond a certain rate, severe hydrogen damage can be anticipated.

Measurement of wall thickness can be determined using ultrasonic nondestructive testing methodology. This method can be used to determine wall thinning, pitting, erosion, and flaws in metals, plastics, and various rubbers and polymers. Some disadvantages of the method include the need to take many readings over a period of time to determine corrosion rate and the fact that high-temperature measurements tend to be inaccurate.

Infrared thermographic techniques can be used to identify hot spots on process equipment. The camera works on the theory that the hotter the object, the higher the frequency of radiation. For off-line corrosion monitoring, borescopes for inspecting tubes, pumps, compressors, and other equipment may be used. Spot chemical testing can indicate the presence of alloy constituents of unknown materials. Television camera and holographic techniques also have been used. The monitoring of pH is an invaluable indicator of possible corrosion problems, particularly in cooling water systems. Monitoring is usually done continuously because pH shifts can take place rapidly in many systems, particularly as a result of a process leak.

Probably the weight loss coupon approach is one of the most reliable methods and is widely used. The accuracy of the data is highly dependent on good techniques and on the statistical significance of the tests. The engineering quality data produced require the efforts of many people over a period of several weeks or months, which makes this information quite costly. However, it is the technique of first choice of many processors.

CORROSION EMBRITTLEMENT. The or loss of ductility of metals due to corrosion, usually as a result of intergranular embrittlement attack, which may not readily be visible.

CORROSION INHIBITION. See **Autodeposition; Conversion Coatings; Paint and Finish Removers; Petroleum.**

CORSITE. An orbicular diorite resulting from the segregation, in rounded concentric forms, of ferro-magnesian minerals. It derives its name from its occurrence on the Island of Corsica, and is also sometimes called Napoleonite.

CORTICOSTERONE. See **Hormones.**

CORTISONE. See **Steroids.**

CORUNDUM. The mineral corundum, Al_2O_3, aluminum oxide, occurs as well-developed hexagonal crystals, which may display prismatic, rhombohedral, pyramidal or tabular habits. The larger crystals are often rounded or barrel shaped. Corundum shows both basal and rhombohedral partings; the fracture is conchoidal; hardness, 9; specific gravity, 4.0–4.1; luster, vitreous to adamantine, may be pearly on base; transparent to translucent. Common corundum is gray, grayish-blue or brown, but may be red, yellow or whitish; it is sometimes called adamantine spar. Transparent corundum may be colorless or of various tints. The highly prized ruby is deep red; the sapphire, blue. Transparent yellow corundum is known as oriental topaz; if violet, oriental amethyst; if green, oriental emerald.

Emery is a mixture of granular corundum of dark color, magnetite and hematite, sometimes with spinel. Quartz may be present. For a long time emery was supposed to be an ore of iron. Until the introduction of artificial abrasives, emery was much used for such purposes.

Corundum is found as an accessory mineral in the crystalline rocks such as crystalline limestone and dolomites, gneisses, schists as well as in the igneous rock types granite and syenite. Corundum syenites are found in Canada, especially in the Province of Ontario. Rubies have long been mined in Upper Burma; both rubies and sapphires are found near Bangkok, Thailand. Numerous localities in India furnish gem stones of high quality.

In the United States, common corundum is found in New York, New Jersey, Pennsylvania, Virginia, North Carolina, South Carolina and Georgia; sapphires of gem quality near Helena, Montana, associated with alluvial gold in the Missouri River. From the crystalline limestones and schists of the islands of Naxos and Samos in the Grecian archipelago most of the emery of commerce comes. Other deposits are near Ephesus in the Middle East, and in the town of Chester in Massachusetts. The word corundum comes from the Hindu, kurand; emery is derived from the Greek name for this substance.

COTTON *(Gossypium species; Malvaceae).* A natural fiber, cellulosic in composition, with the general formula $(C_6H_{10}O_5)_x$, specific gravity, 1.54; moisture regain 7–8.5% (at 70°F (21.1°C) and 65% relative humidity); and a tensile strength of 60–120 × 10^3 psi (same condition of temperature and humidity). Cotton is quite resistant to degradation by heat. After about 5 hours at 121°F (50°C), the material yellows, and above 300°F (149°C), the material decomposes. Cold concentrated acids and hot dilute acids disintegrate cotton. In alkalis, cotton mercerizes without damage. The fiber is quite resistant to most solvents.

Even with the large inroads of synthetic fibers into the textile industry, cotton remains as a major textile fiber, consumption still being expressed in terms of billions of pounds per day. As one of the most versatile of fibers, cotton blends well with other fibers. In addition to the cellulosic content (88–96% depending upon source), cotton contains proteins, pectin, sugar, and wax (about 0.4–0.8%). Much research is going forth to eliminate much of the loss and damage that occur in harvesting and ginning. These factors contribute to price instability.

From the standpoint of use in textiles, cotton is rated excellent for hand (general feel, softness, drape), pilling resistance, and stability to repeated launderings. Cotton is rated good for abrasion resistance, strength, wash and wear performance, and wrinkle resistance. Resistance to sunlight is rated only fair. Pressed-crease retention is rated poor. Safe-ironing temperature for most cotton fabrics is 425°F (219°C).

Important worldwide producers include Brazil, Egypt, India, and the United States.

The uses of cotton are many. First among them is the manufacture of cloth. Cloth may be woven entirely of cotton, as much is, or may be of cotton mixed with other fibers, as synthetics, linen and wool.

Cotton fibers, especially the fuzz, are frequently used to stuff mattresses, pads and upholstered furniture. Treated with chemicals that remove the thin coating of waxy substances that cover the fibers, the latter becomes absorbent cotton, which is capable of absorbing many times its weight of water.

Cotton treated in this way is almost pure cellulose, and so is in great demand by those industries using cellulose. The pure cellulose of the fiber may be dissolved and then precipitated in sheets, giving the familiar thin transparent cellophane. Or the dissolved cellulose may be pressed through fine holes and solidified, giving rayon. If treated with concentrated caustic soda, cotton fibers take on a high degree of luster. The product of this process is called mercerized cotton, after John Mercer, its discoverer.

Treated with nitric acid under various conditions, cotton yields a long series of by-products. Some of them are plastic substances. If highly nitrated, cellulose becomes gun-cotton, used in the manufacture of explosives. Collodion is one of these nitrated products. Many varnishes and lacquers are made from cotton cellulose.

Not all the derivative products of cotton come from the fibers. Some, for example, are obtained from the seeds. In preparing these, the hulls are first removed from the kernel within. These hulls are used as fuel in the ginning mill, as food for cattle, and as fertilizer. The kernels are heated and pressed to remove the oil in cotton. During this pressing the kernels are wrapped in cloth to prevent anything but oil from being expressed. The oil is purified to a soft white substance very similar to lard in appearance. Cottonseed oil is used in making salad oils, oleomargarine and soap. After the oil is expressed, the seed cake may be used as food for stock or as a fertilizer.

COULOMETER. Also known as coulombmeter, a device for the measurement of electric current. Originally developed (1916) by the U.S. National Bureau of Standards, the *silver coulometer* consists of a small platinum vessel, acting as the cathode, into which a pure silver anode is immersed. An aqueous solution of silver nitrate (15% $AgNO_3$, wt) of very high purity is used as the electrolyte. In use, both the quantity of silver deposited and the time are carefully noted. These measurements permit a calculation of the average current strength.

The more practical form for laboratory use employs copper electrodes in a bath of copper sulfate. The thin copper cathode, between two heavy

copper anodes, is removable for weighing; and since one coulomb deposits 0.000329 gram of copper, the weight of the copper deposit enables one to determine the quantity of electricity in coulombs. A solution recommended for this cell consists of 15 grams of crystalline copper sulfate, 5 grams of pure sulfuric acid, and 5 grams of pure alcohol, dissolved in 100 grams of distilled water.

The effect of current flow on electrolyte concentration also can be determined by titrating the electrolyte after electrolysis. A device of this type is known as a *titration coulometer*. Rarely, a coulometer may be referred to as a *voltmeter*.

COUPLING (Chemical). Reactions for the formation of chemical compounds usually by establishing a valence bond between a carbon atom and a nitrogen atom. Phenols and several other organic substances are also said "to couple." Polyphenylene oxides, thermoplastic materials, are produced by means of oxidative-coupling technology.

COTTRELL, FREDERICK G. (1877–1948). A native of California Cottrell obtained his doctorate from Leibig in 1902. His major contribution to industrial chemistry was the discovery of a practical method of dust elimination by electrical precipitation. Used in factory stacks and other large units, this process has contributed greatly to purifying the atmosphere of industrial areas. The principle involves charging a suspended wire with electricity. This creates a field that ionizes the surrounding air, the particles assuming the charge on contact and then moving to the wall of the stack, where they are electrically discharged and precipitated.

COVELLITE. The mineral covellite, cupric sulfide, CuS, is hexagonal, usually in thin platey crystals, but may be massive. It has a hardness of 1.5–2; specific gravity, 4.6; luster, submetallic to resinous; color, dark indigo blue, sometimes showing a purplish tarnish, or if moistened may appear purple in color. Its streak is dark gray to black; it is opaque. Covellite is found associated with chalcopyrite, bornite, and chalcocite, and is believed to be chiefly of secondary origin. Covellite occurs in Yugoslavia, Saxony, Sardinia, Argentina, Chile, Bolivia and Peru, and in the United States at Butte, Montana, and in Colorado, Wyoming, and Utah. This mineral was named for Covelli, who discovered it in the lavas of Mt. Vesuvius.

CRACKING PROCESS. A reaction in which a hydrocarbon molecule is broken or fractured into two or more smaller fragments. Sometimes the term *pyrolysis* is used for this reaction. Possibilities for cleavage of a molecule include: (1) a carbon-hydrogen bond; (2) a bond between an inorganic atom and a carbon or hydrogen atom; and (3) a carbon-carbon bond. Usually the objective of cracking is that of reducing the size of hydrocarbon molecules; hence the target is to fracture the carbon-carbon bonds. The main cracking processes are: (1) thermal cracking; (2) fluid catalytic cracking; and (3) hydrocracking.

Thermal Cracking

Of the thermal cracking processes, two are of major importance: (1) coking, and (2) visbreaking (viscosity breaking). Both of these processes convert nondistillable residues into more valuable products. Thermal cracking was the first of the principal cracking processes used in the petroleum industry. For increasing gasoline production and improving quality, fluid catalytic cracking has essentially replaced thermal cracking.

In *thermal coking*, heavy residual stocks are converted into gas, gasoline, distillates, and coke. Generally, the objective is that of maximizing the yield of distillates; and minimizing the production of gas, gasoline, and coke. Light distillates are used for both domestic and industrial heating oils. There are two types of thermal coking processes: (1) cyclic, semicontinuous process, sometimes referred to as *delayed coking*, decarbonizing, or low-pressure coking; and (2) a continuous fluid coking process. About 70% of the installed capacity in the United States is the delayed coking type.

As shown by Fig. 1, a delayed coking unit is comprised of three sections-a furnace, coke drums, a fractionating unit, plus coke removal and handling equipment. Usually the feedstock is charged to the lower part of the fractionator. Here the feedstock is contacted by hot vapors from the coke drum, causing any light components to be flashed from the feed before the feed joins with the recycle and charged (from the bottom of the fractionator) to the furnace. The charge in the furnace is heated to about 480°C (896°F). The heated effluent from the furnace is introduced into the bottom of one of two or more insulated vessels (coke drums) where, as the result of its contained heat, the material cracks to form a solid coke residue. At the same time, lighter cracked products are evolved and proceed from the top of the coke drums to the fractionator. The reaction in the coke drum is endothermic and thus the temperature of the material drops to about 425°C (797°F). The cracked products leave as vapors; the coke remains in the drum. The fractionator separates the cracked vapors into several side streams as shown on the diagram. When accumulated coke reaches a certain level in the drum, that drum is temporarily taken off-stream and the flow is switched to the second drum. Prior to removal of coke, the drum is steamed to remove vapors. Water is also added to cool the coke.

The fluid coking process accomplishes the coking operation in a continuous manner. Feed is sprayed into a fluid bed of hot coke in a coking reactor. Steam introduced into the bottom of the reactor provides the fluidization energy. The cracked products are quenched in an overhead scrubber and then go to the fractionator. The coke is deposited on the particles in the reactor, which commute with a heater vessel in which a portion of the coke is burned to heat up the returning coke particles to supply the energy for the coking reaction.

Fluid Catalytic Cracking

This process is used principally to create gasoline, C_3/C_4 olefins, and light distillates by the selective decomposition of heavy distillates. The process was introduced during World War II to replace earlier thermal cracking processes. Specially prepared catalysts are used. The resulting gasoline contains substantial proportions of high-octane-number hydrocarbon components, including aromatics, branched paraffins, and olefins. The cracking proceeds in accordance with the carbonium-ion mechanisms. Consequently, there are minor amounts of fragments lighter than C_3 in the products. This is to be contrasted with thermal cracking by the free-radical mechanism, wherein large proportions of fragments lighter than C_3 result. Another product of fluid catalytic cracking is *cycle oil*, a distillate that boils above gasoline. Cycle oils are withdrawn as net products and are used as components in heating oils, feedstocks to hydrocracking units, and for blending with heavy residuals as a means of reducing viscosity. The highly aromatic clarified slurry oils have been found to be useful feeds for the manufacture of carbon black.

Indicated in Fig. 2 is a representative fluid catalytic cracking unit, comprising: (1) a reactor; (2) a regenerator; (3) the main fractionator; (4) an air blower or compressor; (5) a spent-catalyst stripper; (6) catalyst recovery equipment, including cyclones internal in the reactor and regenerator; and slurry settler, and possibly an electrostatic precipitator; and (7) a gas-recovery unit. The catalyst used is essentially a specially prepared composite of silica and alumina.

In operation, preheated feedstock meets a controlled stream of hot, regenerated catalyst. Vaporized oil and catalyst ascend in the riser, such that the catalyst particles are suspended in a dilute phase. Essentially all of the cracking occurs in the riser. The catalyst particles are separated from the cracked vapors at the end of the riser and the catalyst containing a coke deposit is returned to the regenerator. The cracked vapors pass through one or more cyclones located in the upper portion of the reactor and proceed to the fractionator (main column) that produces the side streams indicated.

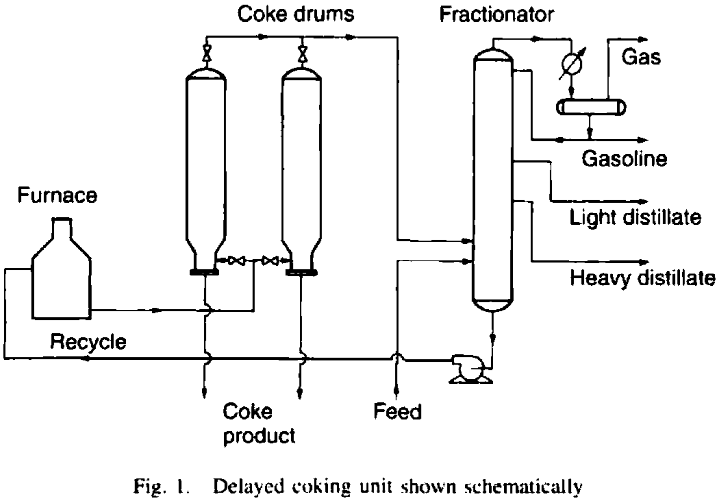

Fig. 1. Delayed coking unit shown schematically

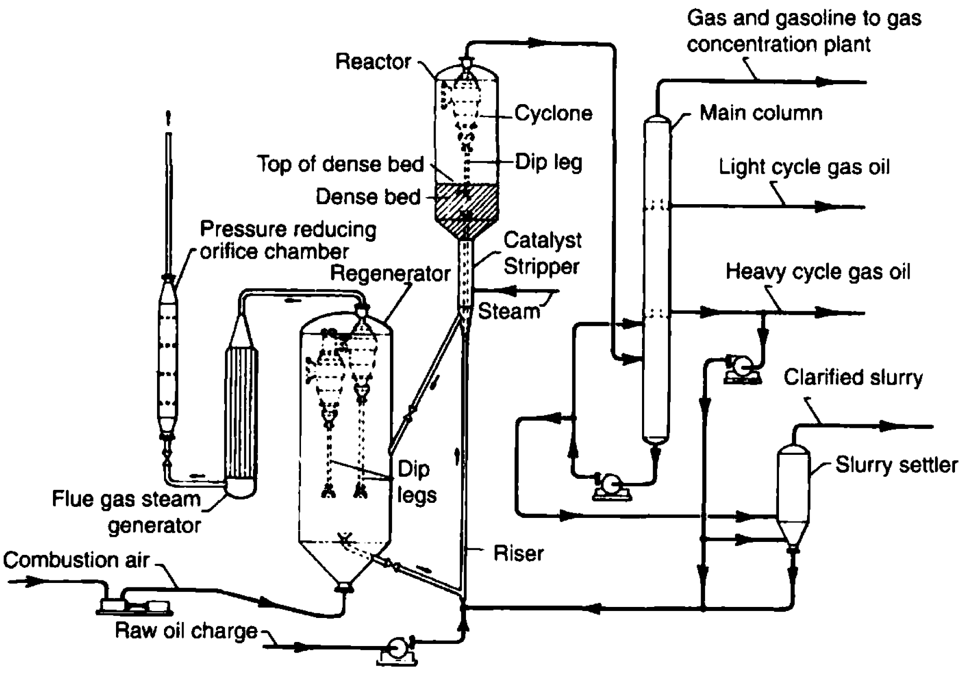

Fig. 2. Fluid catalytic cracking process. (*UOP Inc*)

Hydrocracking

Processes in this category produce gasoline and light distillates from feed distillates that are higher-boiling than the products. Hydrocracked products are not olefinic. The light gaseous hydrocarbons produced by hydrocracking are entirely paraffinic. The processes operate at elevated pressures in the presence of hydrogen and catalysts. Temperatures are usually lower than 482°C (900°F). Pressures run from 800 to 2,500 psig. Both fixed-bed and ebullating-bed configurations are used. Because carbonaceous deposits accumulate very slowly on the catalyst, the on-line periods for these units are quite long, ranging from several months to over a year. Somewhat more costly to build than fluid catalytic cracking, the hydrocracking process has the advantage that it can handle heavier and dirtier feedstocks and also may be adapted to varying product ratios of gasoline to middle distillate.

Technical Staff, UOP Inc.
Des Plaines, Illinois

Editor's Addendum

For any given petroleum processing design, there are competing designs, including cracking processes. Each particular design will have its own specific advantages and limitations (products yielded, product specifications, operating conditions, economic factors, etc.). Once developed by a design group, a given process generally will be licensed to end users or refinery construction and engineering firms, as negotiated.

CRAM, DONALD JAMES (1919–2001). Awarded the Nobel prize for chemistry, together with Jean-Marie Lehn, and Charles J. Pedersen, in 1987 for work in elucidating mechanisms of molecular recognition, which are fundamental to enzymic catalysis, regulation, and transport. He also studied three-dimensional cyclic compounds that maintained a rigid structure, accepting substrates in a structurally preorganized cavity. Cram called these compounds cavitands, while Lehn named them cryptands. Cram received his doctorate from Harvard University in 1947. See also **Cavitand.**

CREEP (Metals). This term usually is associated with the slow, plastic deformation of metals under constant load. Continued plastic deformation, where the applied force does not change, can result from two basic causes. (1) If a metal is deformed, as in tension, its cross section is correspondingly reduced. This raises the stress level in the material and, if the rate of this increase in stress exceeds the rate of strain hardening, creep occurs. (2) Plastic flow may be promoted by thermally activated softening processes occurring in the metal that counteract the mechanisms leading to strain hardening. Thus, thermal energy may aid dislocations in cutting through one another or in passing around inclusions. Thermal energy may also provide the means for dislocations of opposite sign to move toward each other so that they can recombine. This may eliminate dislocations entrapped in each other's force field, thereby allowing additional dislocations to move out from the sources and plastic deformation to continue.

Creep of metals at high temperatures is primarily controlled by thermally activated processes. Since there are many conceivable mechanisms, creep cannot be associated with a single activation energy. However, in a given temperature range, the creep rate may be controlled by a particular mechanism and the temperature dependence of the creep rate in this range will be related to a corresponding activation energy. Thus, several activation energies have been observed for creep in aluminum, each of which is controlling in a different temperature range. In general, the activation energy is larger the higher the temperature range in which it controls. The activation energy for creep of metals at very high temperatures (just below the melting point) often tends to be the same as that for self-diffusion. This implies that vacancy motion or dislocation climb is very important in creep at extremely high temperatures.

From a practical point of view, creep becomes an important natural phenomenon when the temperature at which a metal is loaded lies above about 0.4 to 0.5 of its melting point on an absolute scale. In some metals such as zirconium, which undergo a solid state phase change, creep becomes an important effect above about one-half of the temperature of the phase transformation. In many metals such as steel, creep is almost nonexistent at room temperatures if the metal is not loaded above its annealed yield strength. However, at 900°F (482°C) steel can creep readily at very small stresses, and equipment such as boilers and tubes for petroleum cracking stills, intended to operate at high temperatures for long periods

of time, must be designed on the assumption that creep will occur. Alloy steels and other materials have been developed having much higher creep strengths than carbon steel.

Creep strength is the unit stress that will produce deformation at a specified rate at a specified temperature; for example, the creep strength of a certain 0.15% carbon open-hearth steel at 1000°F (538°C) is 6,100 pounds per square inch (415 atmospheres) for a rate of 0.01% elongation in 1,000 hours. Other values for this material are 6,900 pounds per square inch (469 atmospheres) for a rate of 0.1% and 7,800 pounds per square inch (531 atmospheres) for a rate of 1.0% elongation in 1,000 hours. Creep strength values can only be determined by long- time laboratory tests under carefully controlled conditions of temperature and loading.

CREOSOTE. See **Coal Tar and Derivatives.**

CRICK, FRANCIS HARRY COMPTON (1916–2004). Crick, a British physicist, studied at University College in London. During WW II, he joined the British Admiralty Research Laboratory and worked on developing radar and magnetic mines to be used for naval warfare. Right after the war, he read Erwin Schrodinger's *What is Life? The Physical Aspects of the Living Cell.* The book changed the direction of his life. Crick began studying biochemistry and molecular biology at Cambridge University's laboratory. Later, at Cavendish Laboratory he studied protein structures. Crick wanted to understand how genetic code worked.

In 1951, James Watson, an American biologist, joined Crick's research. Together they pioneered a new era in science when they proposed that the molecular structure of DNA was a double spiral helical chain in a paper published in the scientific journal, *Nature* in 1953. This astonishing work was done by Watson, just 24 years old, and Crick who had not yet even finished his PhD. In 1962, Crick and Watson shared the Nobel Prize in physiology/medicine for contributions in discovering the molecular structure of DNA. Crick continued his studies with DNA as Director of Cambridge University's Molecular Biology Laboratory.

In later years, Dr. Crick became a research professor at the Salk Institute for Biological Studies in California and at age 84, was still researching. He has written several books on the implications of the new findings in biochemistry.

J.M.I.

CRITICAL COMPOSITION. Systems consisting of two liquid layers that are formed by the equilibrium between two partly miscible liquids, frequently have a consolute temperature or a critical solution temperature, beyond which the two liquids are miscible in all proportions. At this temperature, the phase boundary disappears, and the two liquid layers merge into one. The composition of the mixture at that point is called the critical composition. There is, in some cases, a lower consolute temperature as well as an upper consolute temperature.

CRITICAL CONCENTRATION. When two immiscible liquids are heated in contact with each other their mutual solubility is usually increased until, at the critical solution temperature, they become consolute. The composition of the two solutions immediately before they become consolute is termed the critical concentration. See also **Critical Solution Temperature.**

CRITICAL DENSITY. The density of a substance which is at its critical temperature and critical pressure.

CRITICAL MASS. The amount of concentrated fissionable material that can just support a self-sustaining fission reaction. See also **Nuclear Power Technology.**

CRITICAL POINT. (1) A point where two phases, which are continually approximating each other, become identical and form but one phase. With a liquid in equilibrium with its vapor, the critical point is such a combination of temperature and pressure that the specific volumes of the liquid and its vapor are identical, and there is no distinction between the two states. (2) The critical solution point is such a combination of temperature and pressure that two otherwise partially miscible liquids become consolute.

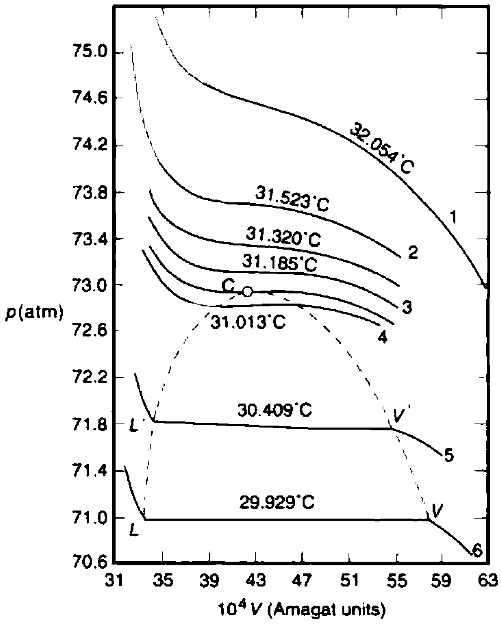

Fig. 1. Isotherms of carbon dioxide in the neighborhood of the critical point

To consider in detail the critical point as defined in (1), examine Fig. 1, which shows the family of isotherms of a pure substance in the fluid range (liquid or gas) such for example as shown in the figure for carbon dioxide.

At sufficiently high temperatures each isotherm is a continuous curve, but at low temperatures the isotherm consists of three portions. The first section of the curve at high pressures corresponds to the liquid state, while that at low pressures refers to the gaseous state. These two curves are joined by a horizontal line, corresponding to the simultaneous presence of two phases, liquid and gas.

The isotherm between those numbered 3 and 4 in the figure represents the transition between isotherms corresponding to the gas phase only, and those including a horizontal portion corresponding to a liquid-gas equilibrium. In this isotherm the horizontal line has contracted to a single point of inflection *C*. This is the critical point characterized by the relations

$$\left(\frac{\partial p}{\partial V}\right)_T = 0;\ \left(\frac{\partial^2 p}{\partial V^2}\right)_T = 0;\ \left(\frac{\partial^3 p}{\partial V^3}\right)_T < 0.$$

The curve *LL'C* gives the molar volume of the liquid. Similarly *VV'C* gives the molar volume of the gas.

At the critical point the molar volumes of the liquid and of the gas become equal. In general a critical state is characterized by the fact that the two coexistent phases (here the liquid and the vapor) are identical.

The curve *VV'CL'L* is called the *saturation curve.*

The experimental data do not indicate the existence of a critical point for the liquid-solid transition.

Above the critical point the substance can no longer exist in the liquid state. The critical temperature is thus the highest temperature at which the liquid and vapor can coexist.

Ternary Critical Point. The point where, upon adding a mutual solvent to two partially miscible liquids (as adding alcohol to ether and water), the two solutions become consolute and one phase results.

CRITICAL SOLUTION TEMPERATURE. For two partially miscible liquids, the compositions of the two conjugate solutions approach each other with increasing temperature. At the critical solution temperature the two solutions have identical compositions and form one layer.

CRITICAL TEMPERATURE. 1. This term is most commonly used to denote the maximum temperature at which a gas (or vapor) may be liquefied by application of pressure alone. Above this temperature the substance exists only as a gas. 2. The critical temperature of a superconducting transition takes place in zero magnetic field.

CRITICAL VOLUME. The volume occupied by unit mass, commonly one mole, of a substance at its critical temperature and critical pressure.

CROCIDOLITE (Blue Asbestos). The mineral crocidolite may be considered as a fibrous variety of the monoclinic amphibole, riebeckite. It is also known as a massive mineral. Its hardness is 4; specific gravity, 3.2–3.3; luster, silky to dull; color, blue or bluish-green. It is found in Austria, France, Bolivia, the Republic of South Africa (the variety known as tiger's-eye); and in the United States, in Massachusetts and Rhode Island. The name crocidolite is derived from the Greek, meaning to weave, in reference to its fibrous appearance. See also **Cat's-Eye**.

CROCOITE. The mineral crocoite, lead chromate, corresponds to the formula $PbCrO_4$, and forms prismatic monoclinic crystals, often acicular. It is also found in columnar or granular masses. It has a rather distinct cleavage parallel to the prism, and a less distinct cleavage parallel to the base. It has a conchoidal fracture, is sectile; hardness, 2.5–3; specific gravity, 5.9–6.1; luster, adamantine to vitreous; color, red; streak, orange-yellow, translucent. Crocoite is a secondary mineral believed to be formed by waters containing chromic acid acting upon lead minerals like galena, with which it is associated. It is found in the former U.S.S.R., Rumania, Tasmania, Brazil, the Philippines, and Arizona. It is not of commercial importance. The name crocoite is derived from the Greek word for saffron in reference to the color of the powdered mineral.

CROSS LINKING. See **Rubber (Natural)**.

CRUCIBLE. A crucible is a vessel made of heat-resistant material and employed to hold a material that is at high temperature, or is to be subjected to high temperature. Crucibles will range in size from the small laboratory types to large ones having a capacity of several tons of molten metal. They are roughly cup- or barrel-shaped, and are made of some material such as clay. In the laboratory, platinum, iron, and porcelain crucibles are used. In the iron and steel industry, clay crucibles have been used, but at the present time most manufacturers employ the graphite crucible, which is made half and half from graphite and fireclay, well-mixed, molded, and burned to vitrification. The crucible may be used to hold a material being melted or burned, as in some processes for making steel, where the raw material is put in the crucible, which is then set in a hot furnace until the contents are melted. Or, a crucible may be used to receive molten metal, which has been produced elsewhere, as from a brass furnace or cupola, in which case it is the means for conveying it from the point of melting to the point of casting, serving thus as the intermediate reservoir between the furnace and the mold. See also **Casting**.

CRYOCHEMISTRY. That branch of chemistry devoted to the study of reactions occurring at extremely low temperatures (−200°C and lower). It permits synthesis of compounds that are too unstable or too reactive to exist at normal temperatures.

CRYOGENIC MATERIALS. Those metals and alloys usable in structures operating at very low temperature, and usually possess improved strength properties at these temperatures. See also **Cryogenics**.

CRYOGENICS. The production and study of phenomena that occur at very low temperatures, i.e., below about 80 K. The first step in attaining the required temperature generally involves the liquefaction of a gas or gases. Liquids can exist over a range of temperatures limited by the critical point at the higher end and the triple point at the low-temperature end. It is thus possible to compress a gas to the liquid phase at the critical point and to cool it by boiling under reduced pressure to its triple point. A series of gases having their critical and triple points overlapping can thus be used in a cascade process each being used as the refrigerant for the next in the series. Pictet used this method to liquefy oxygen, using methyl chloride and ethylene as refrigerants. There are, however, no liquids that cover the range from 77 K to the critical point of hydrogen, or from 14 K to the critical point of helium (5.2 K). Thus, liquid hydrogen and helium cannot be produced by the cascade method.

Expansion of Gases

A gas may also be cooled by making it do work in the course of an expansion. When an ideal gas is expanded through an aperture into a constant volume, no work is done, since there are no interactions between the molecules and the molecules themselves occupy no volume. When a nonideal gas is so expanded, however, an amount of internal work, ($W = (PV)_{final} - (PV)_{initial}$) is done against the intermolecular forces. This work may be positive or negative, resulting in a cooling or heating of the gas. Air is cooled by this Joule-Thomson expansion at room temperature, but hydrogen and helium must be precooled to 90 and 15 K, respectively to obtain further cooling upon expansion. Using this method, Kamerlingh Onnes first succeeded in liquefying helium in 1908. Compressed gases may also be made to do external work, for example, by expansion against a movable piston. In this case, the work is always positive and helium may be cooled and liquefied without any precooling by liquid hydrogen. See also **Ammonia**; and **Helium**.

With liquid helium readily available in the laboratory, research in the temperature range 5 to 0.8 K has become commonplace. By using the isotope of helium ^3He, it is possible to attain temperatures down to about 0.3 K since the isotope has a lower boiling point than ^4He. This is about the lowest temperature practically attainable by boiling liquids at reduced pressure. To reach lower temperatures, it is necessary to use magnetic phenomena.

Magnetic Cooling

Although this concept dates back several decades, as of the early to mid 1993, this was one of the most seriously researched areas for designing supercoolers.

Debye and Giauque pointed out that at 1 K the entropy of paramagnetic salts was still fairly large and, moreover, that it was almost all due to nonalignment of magnetic moments and that the entropy of lattice vibrations was very small. If the electron spins are aligned by application of a magnetic field, the entropy of the salt falls to a low value and the heat of magnetization can be extracted isothermally. The salt can then be thermally isolated and demagnetized adiabatically and its temperature will fall. Temperatures on the order of 0.01 K can readily be reached by this method and the lower limit for a single demagnetization would appear to be about 10^{-3} K. When demagnetization occurs, the spin system reaches equilibrium temperature in about 10^{-10} seconds. It is found that equilibrium is achieved between the spin temperature and the lattice temperature by spin-orbit coupling in times on the order of a few seconds. Paramagnetic salts have relatively high specific heats at low temperature and hence the cold salt can be used to cool other bodies. However, making good thermal contact with the cooled salt can be difficult.

Kurti, Simon, and Gorter suggested that a further reduction in temperature could be attained if adiabatic demagnetization was performed on nuclear moments rather than the electron spin. The temperature which can be reached in an adiabatic demagnetization is determined by the point at which the entropy of the system in zero external field decreases sharply with decrease in temperature due to the alignment of magnetic moments, i.e., the point at which the interaction energy μh equals kT (h = internal field; μ = magnetic moment). Since the interaction energies of nuclear moments are much smaller than electron spin interactions, much lower temperatures should result. The materials used experimentally were metals cooled to 10^{-2} K by contact with a paramagnetic salt. The thermal isolation of the nuclear spins during demagnetization was achieved naturally by the nuclear-spin-conduction electron relaxation time (~100 seconds). Thus, while the nuclear spins cooled to between 10^{-5} and 10^{-6} K, the conduction electrons and lattice remained in thermal contact with the cooling salt at 10^{-2} K.

Magnetic Refrigerators. Magnetic cryogenic refrigerators are presently considered indispensable to the operation of future space-based defense systems, increasing their efficiency, reliability, and life span. These coolers are designed to cool space-based infrared sensors and signal processors to temperatures lower than now practicable with conventional closed, gas-cycle coolers. Magnetic refrigerators employ what is known as the *magneto-caloric* effect, which cools by alternately magnetizing and demagnetizing a solid material. For example, a magnetic solid, such as gadolinium gallium garnet, can be continuously rotated through a strong magnetic field to produce temperatures even lower than gas-cycle coolers. Other possible applications for this new technology include space astronomical observators, space power generation, high-speed rail transportation, medicine, and the commercial gas liquefaction industry.

Another method of attaining temperatures below 1 K is to take advantage of the fact that the entropy of a superconducting metal is less than that of the metal in its normal state. Quenching of a superconductor by the application of a magnetic field can cause a cooling to about 0.1 K. However, since the specific heat of metals is very small at these temperatures, they are not very suitable for cooling other bodies.

Low-Temperature Measurements

Such measurements are usually carried out using secondary thermometers calibrated at certain fixed points previously determined on the absolute scale by a standard instrument. This instrument is generally a constant-volume gas thermometer used at low pressures. When the readings of this instrument are extrapolated to zero pressure, the scale coincides with the thermodynamic scale. In the range of 0.8 to 5.2 K, the vapor pressure of ^{4}He provides the most commonly used secondary scale and it agrees with the absolute scale to within 2 millidegrees over this range. The use of ^{3}He instead of ^{4}He increases the coverage to 0.3 K.

Resistance thermometers are useful over a wide range. For example, platinum is used from 273 to 15 K, and carbon covers the range 20 to 2 K and has the advantage of being quite insensitive to magnetic fields. The foregoing are examples of secondary standards where the scales are interpolated between fixed points.

For temperatures below 0.3 K, the susceptibility of a paramagnetic salt can be measured and the temperature calculated by extrapolation from Curie's Law $\chi = C/T$. This method gives true values for the temperatures so long as Curie's Law holds. Beyond this region, it is necessary to perform a thermodynamic cycle to determine the relationship between the magnetic temperature T^* and the absolute temperature T. The method of Kurti and Simon is to demagnetize adiabatically from a known temperature on the absolute scale, using a number of different field intensities, and hence to determine the relationship between T^* and the entropy S over the required range of temperature. Measurement of the amount of heat Q necessary to raise the temperature from $T_1{}^*$ to $T_2{}^*$ gives the absolute value of the average temperature $T_{1,2}$ from the relationship $\Delta Q = T\Delta S$. The heat is generally supplied to the salt by gamma rays, thus ensuring even heating of the sample, a necessary precaution since the thermal conductivity is poor. The problem of nonlinearity does not arise in the case of nuclear spin demagnetization since, in this case, the susceptibility obeys Curie's Law down to 10^{-7} K.

Cryogenic Phenomena

One of the most interesting phenomena of cryogenics is that of superconductivity, which was also discovered by Onnes. When metals are cooled from room temperature, their resistances decrease and at low temperature, they attain low values, which are fairly independent of temperature. Some metals, however, have a critical temperature below which their resistance goes to zero. Such a metal is known as a superconductor.

Superfluidity

As liquid helium is cooled below 2.18 K, it undergoes a sudden discontinuity of specific heat and a second-order transition to the superfluid state. In this state, the viscosity of the helium becomes a function of the method used to measure it. Measured by an oscillating disk method, the viscosity falls from 23×10^{-6} poise just above the transition to 1×10^{-6} poise at 1.3 K. Measured by passage through very fine capillaries, the viscosity is very nearly zero in the superfluid state. Hence, it is postulated that there are two coexisting, noninteracting fluids, one having the properties of non-"superfluid" helium; and the other having virtually zero viscosity and zero entropy. It is interesting to note that the thermal conductivity of superfluid helium is about 2,000 times greater than that of copper. This is the result of the motion of the entropy-free superfluid rather than normal thermal conductivity. See also **Superfluidity**.

Magnetic Properties

There are several fundamental experiments on the magnetic properties of materials that become possible as a result of the low-temperature environment of cryogenics. The first of these was discovered by deHaas and Van Alphen in 1930. They found that at low temperatures, the susceptibility of bismuth single crystals rose and fell periodically as the magnetic field was increased. Later work shows that the periodicity occurs in all metals at low temperatures and is the result of quantization of electron motion perpendicularly to the applied field. This effect was used to determine the Fermi surface of metals.

Radioactive Decay

The method of alignment of nuclear moments has been used to study radioactive decay as a function of nuclear orientation. The aligning field in this case can be either an externally applied magnetic field or an internal crystal field. One of the more striking of these experiments has been the test of the Lee-Yang theory of nonconservation of parity in weak interactions. A third fundamental experiment of interest was the confirmation of London's concept that flux through a superconducting ring is quantized. The ring was a lead tube of 10^{-3} centimeter diameter and it was suspended from a torsion balance. The tube was made superconducting in the presence of longitudinal magnetic fields, and the frozen-in flux was measured and found to be quantized.

Several practical applications of cryogenics technology are described elsewhere in this encyclopedia. Check Alphabetical Index.

CRYOHYDRATE. An eutectic system consisting of a salt and water, having a concentration at which complete fusion or solidification occurs at a definite temperature (eutectic temperature) as if only one substance were present.

CRYOHYDRIC POINT. The eutectic point in cases in which the system contains water.

CRYOLITE. Cryolite, sodium aluminum fluoride, Na_3AlF_6, crystallizes in the monoclinic system but in forms that closely approach cubes and isometric octahedrons. It is usually found massive. Cryolite has an uneven fracture, is brittle; hardness, 2.5; specific gravity, 2.97; luster, vitreous to greasy; color, snow-white but may be colorless, reddish or brownish; translucent to transparent. The only considerable occurrence of cryolite is at Ivigtut, Greenland, where veins of this mineral are associated with granites and gneisses. Small occurrences of cryolite have been noted in the Ilmen Mountains, Russia, and at Pikes Peak, Colorado. Cryolite has its chief use in the electrolytic production of aluminum, but small amounts are employed in the manufacture of opalescent glass.

The name cryolite is derived from the Greek words meaning frost (ice) and stone in reference to its translucency.

The aluminum industry no longer uses the natural mineral for operation of electrolytic cells except infrequently for start-up operations. The

synthetic cryolite used is produced by two main processes: (1) the sodium aluminate from the Bayer process (see also **Bauxite**) is reacted with hydrofluoric acid: $NaAlO_2 + 2NaOH + 6HF \longrightarrow 3NaF \cdot AlF_3 + 4H_2O$; or (2) sodium carbonate may be used instead of NaOH:

$$NaAlO_2 + Na_2CO_3 + 6HF \longrightarrow 3NaF \cdot AlF_3 + CO_2 + 3H_2O$$

The quality hydrofluoric acid required for these reactions may be prepared from fluorspar: $CaF_2 + H_2SO_4 \longrightarrow 2HF + CaSO_4$. Normally, cryolite is not considered toxic. A continued exposure to finely divided cryolite in the air may lead to *fluorosis*. However, the compound is toxic to insects.

Richmond, Virginia

CRYOPUMP. (1) An exposed surface refrigerated to cryogenic temperature for the purpose of pumping gases in a vacuum chamber by condensing the gas and maintaining the condensate at a temperature such that the equilibrium vapor pressure is equal to or less than the desired ultimate pressure in the chamber.

(2) The act of removing gases from an enclosure by condensing the gases on surfaces at cryogenic temperature. Also referred to as a *cryogenic pump* and not to be confused with *cryogenic fluid pump* for *circulating cryogenic propellants*.

CRYOSCOPE. An instrument for measuring the freezing or solidification point. The Hortvet cryoscope is used for the estimation of added water in milk from the lowering of the freezing point.

CRYOSCOPIC CONSTANT. A quantity calculated to represent the molal depression of the freezing point of a solution, by the relationship

$$K = \frac{RT_0^2}{1000l_f}$$

in which K is the cryoscopic constant, R is the gas constant, T_0 is the freezing point of the pure solvent, and l_f is the latent heat of fusion per gram. The product of the cryoscopic constant and the molality of the solution gives the actual depression of the freezing point for the range of values for which this relationship applies. Unfortunately, this range is limited to very dilute solutions, usually up to molalities of $\frac{1}{100}$ and must be modified for many solutes. See also **Freezing-Point Depression**.

CRYOTRON. A device based upon the principle that superconductivity established at temperatures near absolute zero is destroyed by the application of a magnetic field.

CRYPTATE COMPLEXES. See **Chemical Elements**.

CRYPTOCRYSTALLINE. When the texture of a rock is so finely crystalline (that is, made up of such minute crystals) that its crystalline nature is but vaguely revealed even in a thin section by transmitted polarized light, the rock is said to be cryptocrystalline. Among the sedimentary rocks, chert and flint are cryptocrystalline. Lava flows, especially of the acidic type such as felsites and rhyolites, may have a cryptocrystalline ground mass as distinguished from pure obsidian (acidic), or tachylite (basic), which are natural rock glasses.

CRYPTOCRYSTALLINITY. See **Mineralogy**.

CRYSTAL. A macroscopic sample of a solid substance exhibiting some degree of geometrical regularity, or symmetry, or capable of showing these properties after suitable treatment (e.g., cleavage, etching, etc.). Almost all pure elements and compounds are capable of forming crystals.

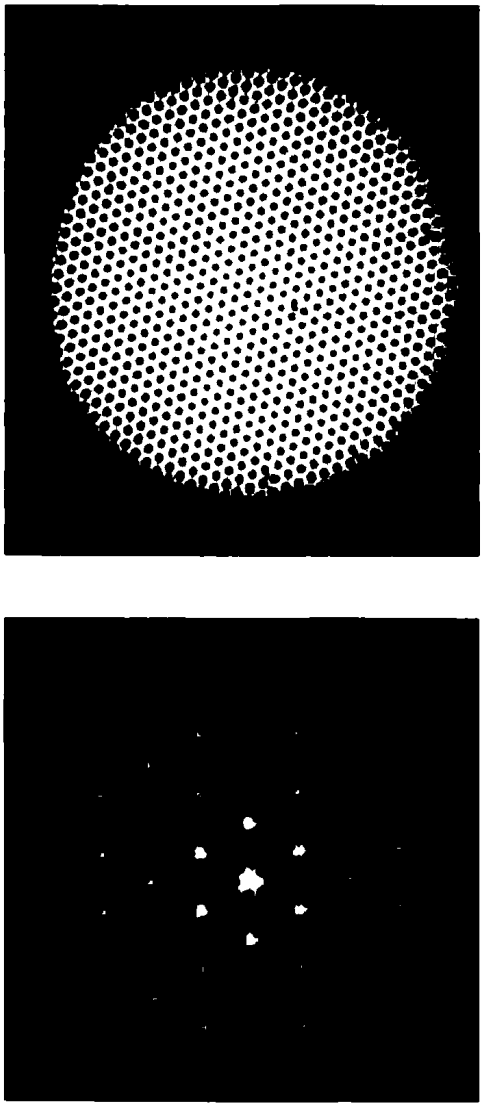
A perfect crystal is one in which the crystal structure would be that of an ideal space lattice. No such crystals exist, all real crystals containing imperfections which have a strong influence on the physical properties of the crystal.

The mechanical and electronic properties of polycrystalline materials depend dramatically upon the boundaries between neighboring regions of different crystallographic orientation-that is the grain boundaries-and it is to these regions that minor alloying and impurity elements segregate. Their presence may be ascertained by high resolution transmission electron microscopy (HRTEM) and computer simulation.

Structure of Crystals

Early investigators suggested that the regular structure of crystals, embodied in the laws of crystallography, could be explained if they were thought of as built up by the repetition of equal polyhedral cells, fitting together to fill space, each cell representing a characteristic group of particles, perhaps the atoms and molecules of the compound. A rough calculation showed that the spacing of these units in many ionic crystals might be of the same order of magnitude as the wavelengths of x-rays, as deduced from quantum theory. Von Laue suggested, and verified, that diffraction of the x-rays occurs when they are passed through a suitably oriented crystal. He knew, from the density and atomic weights, that the number of atoms in a cubic centimeter of rock salt, for example, is about 4.488×10^{22}, and that therefore, if they are equally spaced in all three directions, their distance apart is 2.814×10^{-8} centimeters or 2.814 Å. Certain quantum theory calculations had already indicated that x-rays have wavelengths of this order. It occurred to von Laue that if a beam of x-rays were directed upon a crystal and the crystal turned into a suitable position, one might observe interference maxima analogous to those produced with light by a diffraction grating. This proved to be the case, and the result verified beyond question the existence of regular spacings between reflecting planes of some sort, presumably plane arrays of atoms or ions. The kind of pattern obtainable is demonstrated by Fig. 1.

Subsequent analysis of the problem by Bragg resulted in a formula analogous to that for interference of light reflected by thin plates. If the reflecting layers are spaced at equal distances d, and if the wavelength of the incident x-rays is λ, the angle θ between rays and layers necessary for an interference reflection maximum is given by Bragg's law, viz.,



(a) (b)

Fig. 1. Types of x-ray patterns of crystals: (**a**) Steel balls in a crystalline lattice; (**b**) Bragg reflections with shape S^2

sin $\theta = n\lambda/2d$; in which n is an integer. By slowly turning the crystal, the various plane-families are brought into suitable orientations for the production of maxima. The result is a Laue pattern of black spots on the photographic plate placed beyond the crystal to catch the reflections. Another method, developed by Hull and by Debye and Scherrer, secures the necessary angular variation by crushing the crystal to powder and relying upon the fortuitous orientation of the fragments; the pattern in this case being a system of concentric rings, as exemplified by Fig. 2.

While it is very easy, when one knows the structure of the crystal and the wavelength of the rays, to predict the diffraction pattern, it is quite another matter to deduce the crystal structure in all its details from the observed pattern and the known wavelength. The first step is to determine the spacing of the atomic planes from the Bragg equation, and hence the dimensions of the unit cell. Any special symmetry of the space group of the structure will be apparent from space group extinction. A trial analysis may then solve the structure, or it may be necessary to measure the structure factors and try to find the phases or a Fourier synthesis. Various techniques can be used, such as the F2 series, the heavy atom, the isomorphous series, anomalous atomic scattering, expansion of the crystal and other methods.

By such methods, the structures of crystals have been determined and all of them can be shown to possess space structures corresponding to one or another of the 14 Bravais lattices. See Figs. 3 and 4.

Crystal Systems and Crystallography

The field that deals with the geometrical relations between the atomic planes within them is *crystallography*. Some minerals, if broken, will separate along given 'cleavage planes' into polyhedral fragments. Even when powdered, the minute grains will show this characteristic and measurements will indicate the planes to belong to one or another plane family, the members of any one of which are all parallel. It should be stressed, however, that all minerals do not possess cleavage planes for such experimentation.

In most crystal systems each of the more prominent crystal faces belongs to one of three plane-families intersecting along what are called the crystal axes. In the hexagonal system there are four. These may be conveniently used as coordinate axes, X, Y, Z, though they are not generally at right angles. Haüy discovered that if the ratio of the intercepts of two crystals planes on one of these axes is a simple fraction, such as $\frac{3}{5}$, the ratios of the intercepts on the other axes are likewise simple. This suggests that the two intercepts on any one axis are multiples of a common unit. The units are, however, generally different for the different axes, bearing to each other ratios called the axial ratios.

It is more convenient to use the reciprocals of the intercepts. For example, a plane might have intercepts equal to 10,000, 15,000, and 6,000 of the respective units. The reciprocals have the ratios 1/10,000: 1/15,000:1.6,000, which in lowest terms are 3:2:5. These smallest integers are the Miller indices of the family to which this plane belongs, and the family is thus designated (325). The family (201) is parallel to the Y axis but intersects the X and Z axes. (The hexagonal system has four Bravais-Miller indices for each plane-family.)

Fig. 2. Concentric ring pattern of crystalline materials

If the intercept of any plane has a negative value, that is, if it cuts the axes when extended in a direction opposite to that in the standard arrangement, the fact is shown by a bar over the Miller index, e.g., $(2\bar{2}2)$. The eight faces of an octahedron are (111), $(1\bar{1}1)$, $(\bar{1}11)$, $(\bar{1}\bar{1}1)$, $(1\bar{1}\bar{1})$, $(11\bar{1})$, $(\bar{1}1\bar{1})$, and $(\bar{1}\bar{1}\bar{1})$, that is, they all belong to the form (111).

Close study of the angles, indices, and axial ratios long since made it clear that every crystalline substance has a structure built upon a space "lattice" characteristic of the substance. It has been established that this is due to the regular arrangement of the atoms, molecules, or ions composing the substance. As shown by Table 1, the lattice structures of crystals may be classified into 32 symmetry classes (point groups), which are further divided into seven systems. This topic also is discussed under **Mineralogy**.

Practically all minerals are crystalline, although perfect natural crystals are seldom, if ever, found. Because of the laws of crystallography, however, a crystallographer can usually determine the crystal form of a known species from a fragment of the original crystal, provided that at least two of the crystal faces are visible. Crystalline aggregates are said to be cryptocrystalline when the individual particles are proved to have crystalline structure but their crystal faces are exceedingly small or indistinguishable. A mineral is pseudocrystalline if its external form does not correspond with its crystalline structure.

A new structural form has been proposed of *quasicrystals*—designated *shechtmanite*—which are neither crystalline nor completely amorphous. These materials possess a fivefold symmetry of long-range order. Despite Pauling's contention that data on these structures can be related to the common phenomenon of "twinning," increasing data indicate that this structural system does exist and has long been ignored because the icosahedral, fivefold symmetry upon which it is based cannot serve as a unit cell of a crystal. The difficulties presented in composing structures based upon icosahedra require also the concept of "tiling," that is, the filling of a three-dimensional space gap with two-dimensional structures or "tiles" while maintaining a periodicity of structure. Penrose of Oxford has laid down the essential criteria for such structures.

Determination of Crystal Structure

The object of a crystal-structure determination is to ascertain the position of all of the atoms in the unit cell, or translational building block, of a presumed completely ordered three-dimensional structure. In some cases, additional quantities of physical interest, e.g., the amplitudes of thermal motion, may also be derived from the experiment. The processes involved in such crystal-structure determinations may be divided conveniently into (1) collection of the data, (2) solution of the phase relations among the scattered x-rays (phase problem)—determination of a correct trial structure, and (3) refinement of this structure.

The data consist of intensities I (hkl), where h, k, and l (the Miller indices represent a vector triplet which conveniently identifies the beam diffracted from a single crystal. In a typical determination, there may be

TABLE I. ELEMENTS OF CRYSTAL SYSTEMS

System	Crystallographic elements	Essential symmetry	Number of point groups
Cubic, or regular	Three axes at right angles: all equal.	4 triad axes: 3 diad, or 3 tetrad axes	5
Tetragonal	Three axes at right angles: two equal	1 tetrad axis	7
Orthorhombic or rhombic	Three axes at right angles: unequal.	3 diad axes, or 1 diad axis and 2 perpendicular planes intersecting in a diad axis	3
Monoclinic	Three axes, one pair not at right angles: unequal.	1 diad axis, or 1 plane	3
Triclinic or anorthic	Three axes not at right angles: unequal.	No axes or planes	2
Hexagonal	Three axes co-planar at 60°: equal. Fourth axis at right angles to other three.	1 hexad axis	7
Rhombohedral or trigonal	Three axes equally inclined, not at right angles: all equal.	1 triad axis	5

one to two thousand such I (hkl). The intensity is related to the structure factor F (hkl) by the relation.

$$I(hkl) = K F(hkl) F^*(hkl) \qquad (1)$$

where K is a known relative factor, and where F^* is the complex conjugate of F. The structure factor itself is related to the scattering by the j atoms in the unit cell by the relation,

$$F(hkl) = \sum_j f_j T_j \exp[2\pi i(hx_j + ky_j + lz_j)] \qquad (2)$$

where f_j are the individual atomic scattering factors, T_j are the individual modifications of the scattering as a result of thermal motion, and x_j, y_j, z_j are the fractional positions of atom j along the three crystallographic axes. In a typical determination, j may be between 10 and 60. The *scattering density* ρ (xyz) is derivable from the relation,

$$\rho(xyz) = V^{-1} \sum_{-\infty h,k,l}^{\infty} F(hkl)\exp[-2\pi i(hx_j + ky + lz)] \qquad (3)$$

where V is the volume of the unit cell.

The "phase problem" in crystallography arises because in the usual experiment (Eq. 1) the magnitudes of the complex structure factors are obtained, but not the phases. Yet in order to obtain the scattering density,

and hence the positions of the atoms, the phases as well as the magnitudes of the structure factors are necessary (Eq. 3).

Once the phase problem is solved, then the positions of the atoms may be refined by successive structure-factor calculations (Eq. 2) and Fourier summations (Eq. 3) or by a nonlinear least-squares procedure in which one minimizes, for example, $\sum w(|F_{obs}| - |F_{calc}|)^2$ with weights w taken in a manner appropriate to the experiment. Such a least-squares refinement procedure presupposes that a suitable calculational model is known.

It is perhaps useful to indicate how the attention of crystallographers to these three steps in the solution of a structure has changed in recent years. In 1954, the time involved in the arduous task of collecting the three-dimensional data—step (1)—needed for the solution of a complex problem was generally short in comparison with the time needed to solve the phase problem—step (2). This time involved in step (2) of course depended (and still depends) upon the complexity of the problem, and on the ingenuity, luck, and perseverance of the investigator, but it was true in many cases that step (2) was the rate-determining step in the entire process. This in part was because little attention was paid to detailed refinements—step (3); in 1954, three-dimensional least-squares refinements of complex structures were out of the question computationally, and even Fourier refinements were rare, for on computing systems advanced for those days (e.g., punched-card tabulators, sorters, and primitive electronic computers), a three-dimensional Fourier summation might require forty man-hours. In fact, in 1954 it was usual for the crystallographer to examine the unit cells of a number of related substances and to pick the problem that was crystallographically most favorable (and perhaps soluble from two-dimensional data), even though this problem might not be the one of greatest chemical or physical interest. Ten years later the situation had changed markedly, mainly because of the availability of high-speed computers. It is still true that there are classes of problems where step (2) is rate-determining, but these problems are far more complex than those attempted in 1954. Yet there is an extensive class of problems in which today the solution of the phase problem is straightforward and rapid. The crystallographer is thus often working on the problem of greatest chemical or physical interest, and is able to obtain a solution in feasible time. Relatively complete refinement of structures is now the rule, since it is a reasonably fast and effortless procedure. Thus it turns out that in many crystallographic problems the rate-determining step is data collection. For this reason, there has been a dramatic increase in interest in ways of making data collection less tedious, more rapid, and more accurate.

Although in the early days the Braggs and others used ionization chambers for the collection of x-ray intensities, these methods were gradually abandoned in favor of photographic film techniques. Until a few years ago the great majority of structure determinations were based on photographically recorded intensities, usually visually estimated. This process is a slow one: the typical time involved in the collection and estimation of a data set of two thousand intensities is perhaps six to eight weeks. Collection of intensity data from protein crystals is far more challenging and time-consuming, both because the number of data to be collected is far greater and because the crystals are unstable and rapid collection is thus desirable. For these reasons, Harker and his co-workers, particularly Furnas, then at Brooklyn Polytechnic Institute, were among those instrumental in developing scintillation-counter methods for collecting three-dimensional x-ray data. Diffractometers with single-crystal orienters, based on the so-called Eulerian geometry developed by Harker and Furnas, as well as on the more conventional Weissenberg geometry are available commercially and have engendered widespread interest in counter techniques. Data collection by counter techniques, as practiced by most workers, is still an arduous task, since the setting of a number of orientation angles is involved. Program or computer control of such setting operations is an obvious extension. Especially for neutron diffraction studies, such programmed control of diffractometers has been the rule for some time.

Nevertheless, a programmed unit will do only what it was designed to do, whereas a computer can be programmed to perform new tasks or operations as they seem necessary. There are several installations of computer-controlled diffractometers. Counter methods, particularly when semiautomatic or completely automatic, enable more rapid data collection than is possible photographically. What is equally important is that they should also enable more accurate data to be collected. The general level of accuracy of intensities obtained photographically is perhaps 15 to 20%. Such a level has proved sufficient for the solution of conformational or stereochemical problems, but not necessarily for the determination of meaningful descriptions of thermal motion or bonding.

There are two approaches to the solution of the phase problem that have remained in favor. The first is based on the tremendously important discovery of Patterson in the 1930s that the Fourier summation of Eq. 3, with the experimentally known quantities F^2 (hkl) replacing $F(hkl)$ leads not to a map of scattering density, but to a map of all interatomic vectors. The second approach involves the use of so-called direct methods developed principally by Karle and Hauptman of the U.S. Naval Research Laboratory and which led to the award of the 1985 Nobel Prize in Chemistry. Building upon earlier proposals that the relative intensities of the spots in a diffraction pattern contain information about a crystal phase, Hauptman and Karle developed a mathematical means of extracting the information. A fundamental proposition of their direct method is that if three intense spots in the pattern have positions whose coordinates add up to zero, their relative phases will cancel out. Computations done with many triads of spots yield probable phases for a significant number of diffracted waves and further mathematical analysis leads to a likely solution for the structure of the molecule as a whole.

The *Patterson function* has been the most useful and generally applicable approach to the solution of the phase problem, and over the years a number of ingenious methods of unraveling the Patterson function have been proposed. Many of these methods involve multiple superpositions of parts of the map, or "image-seeking" with known vectors. Such processes are ideally suited to machine computation. Whereas the great increase in the power of x-ray methods of structure determination in the past few years has come simply from our ability to compute a three-dimensional Patterson function, it is reasonable to expect that, as machine methods of unraveling the Patterson function are developed, this power will increase many fold.

Step (3), the refinement of crystal structure, continues to enjoy a considerable amount of interest. Reasonably complete refinement is routine these days, owing in large measure to the availability of suitable computers. For reasons that are both practical and mathematically sound, the least-squares approach to refinement has gained favor over the successive structure-factor-Fourier approach. Yet the computational problems often tax this generation of computers. If one assigns a single isotropic thermal parameter to each atom, then there are four parameters, three positional and one thermal, to be determined for each atom. In the least-squares procedure, if one stores the upper right triangle of the normal-equations' matrix, then $\frac{1}{2}N(N + 1)$ elements are required, where N is the number of variables. In a machine with a memory of 32,000 words, a practical limit is reached at about $N = 200$, if one wishes to keep the rest of the program in core. Thus refinement of a 50-atom problem often taxes the memory capacity of the machine, and for larger problems special computational or mathematical tricks are needed. One of these tricks is to make use of known features of the structure or the thermal motion to reduce the number of parameters. But, even with increased numbers and more rapid availability of data, computerized solutions to crystallographic problems still suffer from a degree of uniqueness. Programs written to operate on one machine must often be extensively revised to be used on another. An international group of workers at the National Resource for Computation in Chemistry at the Lawrence Berkeley Laboratory is trying to overcome this problem of interchangeability by writing a program designed to run on any medium or large sized computer. When completed, the program will allow a crystallographer, armed only with experimental data and a computer, to determine the structure of any crystal without having to write special programs.

Crystal Growth

The direct growth of an ideal and perfect crystal is difficult except at very high supersaturations because of the difficulty of nucleating a new surface on a completed surface of the crystal. But, if there is a screw dislocation present, it is not necessary to start a new surface, and growth proceeds in a spiral fashion by the accretion of atoms at the edge of growth steps. The resultant growth spirals have been observed, and it is believed that most crystals grow in this manner. See Fig. 5. But spiral growth is not the only mechanism that enables crystal growth at fast rates. Gilmer, in particular, has employed computer simulation models in studies of crystal growth and has demonstrated that, among other influences, temperature and impurity levels have decisive effects upon growth rates. Again, since different crystal faces have different kinetic properties, the particular crystal plane exposed to growth will also be a partial determinant of growth rate.

In modern technology based upon solid state chemistry and physics, much emphasis is placed upon the availability of elements and compounds

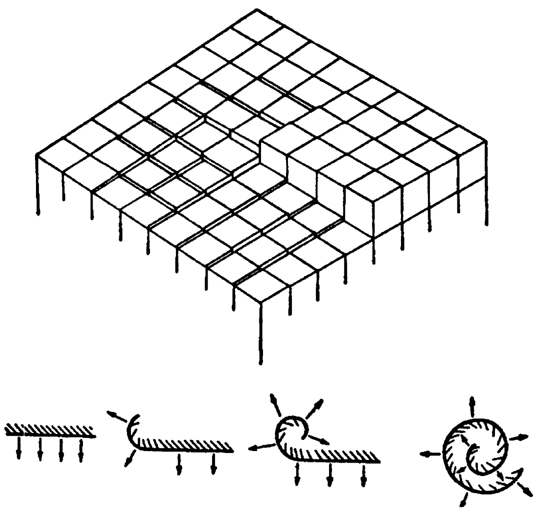

Fig. 5. Highly schematic representation of crystal growth. (*F.C. Frank*)

in single-crystal form. Over the past twenty-five years a highly sophisticated technology has developed in this area. From the relatively simplistic growth of ammonium and potassium dihydrogen phosphates (ADP and KDP) from saturated solutions for transducer elements, a level has been obtained at which pure metals (Cu, Pb, Al, Ag, Fe, etc.), a semi-metals (Si, Ge, As, etc.), and compounds (GaAs, InAs, InSb, InP, etc.) are available and even essential in large single crystal form to the electronics industries. Synthetic gems (rubies, spinels, sapphires, emeralds, and zircons) are single crystals of aluminum, beryllium, and zirconium silicates or oxides with controlled impurity levels of transition elements.

Growth of such single crystals can follow several techniques, with thermodynamic constraints dictating the technique for any particular material: crystallization by cooling a supersaturated solution of a compound in a high-temperature flux; crystallization by dropping powder through an intense flame onto a seed pedestal, known as the Verneuil technique (see Fig. 6); crystallization by pulling a "seed" crystal from the surface of a liquid melt, known as the Czochralski method (see Fig. 7); crystallization by lowering a melt through a small, controlled thermal gradient, known as the Stockbarger technique (see Fig. 8); crystallization by zone-melting, known as the Pfann method (see Fig. 9); and crystallization by the vapor-phase approach (see Fig. 10). All of these procedures, however, require three essential ingredients: (1) A good "seed" crystal from which spiral and sometimes oriented growth can occur and develop; (2) highly precise operational conditions-movement of fractions of a millimeter, or temperature variations of 0.5°C per hour; and (3), as previously indicated, materials of a specific impurity level. Given these conditions, single crystals can be grown in large quantities-ranging from the multimillion carat operations of Linde (United States) and Djevaherdijian (Switzerland), using the Verneuil technique, to the multikilo manufacture of single crystal silicon by Texas Instruments Incorporated (United States), employing the Czochralski and zone melt methods, and including a 27-kilogram single crystal of dislocation-free silicon by the Kayex Corporation (United States) grown by a modified Czochralski approach.

See also **Semiconductors**.

Dislocation in Crystalline Solids

This type of imperfection in a crystalline solid is generated as follows: A closed curve is drawn within the solid, and a cut made along any simple surface which has this curve as boundary. The material on one side of this surface is displaced by a fixed amount called the Burgers vector relative to the other side. Any gap or overlap is made good by the addition or removal of material, and the two sides are then rejoined, leaving the strain displacement intact at the moment of rewelding, but afterwards allowing the medium to come to internal equilibrium. If the Burgers vector represents a translation vector of the lattice, the weld is invisible, and the dislocation is characterized only by the original curve, or dislocation line and by the Burgers vector.

A dislocation line may only terminate at the surface of the crystal. The energy of a dislocation is largely stored as strain in the surrounding lattice. The important property of a dislocation is its ability to move quite easily

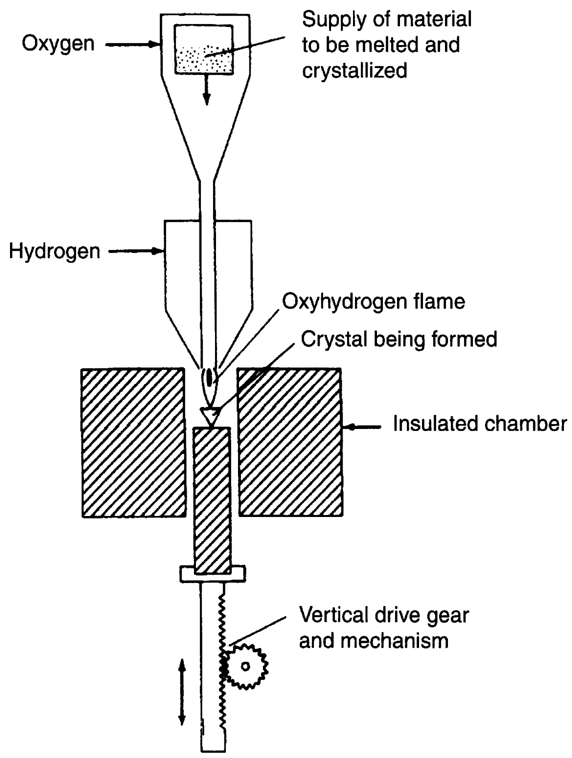

Fig. 6. Verneuil technique for growing crystals

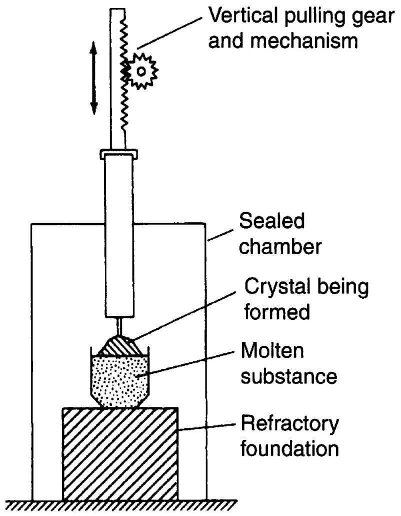

Fig. 7. Czochralski method for growing crystals

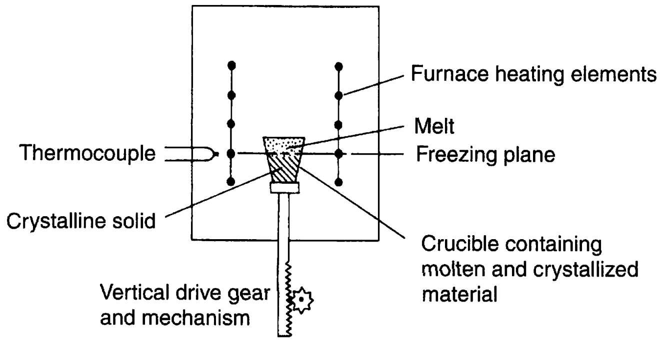

Fig. 8. Stockbarger technique for growing crystals

through the lattice, and hence to allow the rapid propagation of slip. The general dislocation defined above usually separates into its components, edge and screw dislocations, which may be treated as rather stable entities

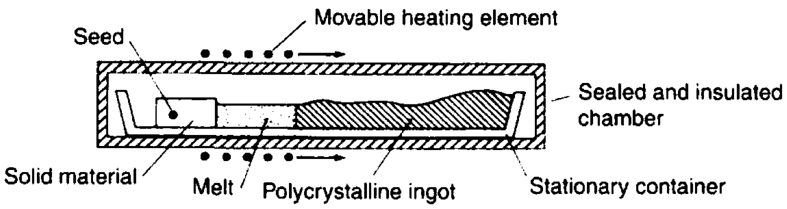

Fig. 9. Zone-melting or Pfann method for growing crystals

in the theory. Direct evidence for the existence of dislocations is the observation of dislocation networks in crystals of silver bromide, and, for their motion, from the spiral growth patterns in crystals.

In recent years high-resolution electron microscopes have been used to study dislocations and their movements in thin crystals. This is possible in both metals and nonmetals. Other techniques that have been applied successfully are field ion microscopy and x-ray microscopy. Dislocations are important in determining the mechanical and electrical properties of solids, and play an important part in solid state physics. The density of dislocations (i.e., the concentration of dislocation lines), for example, is believed to vary from about 100,000,000 per square centimeter in good natural crystals, through 1,000,000,000 in good artificial crystals up to about 1,000,000,000,000 in cold-worked specimens. These estimates are based on the energy stored by cold work, on x-ray analysis, and on measurements of electrical resistivity. Among the various types of dislocation are the *edge dislocation*, which is defined as having its Burgers vector (line of displacement) normal to the line of the dislocation. An edge dislocation may be thought of as caused by inserting an extra plane of atoms terminating along the line of the dislocation (Fig. 11). For example, if the dislocation were along the Z-axis and its Burgers vector along the X-axis, then one might think of an extra half plane of atoms being inserted at the surface $x = 0$, $y > 0$. Such a dislocation would be of positive sign. An edge dislocation may move easily only parallel to its Burgers vector, i.e., in its slip plane.

The *screw dislocation* has its Burgers vector parallel to the line of the dislocation. In a screw dislocation, the atomic planes are joined together in such a way as to form a spiral staircase, winding round the line of the dislocation (Fig. 12). A screw dislocation is capable of easy movement in any direction normal to itself. The growth spirals formed in crystal growth appear where such dislocations intersect the surface. Edge dislocations of the same sign repel each other along the line between them, but are most stable when arranged vertically above each other. Edge dislocations of opposite signs attract one another, but otherwise prefer to lie so that the line between them makes an angle of 45° with their slip planes. Screw dislocations of opposite sign attract, of like sign repel.

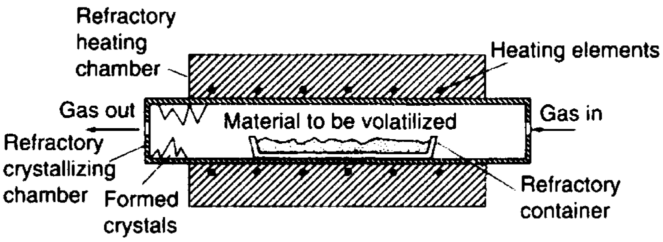

Fig. 10. Crystallization by the vapor-phase approach

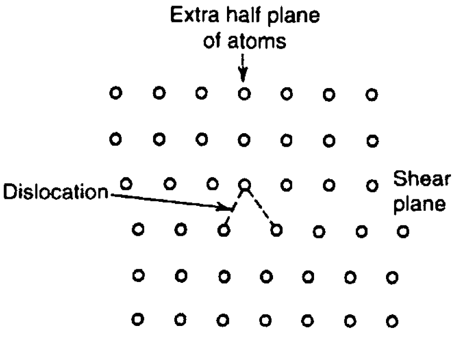

Fig. 11. Atomic arrangement in an edge dislocation

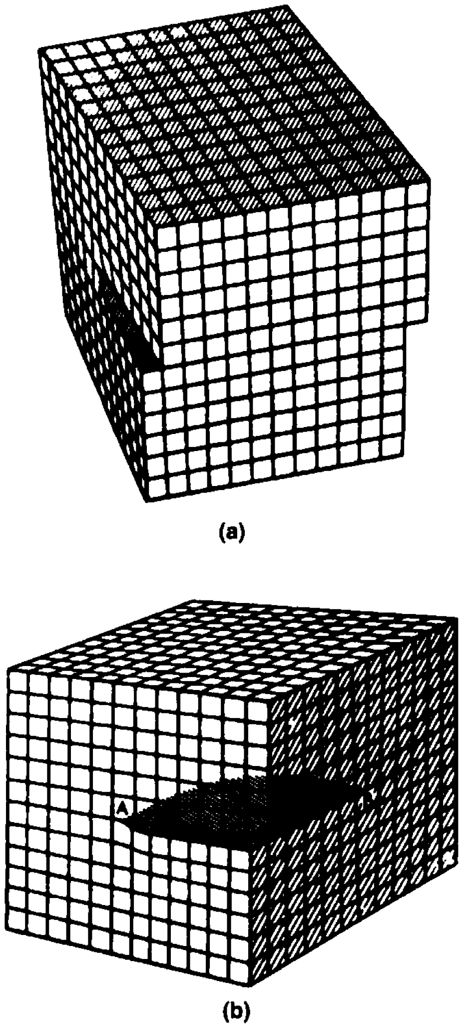

Fig. 12. **(a)** Simple type of screw dislocation; **(b)** both screw and edge dislocation along the arc from A to B

Dislocation Line

The curve separating displaced and undisplaced positions of a crystal, and thus at the center of a dislocation, is termed the dislocation line. Within a distance of one or two lattice constants of the dislocation line the atoms are displaced by an amount more than can be represented fairly as a strain. A screw location may have a substantial hole down the dislocation line, through which impurity atoms may diffuse.

Dislocation Climb

This is a type of dislocation motion, differing fundamentally from slip, associated with the edge components of dislocations. In climb, an edge dislocation moves in a direction perpendicular to its slip plane as atoms are either added to or taken away from the extra plane of the dislocation. The motion of atoms to and from the dislocation is accomplished by vacancy movements. If an atom in the plane next to the edge jumps out of its position and attaches itself to the extra plane, as indicated in the

accompanying figure, a vacancy is created which can then diffuse off into the lattice. Repetition of this process over and over will cause the extra plane to grow in size and, if this occurs, the process is said to be negative climb. On the other hand, if vacancies diffuse up to the extra plane of the dislocation and remove atoms from it, the plane grows smaller in size and positive climb is said to occur.

Dislocation climb only becomes of practical significance at elevated temperatures because of its dependence upon vacancies whose number and mobility depend very strongly on the temperature. Dislocation climb is important in high temperature creep and recovery phenomena. See Fig. 13.

Crystal Slip

This is the process by which a crystal undergoes plastic deformation, as a result of which one atomic plane moves over another. Slip is believed to occur through the movement of dislocations. The total deformation of a given crystal is the sum of many small lateral displacements in parallel crystallographic planes of a given family. Moreover, each slip plane becomes more resistant to further deformation than the remaining potential slip planes.

Cross-Slip

This is slip that occurs simultaneously on several slip planes having the same slip direction. See Fig. 14. This type of plastic deformation is normally associated with the movement of screw dislocations. Screw dislocations can move on any slip plane that passes through the dislocation. This is a result of the fact that the slip plane of a dislocation is that plane which contains both the dislocation and its Burgers vector, and the fact that the Burgers vector of a screw dislocation lies parallel to the dislocation itself.

Quasicrystals

The existence of quasicrystals was discovered by the Israeli scientist, D. Shechman, in the early 1980s. After years of experimentation, the first practical application for such materials was announced in the early 1990s in connection with the development of a nonstick, abrasion-resistant coating for cookware. They appear to be good candidates for a number of tribological uses because of their excellent wearability and abrasion resistance. Patents along these lines have been granted to the Centre National de la Recherche Scientifique in France. Researchers targeted two compounds with the nominal composition (atomic percent) of $Al_{65}Cu_{20}Fe_{15}$ (designated as alloy A) and $Al_{64}Cu_{18}Fe_{8}Cr_{8}$ (designated as alloy B). Powders were prepared by mechanically grinding ingots to a mesh size

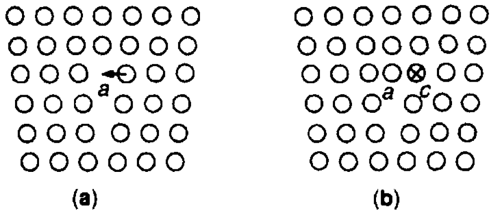

Fig. 13. Negative climb of an edge dislocation

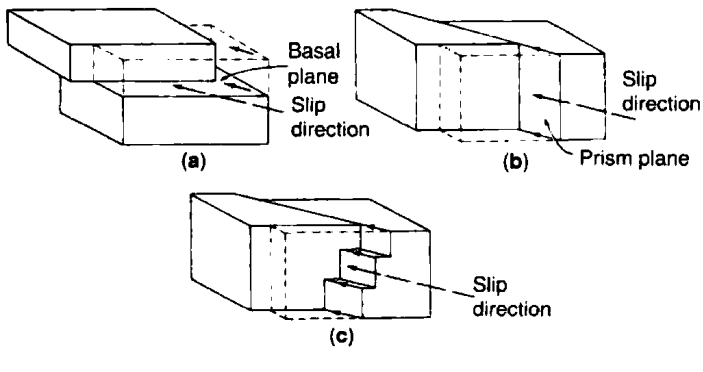

Fig. 14. Schematic representation of cross-slip in a hexagonal metal: (**a**) slip on basal plane; (**b**) skip on prism plane; (**c**) cross-slip on basal and prism planes

ranging from 20 to 75 micrometers (0.0008 to 0.003 in.) and were thermally sprayed onto "soft" aluminum alloy, pure copper, and low-carbon steel substrates using flame, supersonic, and plasma-arc spraying. The deposited materials consist of a mixture of quasicrystals and crystalline phases. Alloy A contains about 70 percent icosahedral phase, while alloy B contains about 70 percent quasicrystalline (icosahedral plus decagonal) phases. An icosahedron is a polygon having 20 faces and a decagon is a polygon having ten angles and ten faces.

As pointed out by Stephens and Goldman (State University of New York at Stony Brook), "Quasicrystals are neither uniformly ordered like crystals nor amorphous like glasses. Many features of quasicrystals can be explained, but their atomic structure remains to be described fully." See also **Aluminum Alloys and Engineered Materials**.

CRYSTAL FIELD THEORY. A theory developed in the early 1930s in research on magnetism by Bethe, Van Vleck and others. It applied

particularly to the transition metal ions, and is therefore conveniently treated by reference to those ions.

A transition metal ion in a complex or compound is considered to be subject to the electrostatic field of the molecules and ions in its neighborhood, particularly by those constituting its nearest neighbors. In the compounds to which the theory applies, the only nearest neighbors important to the theory are either negative ions, or molecules such as NH_3 which have unshared electron pairs and which orient themselves so that the negative end of the electron-pair dipole is directed toward the transition metal ion. The effect of these negative ions or negatively oriented dipoles (which we shall hereafter call ligands, with the understanding that ligand field theory is a later development of crystal field theory) is to produce a negative field about the positive transition metal ion.

In the absence of this negative field, the *d*-electrons of the central ion have orbitals of equal energy, i.e., degenerate orbitals, but the field of the ligands affects the energies of these orbitals to different degrees. To show how this effect arises, consider the example chosen by Griffith and Orgel. This is the regular octahedral complex MX_6, where M is a metal ion of the first transition series of the elements (see **Periodic Table of the Elements**), and X is a ligand such as H_2O, NH_3 or Cl^-.

The five 3*d* orbitals of M have the forms indicated in Fig. 1, in which the coordinate axes lie along the MX bond directions. It is clear from the figure that the d_{z^2} and $d_{x^2-y^2}$ orbitals have substantial amplitudes in the directions of the ligands but that the orbitals d_{xy}, d_{yz}, and d_{zx} tend to avoid them. Hence the energy of an electron in the d_z^2 or $d_{x^2-y^2}$ orbitals will be substantially raised by the repulsive field of the ligands, whereas the energy of an electron in the d_{xy}, d_{yz}, or d_{zx} orbitals will be comparatively little affected. Furthermore, it is obvious from symmetry that the degeneracy of the last three orbitals is maintained in the octahedral complex and it can be shown by group theory that the d_{z^2} and the $d_{x^2-y^2}$ orbitals also remain degenerate. Consequently the five *d* orbitals split into a lower group of three and an upper group of two, the two groups being usually designated as t_{2g} and e_g respectively (or sometimes as γ_5 and γ_3, and as $d\epsilon$ and $d\gamma$ respectively).

In tetrahedral complexes it can be shown similarly that the *d* orbitals are again split into groups of three and two, respectively, but now the doubly degenerate orbital is lower. In all other important cases the degeneracy of the *d* orbitals is reduced even further.

In order to understand the electronic structure of an octahedral complex and the optical transitions it can undergo, it is necessary to appreciate the principles determining the distribution of the *d* electrons among the t_{2g} and e_g orbitals. Let us begin by considering the ground state. Two separate tendencies are at work. The first is the tendency for the electrons to occupy, as far as possible, the orbitals of lowest energy in the ligand field. The second is for the electrons to go into different orbitals with their spins parallel, since this gives a lower electrostatic repulsive energy and a more favorable exchange energy. Let us now see how these ideas apply to an octahedral complex containing *n*3*d* electrons.

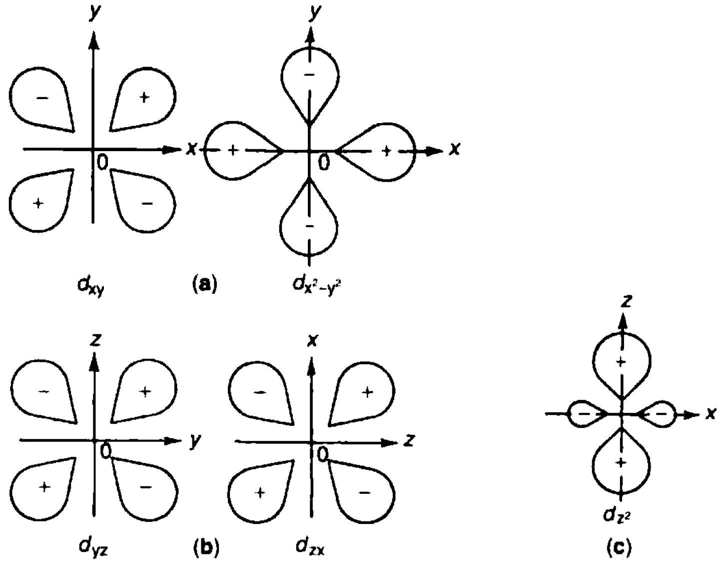

Fig. 1. Cross section of the five *d* orbitals, chosen in real form

The ion $[Ti(H_2O)_6]^{3+}$ has one *d* electron. In the ground state this will obviously occupy one of the t_{2g} orbitals. A transition is possible in which this electron is transferred to one of the e_g orbitals, and this occurs at 20,400 cm^{-1}. (The intensities of such transitions are low—ϵ_{max}; ≈10—as they are symmetry-forbidden.) The converse situation arises in the hydrated copper(II) ion which has nine *d* electrons. In this ion the vacancy in the *d* shell is one of the e_g orbitals. This vacancy can be filled by exciting an electron from one of the t_{2g} orbitals, giving rise to a transition at about 12,500 cm^{-1}. However, the ion $[Cu(H_2O)_6]^{2+}$ is strongly distorted in its ground state so that most of the degeneracy of the t_{2g} and e_g orbitals is removed and there is more than one transition in this region. From these two examples we see that the splitting between the t_{2g} and the e_g orbitals may be quite large, being usually in the range 20–50 kcal $mole^{-1}$.

It is only when we come to consider complexes with several *d* electrons that complications arise. If there are only two or three *d* electrons, both the above-mentioned tendencies can be satisfied simultaneously by placing the electrons in different t_{2g} orbitals with their spins parallel. However, when there are more than three *d* electrons this is no longer possible. If there are 4–7*d* electrons we then have the choice either of putting as many as possible into the low-energy t_{2g} orbital or distributing them so as to maintain a maximum number of parallel spins. This is illustrated in Table 1.

The former choice will be favored if the orbital separation Δ is large, and the latter will be realized if Δ is small. The value of Δ depends primarily on the nature of the ligand and the charge on the ion, and the following generalizations can be made for the first transition series. (1) For hydrated bivalent ions Δ falls in the range 7,500–12,500 cm^{-1}. (2) For hydrated tervalent ions Δ falls in the range 13,500–21,000 cm^{-1}. (3) The common ligands can be arranged in a sequence so that Δ for their complexes with any given metal increases along the sequence. A shortened series is I^-, Br^-, Cl^-, F^-H_2O, oxalate, pyridine, NH_3, ethylenediamine, NO_2^-, CN^-. Finally, Δ for the compounds of the second and third series is 40–80% larger than for corresponding compounds of the first series.

With these considerations in mind let us consider in turn the two extreme possibilities, known respectively as the "strong-field" and the "weak-field" case. If Δ is very large the tendency for electrons to go into separate orbitals will be outweighed by their tendency to occupy the t_{2g} orbitals (as against the e_g orbitals) in circumstances where these two tendencies conflict. In the strong-field case, therefore, a complex with up to six *d* electrons will have all these in t_{2g} orbitals with the maximum number of unpaired spins consistent with the restriction to the t_{2g} orbitals. As examples we may take the hexacyanoferrates(II) and (III) which possess six and five *d* electrons, respectively, all in t_{2g} orbitals with the maximum number of unpaired spins consistent with the restriction to the t_{2g} orbitals. As examples we may take the hexacyanoferrates(II) and hexacyanoferrates(III) which possess six and five *d* electrons respectively all in t_{2g} orbitals. The former has no unpaired electrons and the latter one. The next four electrons will then enter the e_g orbitals; the first two will go into different e_g orbitals with their spins parallel as in the octahedral complexes of Ni^{2+}. In Co^{2+} there is just one e_g electron.

The complex $[Co(NH_3)_6]^{3+}$ provides a good example of the strong-field case. The ground state is $(t_{2g})^6$ and the transitions observed at the longest wavelengths involve taking one of these electrons and putting it in an e_g orbital. According to the choice of the orbitals involved the final state may be one of the two triply degenerate states, and the bands associated with

TABLE 1. *d*-ELECTRON ARRANGEMENTS IN OCTAHEDRAL COMPLEXES

9	↑↓↑↓↑↓	↑↓↑	16	↑↓↑↓↑↓	↑↓↑	16	0

N Number of distinct pairs of electrons with parallel spin.

the two transitions have been observed for a number of d_6 complexes in each of the three transition series. (The separation between the bands is not in very good agreement with theory, however, so that it is difficult to obtain a reliable value of Δ for such cobalt(III) complexes. The reasons for this are not fully understood at present.)

The weak-field case is that in which the separation Δ is not large enough to overcome the tendency of the d electrons to go into different orbitals with their spins parallel. For example, in the hydrated manganese(II) ion the five d electrons each occupy one of the five d orbitals; this is because the separation Δ is insufficient to break up the highly stable half-filled shell in which all the electron spins are parallel. The same is true of $[Fe(H_2O)_6]^{3+}$ and of the hydrated iron(II) ion, which has six d electrons, the extra one being in one of the t_{2g} orbitals. It may be noted again that, only in those complexes containing four, five, six, or seven d electrons, is there an important distinction between the strong- and the weak-field cases; if there are one, two, or three d electrons, they will necessarily occupy t_{2g} orbitals, while if there are eight or nine, the vacancies in the d shell will occur in the e_g orbitals in both the strong- and the weak-field case.

CRYSTAL HABIT. The external shape of a crystal, which depends on the relative development of the different faces, as well as upon the interfacial angles characteristic of the crystal.

CRYSTAL (Homometric Pairs). Two crystal structures having the same x-ray diffraction pattern. This is possible because, basically, a diffraction pattern depends only on the relative vector distances between the atoms in the lattice, not on their absolute positions in space.

CRYSTAL (Isomorphous). One of two or more crystals which are similar in crystalline form and in chemical properties and are related in chemical composition in that one or more of the atoms and radicals in one are of similar chemical type to the corresponding atoms or radicals in the other. Usually, one or more of their other atoms or radicals are identical.

CRYSTALLIZATION. Crystals are formed (1) from solution, (2) from fusion, and (3) by sublimation.

The formation of crystals from solution, starting with an unsaturated solution, takes place when a solution is evaporated or cooled below the saturation point, except as retarded by supersaturation. Supersaturation is prevented by the addition of seed crystals of the substance. Since, in the case of the majority of soluble substances, solubility increases with increase of temperature cooling below the saturation point favors the formation of crystals. In very few cases, such as sodium sulfate above 32.4°C, calcium sulfate (slightly soluble), calcium hydroxide (slightly soluble), solubility decreases with increase of temperature, and the above statement would not apply. A case of wide scope and great importance is that of crystal formation by precipitation upon mixing two solutions. Actually, this is the same as for substances of greater solubility, since the substance precipitated is first formed in solution and the excess above the saturation point separates as precipitate. As a rule the crystals are larger and more perfect the slower their growth. Conversely, when small crystals are desired, rapid stirring and quick cooling are practical. The smaller the crystals of a given substance, the purer the material generally is. Small crystals may be increased in size by allowing them to stand in the mother liquor before separation.

An industrial forced-circulation evaporative crystallizer is shown in Fig. 1. Sizes range from 18 inches (~46 centimeters) to over 42 feet (12.6 meters) in diameter, with no inherent limit to the size of the vessel. Slurry is moved by the circulation pump through the heat exchanger, where it is subjected to a temperature rise of 2 to 10°F. The heated liquor is discharged tangentially into the body at a point sufficiently far beneath the surface so that the liquor entering tangentially is just at the boiling point for the liquid depth at which it is submerged. As the liquid rotates around the body and rises toward the surface, it starts to boil, and this boiling induces a secondary circulation which creates a spinning toroid of fluid within the body. Depending on the location of tangent inlet with respect to the cone, this toroidal circulation can result in considerable secondary circulation and agitation within the body of the vessel. When properly designed, this type of vessel is capable of producing a smooth boiling action with relatively small amounts of salt being deposited on the walls, while still maintaining a suitable suspension of product crystals within the boiling zone and in the lower part of the vessel. Crystalline materials produced in this type of equipment include sodium carbonate, sodium sulfate, and sodium chloride. Operating cycles of this equipment between washouts to remove salt growth from the walls of the body or from the heat exchangers normally range from 30 to 90 days.

To achieve some control of the number of fine particles within the crystallizer body, and thereby increase the overall particle size, it is necessary to selectively remove the fine particles so that they can be destroyed by the action of heat or dilution. A draft-tube baffle crystallizer of the type shown in Fig. 2 achieves these objectives. A body of growing crystals is suspended by the circulation flowing up the draft tube from the propeller shown close to the bottom of the vessel. From the areas surrounding this body of circulated slurry, a stream is removed at relatively low velocity so that gravitational settling will produce a separation between the product-size crystals and relatively fine crystals, which are removed with the clarified mother liquor leaving by the circulating pipe. In the draft-tube baffle crystallizer, both the velocity of the liquor in the settling zone and the quantity of liquor removed by the circulating pump are important to insure that the proper end-product size is achieved and that reasonable stability in particle size is obtained. The equipment is used to crystallize potassium chloride, ammonium sulfate, and other relatively fast-growing inorganic salts.

The foregoing descriptions cover only two of several industrial crystallizer configurations.

The formation of crystals from fusion takes place when the melted substance is cooled sufficiently slowly near and below the fusion point. If the cooling is rapid the fusion may result in the formation of an undercooled liquid of rigidity corresponding to a solid. Glasses, whether artificial, such as glass, vitreous enamels, and slags, or natural, such as vitreous rocks and minerals, e.g., obsidianite, are undercooled liquids. Rocks and minerals that have cooled sufficiently slowly from fusion form crystals, for example, granite. An important method of forming pure crystals is zone melting.

The formation of crystals by sublimation takes place when the vapor of a substance is condensed as a solid without passing through the liquid

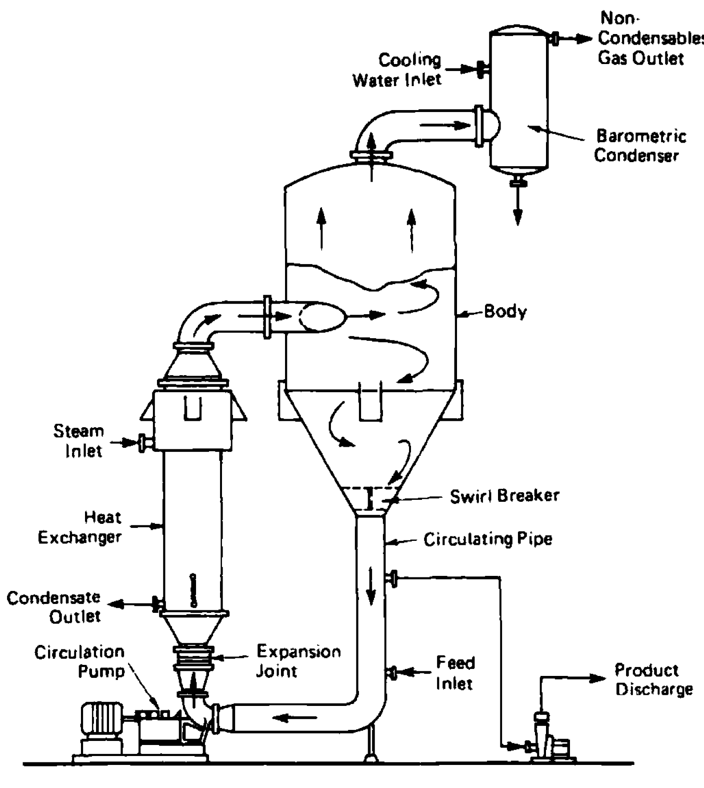

Fig. 1. Forced-circulation evaporative crystallizer

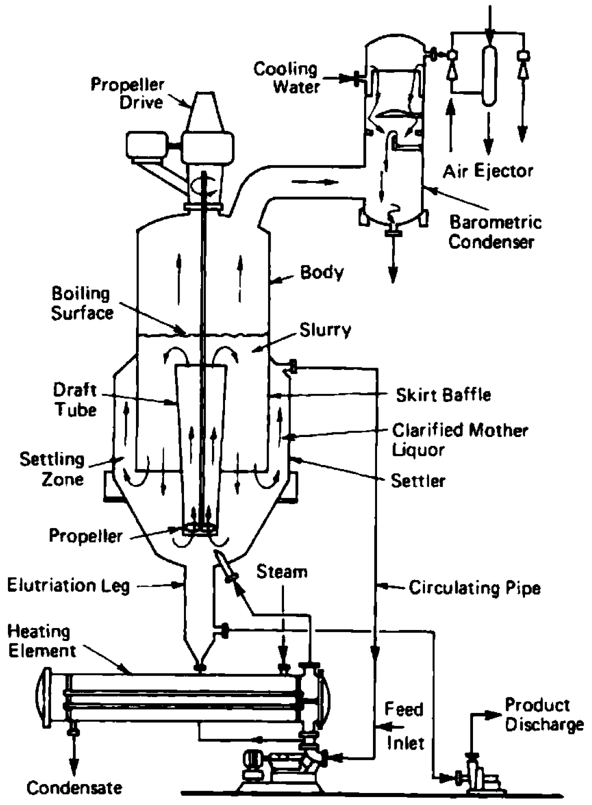

Fig. 2. Draft-tube baffle crystallizer

phase in so doing. This occurs when the temperature of the condenser is below that of the melting point of the substance.

The heat of crystallization is in amount the same as the heat of solution of a given substance but of opposite sign.

CRYSTALLOID. See **Colloid Systems**.

CRYSTAL (Mixed). A crystal consisting of two or more chemical compounds, which may have the same positive radical or the same negative radical, and which, in their pure form, are isomorphous, i.e., have the same crystal form.

CRYSTAL OSCILLATOR. This device is a precise mechanical resonator and frequency generator. The need for a stable, accurate, and low-cost frequency generator for the precise control of commercial radio and other higher communication frequencies led to the development of piezoelectric resonators, notably quartz crystals, for a wide variety of applications. The quartz crystal has become highly developed as a frequency standard for timekeeping and as a *time-signal* generator. See also **Piezoelectric Effect**.

Piezoelectricity was discovered by the Curie brothers in 1880. The term *piezo* is derived from the Greek word meaning "to press." The effect causes a crystal to exhibit electrical polarity when the crystal is subjected to mechanical pressure. Conversely, the crystal is physically deformed when subjected to an electrical potential. Specifically, piezoelectricity is a property of nonconducting solids that have a crystal lattice that does not have a center of symmetry.

Quartz, tourmaline, and rochelle salts and such synthetic crystals as ethylene diamine tartrate (EDT), dipotassium tartrate (DKT), and ammonium dihydrogen phosphate (ADP) have varying suitability as piezoelectric elements. Tourmaline, an expensive material used mainly in hydrostatic pressure-measuring devices, is more durable than quartz and, for a given frequency, normally is more rugged than quartz. Rochelle salt has a greater piezoelectric effect than any other crystal but has the disadvantage of a greater sensitivity to temperature change than quartz. EDT has an advantage over quartz when used in frequency-modulated oscillators because of the wide gap between its resonant and antiresonant frequencies.

All piezoelectric crystals should have a good temperature coefficient, that is, should show as little change in resonant frequency as possible under large variations in temperature. Ideally, the piezoelectric constant of proportionality between the mechanical and electrical variables must be the same for both direct (pressure-to-electricity) and converse effects.

Natural quartz crystal and new synthetic quartz crystal have been found best to meet the properties required of a piezoelectric element. Quartz is hard (7 on Mohs' scale as compared with a diamond, which is 10) and is relatively abundant and stable. Because of the anisotropic structure of quartz, cutting a crystal in different orientations makes it possible to obtain crystals for the widest range of applications, including frequency control, filters, resonators, and electromechanical transducers. Each of these uses depends on the orientation of the crystal cut with respect to the crystallographic axes. As shown in Fig. 1, the principal axes in quartz are identified as the optic (Z), the mechanical (Y), and the electrical (X) axes. By use of polarized light and x-ray diffraction techniques, the various axes may be properly located, permitting a crystal plate to be cut from the quartz with the performance characteristics desired. After cutting and extensive processing, the crystal plate is mounted at the nodal points of its normal vibration. These points, which also serve as electrical connecting points, allow the crystal to vibrate freely with a minimum of damping. Finally, the mounted crystal is hermetically sealed in a dry inert atmosphere within a crystal holder.

A stability of 1 part in a billion is routinely possible by the use of proportional ovens that can regulate the crystal temperature within $\pm 0.001^\circ C$. By employing multiplying or binary techniques, frequency-generating devices in the range of from less than 1 Hz to more than 600 MHz are available. In the temperature-compensated crystal oscillator (TCXO), stability over a wide range of temperatures is obtained by a compensating network that shifts the frequency of the crystal by an amount approximately equal and opposite to the shift of frequency caused by the

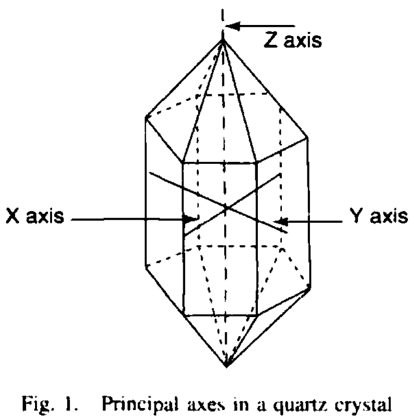

Fig. 1. Principal axes in a quartz crystal

temperature change. This network eliminates the need for an oven. TCXOs are available with temperature stabilities of ±0.5 ppm over a temperature range of minus 40 to plus 70°C.

CRYSTAL PHASES (α^-, β^-, γ^-, ϵ^-, η^-, etc.). Certain alloy systems may form different crystal structures, according to the relative proportions of the constituents, e.g., Cu-Zn, for which no less than five different phases are known. In many cases, the same crystal structure occurs with quite different constituent metals, so that it is often possible to use one expression such, for example, as β-phase, to cover a wide variety of compounds all having the same basic structure. This effect is explained by the Hume-Rother rules. Pure substances, as well as alloys, may exhibit more than one crystal structure, depending on temperature and past history, e.g., cobalt, iron, titanium.

CRYSTAL PICKUP. Since piezoelectric crystals produce electrical voltages when subjected to mechanical stresses they offer possibilities for various electromechanical processes. One of these is the phonograph pickup, where the phonograph needle operating in the groove of the record must transmit mechanical motion to something which will convert it into electrical effects so electronic amplifiers may be used. The crystal is one of the most sensitive and at the same time one of the highest fidelity devices for doing this. While many crystals exhibit the piezoelectric effect, Rochelle salt is the most sensitive and is used for pickups, microphones, etc. Among the other crystals used, quartz is noted for its durability. Through a mechanical linkage the motion of the needle is transmitted into mechanical stresses on the crystal and hence produces electrical effects which may be amplified and then converted to sound by the loudspeaker.

CUMMINGTONITE. The mineral cummingtonite is a variety of amphibole which is essentially $(Mg, Fe, Mn)Si_8O_{22}(OH)_2$, the amounts of magnesium and iron varying as they replace one another. Cummingtonite is generally restricted to material containing from 50 to 70% $MgSiO_3$. The name *grunerite* has been applied to cummingtonite which contains more than 50% $FeSiO_3$. Cummingtonite usually occurs as a dark green to brown fibrous to lamellar mineral. It derives its name from Cummington, Massachusetts. See also **Amphibole**.

CUMULATIVE EXCITATION. An excited atom, in the metastable state, may receive a further increment of energy by collision, as with an electron, and thus be raised to a still higher energy state. This process by which an atom is raised by collision from one excited state to higher states is known as cumulative excitation. In fact, it is possible for an atom in the metastable state to receive sufficient energy by this process to be ionized and this process is designated as cumulative ionization.

CUPRITE. The mineral cuprite, cuprous oxide, Cu_2O, occurs as isometric crystals, usually octahedrons, but may be cubes, dodecahedrons or modified combinations. It also is found as a massive, earthy material. Its fracture is conchoidal to uneven; brittle; hardness, 3.5–4; specific gravity, 6.14; luster, submetallic to earthy; color, red; nearly transparent to nearly opaque. Its streak is shining brownish-red. Cuprite is a secondary mineral resulting doubtless from the oxidation of copper sulfides. It is often found associated with native copper, malachite and azurite.

Cuprite is a fairly common mineral, and of the many localities in which it occurs may be mentioned the Province of Perm, in the former U.S.S.R.; Chessy, France; Broken Hill, New South Wales; Corocoro, Bolivia; Andacollo, Chile; Bisbee, Arizona; and Del Norte County, California. Magnificent large transparent red gem crystals, some with a coating of malachite, have been found at Ojunga, S.W. Africa. The name cuprite is derived from the Latin *cuprum*, copper.

CURIE, PIERRE (1859–1906) CURIE, MARIE (1867–1934). Pierre Currie was born and raised in Paris. With his brother, Jacques, he studied crystals and in 1880 discovered piezoelectricity. Piezoelectricity is the production of an electric charge by pressure on certain crystals. Pierre became director at the School of Industrial Physics and Chemistry in Paris where he worked for 22 years. His doctoral thesis on magnetism led to his discovery, the Curie point, a temperature at which ferromagnetic substances lose their magnetism.

Pierre met a Polish born woman named Marie Sklodovska when she was studying mathematics, chemistry, and physics at the Sorbonne. They married in July 1895 and began working together. In 1897, Marie began searching for a topic for her doctoral research. She became interested in Becquerel's work and decided to investigate the rays Becquerel had discovered coming from uranium. She discovered "radioactivity" from this work. Upon further research, Marie realized that the radiation coming from uranium ore was too large to be produced by uranium alone. Pierre stopped his research and began working with Marie on radioactivity in pitchblende. As a result, they discovered polonium and radium. It took the Curies years to obtain a few grains of pure radium. Their work revolutionized the scientific world's understanding of atomic structure. The Curies also introduced the technique of radiation therapy into medicine. In 1903, the Curies and Henri Becquerel shared the physics Nobel Prize for their work on radioactivity. Marie Curie was the first female recipient of a Nobel Prize.

In 1906, Pierre was killed. Marie continued her work, was the first woman to teach at the Sorbonne, and in 1911 won an unprecedented second Nobel Prize in chemistry for her discovery and study of polonium and radium. On July 4, 1934, Marie died of leukemia from exposure to radiation.

Marie's daughter, Irene, joined in the work at the Radium Institute. With her husband, Frederic Joliot, and under the combined name Joliot-Curie, continued the work of the Curies in 1935, the pair won a Nobel Prize for their discovery of artificial radioactivity.

See also **Curie-Weiss Law**; and **Radioactivity**.

J.M.I.

CURIE POINT (or Curie Temperature). Ferromagnetic materials lose their permanent or spontaneous magnetization above a critical temperature (different for different substances). This critical temperature is called the Curie point. Similarly, ferroelectric materials lose their spontaneous polarization above a critical temperature. For some such materials, this temperature is called the "upper Curie point," for there is also a "lower Curie point," below which the ferroelectric property disappears. See also **Ferromagnetism**.

CURIE-WEISS LAW. The transition from ferromagnetic to paramagnetic properties, which occurs in iron and other ferromagnetic substances at the Curie point, is accompanied by a change in the relationship of the magnetic susceptibility to the temperature. P. Curie stated in 1895 that above this point the susceptibility varies inversely as the absolute temperature. But this was found to be not generally true, and was modified in 1907 by P. Weiss to state that the susceptibility of a paramagnetic substance above the Curie point varies inversely as the excess of the temperature above that point. At or below the Curie point, the Curie-Weiss law does not hold.

CURIUM. [CAS: 7440-51-9]. Chemical element, symbol Cm, at. no. 96, at. wt. 247 (mass number of the most stable isotope), radioactive metal of the Actinide series, also one of the Transuranium elements, mp estimated 1350 ± 50°C. ^{247}Cm has a half-life of 1.64×10^7 years. Other long-lived isotopes are ^{245}Cm ($t_{1/2} = 9320$ years), ^{246}Cm ($t_{1/2} = 5480$ years), ^{248}Cm ($t_{1/2} = 4.7 \times 10^5$ years), and ^{250}Cm ($t_{1/2} = 2 \times 10^4$ years). Other known isotopes are ^{238}Cm, ^{242}Cm, ^{244}Cm, and ^{249}Cm. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^7 6s^2 6p^6 6d^1 7s^2.$$

Ionic radius: Cm^{3+} 0.98 Å. See also **Chemical Elements**.

First identified in 1944 by G.T. Seaborg, R.A. James, and A. Ghiorso, who found ^{242}Cm in the product obtained by bombarding ^{239}Pu with alpha particles of resonance energies. Later L.B. Werner and I. Perlman produced and isolated the same isotope by the action of neutrons upon ^{241}Am.

In experiments the concentration of curium must be kept low in order to avoid the formation of a reducing medium due to the action of the ^{242}Cm alpha particles on H_2O. At a concentration of 10^{-5} molar in curium, and under conditions where americium(III) is oxidized to americium(VI) in the same solution, the curium is not oxidized above the (III) state with ammonium peroxydisulfate.

The solubility properties of curium(III) compounds are in every way similar to those of the other tripositive Actinide elements and the tripositive Lanthanide elements. Thus the fluoride and oxalate are insoluble in acid solution, while the nitrate, halides, sulfate, perchlorate, and sulfide are all soluble.

Solid curium trifluoride has been prepared by drying the fluoride, which precipitates from dilute HNO_3 upon the addition of hydrofluoric acid.

Curium trifluoride can be reduced to the metal by heating at 1275°C in a beryllia crucible with barium vapor. The metal is silvery in color and has the properties of an *electropositive element* in common with the other Actinide elements.

The ion Cm^{3+} is colorless, as are its compounds generally. CmF_3 is hexagonal, Cm_2O_3 is white and CmO_2 is black and hexagonal. $CmCl_3$ is light yellow and hexagonal. Cm^{4+} is known in solution only as the complex fluoride.

In research at the Institute of Radiochemistry, Karlsruhe, West Germany during the early 1970s, investigators prepared alloys of curium with iridium, palladium, platinum, and rhodium. These alloys were prepared by hydrogen reduction of the curium oxide or fluoride in the presence of finely divided noble metals. The reaction is called a *coupled reaction* because the reduction of the metal oxide can be done in the presence of noble metals. The hydrogen must be extremely pure, with an oxygen content of less than 10^{-25} torr.

Curium was first isolated in the form of a pure compound, the hydroxide, of curium-242 (produced by the neutron irradiation of americium-241) by Werner and Perlman at the University of California in the autumn of 1947. Much of the earlier work with curium used the isotopes ^{242}Cm and ^{244}Cm, but the heavier isotopes offer greater advantages mainly because of their longer half-lives. The isotope ^{248}Cm, obtainable in relatively high isotopic purity as the alpha particle decay daughter of ^{252}Cf, is the most practical for chemical studies. See also **Radioactivity**.

A gram of ^{242}Cm generates approximately three thermal watts of energy-very high as compared with one-half thermal watt per gram of ^{238}Pu. This property has given consideration to the possible use of curium as an isotope power source.

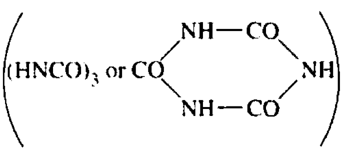
The trio won for the discovery of the C_{60} compound called buckminsterfullerene. He graduated from Rice University and received a Ph.D. from the University of California, Berkeley in1957.

See also **Buckminsterfullerene (Buckyballs)**; and **Carbon**.

CYANAMIDES. [CAS: 420-04-2]. Cyanamide NC·NH_2 or HN:C:NH is a white solid, melting point 44°C, boiling point 140°C at 20 mm pressure, transformed at 150°C into cyanuramide, tricyantriamide (NC·$NH_2)_3$. Cyanamide reacts (1) as a base with strong acids forming salts, (2) as an acid forming metallic salts, such as calcium cyanamide $CaCN_2$. Cyanamide is formed (1) by reaction of cyanogen chloride CN·Cl plus ammonia (ammonium chloride also formed), (2) by reaction of thiourea plus lead hydroxide (lead sulfide also formed).

When calcium cyanamide is boiled with water, dicyandiamide (NC·$NH_2)_2$, melting point 207°C is formed (along with calcium hydroxide). Fusion of dicyandiamide with sodium carbonate plus carbon produces sodium cyanide plus ammonia (also some tricyantriamide). Diethylcyanamide $(C_2H_5)_2N$·CN is a colorless liquid, boiling point 189°C at 748 mm pressure, and when hydrolyzed yields diethylamine $(C_2H_5)_2NH$ plus ammonia plus carbon dioxide. Diphenylcyanamide C_6H_5N:C:NC_6H_5 when hydrolyzed yields aniline plus carbon dioxide. Benzylcyanamide $C_6H_5CH_2$·NH·CN is a white solid, melting point 43°C.

CYANIC ACID AND RELATED COMPOUNDS. Cyanic acid, HCNO or HOCN, is a colorless, odorless liquid; soluble in water and in ether; volatile with decomposition when heated; passing at ordinary temperature into a mixture of cyanuric acid, $(HNCO)_3$, and cyamelide, $(CONH)_x$, white solid, which on vaporizing yields cyanic acid; when cyanic acid vapor is rapidly cooled in a freezing mixture, unstable, liquid cyanic acid is obtained, and when the vapor is condensed above 105°C, cyanuric acid



is obtained. Cyamelide dissolves in sulfuric acid unchanged and addition of water causes precipitation of cyamelide; passes into cyanuric acid when warmed with concentrated sulfuric acid, finally into carbon dioxide plus ammonia; dissolves in sodium hydroxide solution forming sodium cyanate. Sodium cyanate is prepared by heating sodium cyanide and an oxide such as lead monoxide, PbO, trilead tetroxide, Pb_3O_4, or lead dioxide, PbO_2, addition of water and separation of the sodium cyanate solution from the lead oxide by filtration. Sodium cyanate solution upon boiling changes into sodium carbonate plus urea, $CO(NH_2)_2$.

Ammonium cyanate, $CNONH_4$, white solid, formed by reaction of sodium cyanate and ammonium sulfate solutions, is transformed to urea upon being heated at 100°C. This reaction was carried out in 1828 by Wöhler, and is the first record of a so-called inorganic substance being transformed outside a living organism into a so-called organic substance. The following esters are known:

Methyl isocyanate, CH_3NCO, boiling point 44°C

Ethyl cyanate, C_2H_5OCN, decomposes on heating

Ethyl isocyanate, C_2H_5NCO, boiling point 60°C

Phenyl isocyanate, C_6H_5NCO, boiling point 166°C

Ethyl cyanurate 
Ethyl isocyanurate 
The extensive use of organic isocyanates in various industrial processes for production of high polymers has brought about tonnage production. Toluene diisocyanate is made by nitrating toluene to the dinitro compound, which is then reduced to the diamine, and treated with phosgene to obtain the diisocyanate:

$$C_6H_5CH_3 \xrightarrow{HNO_3} C_6H_3(NO_2)_2CH_3H \xrightarrow{H}$$

$$C_6H_3(NH_2)_2CH_3 \xrightarrow{COCl_2} C_6H_3(NCO)_2CH_3$$

Toluene diisocyanate is widely used in the manufacture of urethane plastics, particularly the urethane foamed plastics. Another isocyanate, diphenylmethane 4,4′-diisocyanate, is produced by reaction of aniline and formaldehyde, followed by reaction with phosgene:

$$2C_6H_5NH_2 \xrightarrow{HCHO} CH_2(C_6H_4HN_2)_2 \xrightarrow{COCl_2} CH_2(C_6H_4NCO)_2$$

The diphenylmethane 4,4′-diisocyanate is used in the manufacture of solid urethane elastomers (primarily for heavy-duty tires) and chemically resistant coatings.

Fulminic acid, HONC, and the fulminates are violently explosive. Utilizing this property, mercuric fulminate, $Hg(ONC)_2 \cdot \frac{1}{2}H_2O$, is used as a detonator for other explosives. Mercury fulminate is made by the reaction of ethyl alcohol and mercuric nitrate in excess of nitric acid, from which insoluble mercuric fulminate separates. Silver fulminate, Ag(ONC), is more explosive than mercuric fulminate, and is used in the manufacture of firecrackers. Free fulminic acid may be obtained by reaction of potassium fulminate and excess of ether. It volatilizes with the ether upon distilling, and changes rapidly to metafulminic acid. Related to fulminic acid is fulminuric acid, $(HONC)_3$, or NO_2·CH(CN)·$CONH_2$.

CYANOGEN. [CAS: 460-19-5]. Cyanogen $(CN)_2$ is a colorless gas of marked characteristic odor, very poisonous, density 1.8 (air equal to 1.0), melting point −28°C, boiling point −20°C, soluble. When passed into water at 0°C, cyanogen forms hydrocyanic acid plus cyanic acid, but at ordinary temperatures the reaction is complex. With sodium hydroxide solution, there is formed with cyanogen sodium cyanide plus sodium cyanate, with dilute sulfuric acid oxamic acid $COOH{\cdot}CONH_2$, oxalic acid $COOH{\cdot}COOH$. By reaction with tin and hydrochloric acid, cyanogen is reduced to ethylene diamine $CH_2{\cdot}NH_2{\cdot}CH_2{\cdot}NH_2$. Cyanogen reacts with hydrogen to form hydrocyanic acid, and with metals, e.g., zinc, copper, lead, mercury, silver, to form cyanides. Cyanogen, (1) when burned in air produces a violet flame forming carbon dioxide and nitrogen in the outer part and carbon monoxide and nitrogen in the inner part, (2) when exploded with oxygen produces carbon dioxide or carbon monoxide and nitrogen depending upon the ratio of oxygen to cyanogen (2 volumes oxygen plus 1 volume cyanogen yields 2 volumes carbon dioxide plus 1 volume nitrogen; 1 volume oxygen plus 1 volume cyanogen yields 2 volumes carbon monoxide plus 1 volume nitrogen). The flame spectrum contains characteristic bands in the blue and violet. By means of the electric spark, the electric arc or a red hot tube, cyanogen is decomposed into carbon plus nitrogen. When heated at ordinary pressure at about 300°C, or under 300 atmospheres pressure at about 225°, cyanogen is converted into paracyanogen, a brown powder, also formed when mercuric cyanide is heated. Cyanogen is prepared (1) by reaction of sodium cyanide and copper sulfate solutions, whereby one half the cyanogen is evolved as cyanogen gas and one half remains as cuprous cyanide. From the filtered cuprous cyanide, by treatment with ferric chloride solution, cyanogen is evolved with accompanying formation of ferrous chloride, (2) by heating ammonium oxalate $COONH_4{\cdot}COONH_4$ with phosphorus pentoxide, water being abstracted. Small amounts of cyanogen are present in blast furnace gas and raw coal gas.

CYANOHYDRINS. A cyanohydrin is an organic compound that contains both a cyanide and a hydroxy group on an aliphatic section of the molecule. Cyanohydrins are usually α-hydroxy nitriles which are the products of base-catalyzed addition of hydrogen cyanide to the carbonyl group of aldehydes and ketones. The IUPAC name for cyanohydrins is based on the α-hydroxy nitrile name. Common names of cyanohydrins are derived from the aldehyde or ketone from which they are formed.

The outstanding chemical property of cyanohydrins is the ready conversion to α-hydroxy acids and derivatives, especially α-amino and α,β-unsaturated acids. Because cyanohydrins are primarily used as chemical intermediates, data on production and prices are not usually published. The industrial significance of cyanohydrins is waning as more direct and efficient routes to the desired products are developed.

Properties

Cyanohydrins are usually colorless to straw yellow liquids with an objectionable odor akin to that of hydrogen cyanide. Table 1 list physical properties of some common cyanohydrins.

Cyanohydrins can react either at the nitrile group or at the hydroxyl group.

Preparation

Cyanohydrins can be formed by the acid- or base-catalyzed reaction of hydrogen cyanide with an aldehyde or ketone, the displacement of bisulfite ion by cyanide ion on the bisulfite addition compounds of aldehydes and ketones, or the exchange of cyanide ion between a ketone cyanohydrin and an aldehyde to give the usually more stable aldehyde cyanohydrin.

Shipping, Storage, and Handling

Cyanohydrins should be stabilized with acid to pH 3–4 to prevent decomposition to hydrogen cyanide and carbonyl compound. When cyanohydrins are shipped, steel drums, carboys, tank cars, and barges are used. In general, cyanohydrins are combustible liquids and many decompose upon heating. They should be stored in a cool, dry place, preferably outside and separated from other storage. Containers should be protected against physical damage.

Health and Safety

Cyanohydrins are highly toxic by inhalation or ingestion, and moderately toxic through skin absorption. Special protective clothing should be worn and any exposure should be avoided. The area should be adequately ventilated. Immediate medical attention is essential in case of cyanohydrin poisoning.

Specific Compounds

Formaldehyde Cyanohydrin. This cyanohydrin, also known as glycolonitrile, is a colorless liquid with a cyanide odor. It is soluble in water, alcohol, and diethyl ether. Equimolar amounts of 37% formaldehyde and aqueous hydrogen cyanide mixed with a sodium hydroxide catalyst at 2°C for one hour give formaldehyde cyanohydrin in 79.5% yield.

Acetaldehyde Cyanohydrin. This cyanohydrin, commonly known as lactonitrile, is soluble in water and alcohol, but insoluble in diethyl ether and carbon disulfide. Lactonitrile is used chiefly to manufacture lactic acid and its derivatives, primarily ethyl lactate. Lactonitrile is manufactured from equimolar amounts of acetaldehyde and hydrogen cyanide containing 1.5% of 20% NaOH at −10–20°C. The product is stabilized with sulfuric acid.

Acetone Cyanohydrin. This cyanohydrin, also known as α-hydroxyisobutyronitrile and 2-methyllactonitrile, is very soluble in water, diethyl ether, and alcohol, but only slightly soluble in carbon disulfide or petroleum ether. Acetone cyanohydrin is the most important commercial cyanohydrin as it offers the principal commercial route to methacrylic acid and its derivatives, mainly methyl methacrylate. see also **Methacrylic Acid and Derivatives**. The principal U.S. manufacturers are Rohm and Haas Company, DuPont, CyRo Industries, and BP Chemicals.

Acetone cyanohydrin is manufactured by the direct reaction of hydrogen cyanide with acetone, catalyzed by base, generally in a continuous process.

Benzaldehyde Cyanohydrin. This cyanohydrin, also known as mandelonitrile, is a yellow, oily liquid, insoluble in water, but soluble in alcohol and diethyl ether. Mandelonitrile is a component of the glycoside amygdalin, a precursor of laetrile found in the leaves and seeds on most ***Prunus*** species (plum, peach, apricot, etc). It is commercially prepared from benzaldehyde and hydrogen cyanide.

Ethylene Cyanohydrin. This cyanohydrin, also known as hydracrylonitrile or glycocyanohydrin, is a straw-colored liquid miscible with water, acetone, methyl ethyl ketone, and ethanol, and is insoluble in benzene, carbon disulfide, and carbon tetrachloride. Ethylene cyanohydrin differs from the other cyanohydrins discussed here in that it is a β-cyanohydrin. It is formed by the reaction of ethylene oxide with hydrogen cyanide.

CYBOTAXIS. A condition in which certain liquids, under x-ray examination, give evidence of structure resembling that of crystals. By passing a beam of x-rays through various alcohols and other organic liquids, G.W. Stewart and his collaborators have obtained one, two, or even three diffraction maxima or halos, somewhat like the diffraction rings produced by powdered crystals. These suggest that molecules are temporarily arranged in rows, layers, or stacks like bricks in a pile and that they have one, two, or even three different dimensions or spacings, corresponding, in accordance with Bragg's law, to the different angles of diffraction observed.

A closely related property is exhibited by certain substances known as "liquid crystals," which appear to be intermediate between merely cybotactic liquids and true crystals. In these there appear to be large groups of molecules which, though able to move and turn about, retain their structural arrangement. Such mesomorphic substances manifest even some of the optical properties of crystals, which the former type do not.

See also **Liquid Crystals**.

CYCLOHEXANOL-CYCLOHEXANONE. Cyclohexanol is a colorless, viscous liquid with a camphoraceous odor. It is used chiefly as a chemical intermediate, a stabilizer, and a homogenizer for various soap detergent emulsions, and as a solvent for lacquers and varnishes. Cyclohexanol was first prepared by the treatment of 4-iodocyclohexanol with zinc dust in glacial acetic acid, and later by the catalytic hydrogenation of phenol at elevated temperatures and pressures.

Cyclohexanone is a colorless, mobile liquid with an odor suggestive of peppermint and acetone. Cyclohexanone is used chiefly as a chemical intermediate and as a solvent for resins, lacquers, dyes, and insecticides. Cyclohexanone was first prepared by the dry distillation of calcium pimelate, $-OOC(CH_2)_5COO^- Ca^{2-}$, and later by Bouveault by the catalytic dehydrogenation of cyclohexanol.

Physical Properties

Important physical properties of cyclohexanol and cyclohexanone are shown in Table 1. Cyclohexanol is miscible in all proportions with most organic solvents, including those customarily used in lacquers. It dissolves many oils, waxes, gums, and resins.

Cyclohexanone is miscible with methanol, ethanol, acetone, benzene, *n*-hexane, nitrobenzene, diethyl ether, naphtha, xylene, ethylene glycol, isoamyl acetate, diethylamine, and most organic solvents. This ketone dissolves cellulose nitrate, acetate, and ethers, vinyl resins, raw rubber, waxes, fats, shellac, basic dyes, oils, latex, bitumen, kaure, elemi, and many other organic compounds.

Reactions

Cyclohexanol shows most of the typical reactions of secondary alcohols. Cyclohexanone shows most of the typical reactions of aliphatic ketones.

Economic Aspects

Estimated annual cyclohexanone production capacities were 665×10^3 t in 1992; the production is greater than 90% captive for caprolactam production. The annual cyclohexanol production is only 10 thousand metric tons. These production figures do not include KA-oil (cyclohexanol-cyclohexanone) production for adipic acid. Worldwide annual capacity for cyclohexanone is approximately 3.0 million metric tons, also primarily for caprolactam production. Projected new capacity for caprolactam could add 0.5 million metric tons worldwide in this decade.

[a] To convert J to cal, divide by 4.184.

Health and Safety Factors

Cyclohexanol is slightly toxic by the oral route of exposure and is slightly irritating to the skin. It can cause severe eye irritation and transient corneal injury.

The ACGIH threshold limit value (TLV), time-weighted average for an 8-h workday, 40-h workweek, was set at 50 ppm (~ 200 mg/m^3) with a notation for skin absorption.

Cyclohexanone has only slight toxicity by the oral, dermal, and inhalation routes of exposure. Liquid or vapor exposures may result in transient corneal injury. Primary irritation and defatting of the skin can result from substantial or prolonged contact with cyclohexanone. Exposure to high vapor concentrations can cause central nervous system (CNS) depression, an effect which can also occur after ingestion or repeated dermal exposure.

The time-weighted average OSHA permissible exposure limit (PEL), as well as the ACGIH threshold limit value (TLV), for cyclohexanone is 25 ppm (100 mg/m^3) with a notation for skin absorption.

The precautions usually observed when handling volatile solvents should be observed as a matter of course with cyclohexanone and cyclohexanol. These include adequate and proper ventilation, avoidance of prolonged breathing of vapor or contact of the liquid with the skin, avoidance of internal consumption, and protection of the eyes against splashing liquids.

CYCLOTRON. A device for accelerating charged particles to high energies by giving particles traveling in a spiral path successive increments of energy from an alternating electric field between electrodes placed in a constant magnetic field. The path radius increases as energy increases. It was invented in 1929 by E. O. Lawrence (1901–1958) at the University of California at Berkeley. It is now used chiefly for basic nuclear research.

CYSTEINE. See **Amino Acids**.

CYSTINE. See **Amino Acids**.

CYTOCHROMES. The cytochrome *c*-cytochrome oxidase system represents the terminal segment of the respiratory chain common to the vast majority of organisms utilizing oxygen as the terminal oxidant in tissue respiration. The complete respiratory chain consists of a number of electron carriers, both protein and nonprotein in nature, organized in a definite sequence within the walls and internal partitions of subcellular organelles known as mitochondria. These structures carry the electrons that come from the substrates being oxidized and eventually react with oxygen. The energy released in several of the many steps of this series of reactions is utilized to make the high-energy compound adenosine triphosphate, a process known as *oxidative phosphorylation*. The high-energy compound is, in turn, employed to drive the many reactions of metabolism which require chemical energy. Every component of the terminal respiratory chain is reduced by the component immediately proceeding it and then reduces the component immediately following it in the chain, itself becoming reoxidized. The *c*-cytochrome oxidase system is common to all vertebrates and invertebrates, plants, as well as numerous microorganisms, and must

be distinguished from systems having similar functions, but very different properties, which occur in numerous bacteria.

The cytochromes were first observed by MacMunn as early as 1886. He described their spectral absorption bands in a large variety of organisms and tissues. His discovery was, however, forgotten after a controversy with Hoppe-Seyler had raised doubts as to the validity of some of his conclusions, and it was not until 1925 that Keilin independently rediscovered the remarkable cytochrome spectrum in the flight muscles of a living insect.

Keilin's observations came at a time when the understanding of tissue respiration had advanced to the point of providing the foundations necessary for the unraveling of the physiological role and chemical nature of cytochromes. The first step had indeed been taken some 40 years earlier by Ehrlich when he found that a variety of animal tissues could transform a mixture of α-napththol and dimethyl-*p*-phenylenediamine to indophenol, in the presence of oxygen. A decade later, the enzyme responsible for this effect had been named indophenol oxidase, and it was shown that its activity was inhibited by cyanide. In the first decades of the twentieth century, Warburg, from studies of the catalysis of the oxidation of cysteine by iron-charcoal, considered a "model" of cellular respiration. He concluded that oxygen activation was the all-important process in cellular respiration and that an iron-containing enzyme, the "respiratory enzyme" or *Atmungsferment*, is solely responsible for the transport of the oxidizing equivalents of oxygen to the substrates. An opposing view was taken by Thunberg, who had detected a large variety of dehydrogenases in tissues, and by Wieland, who used palladium-hydrogen as a "model" of tissue respiration and believed that substrate-specific hydrogen activations were characteristic of all biological oxidation processes, the reaction with oxygen being nonspecific and relatively unimportant.

The controversy as to the respective roles and importance of hydrogen and oxygen activation faded into the background when, following his initial observations, Keilin demonstrated that the four-banded spectrum of cytochrome, observed in a large variety of tissues and organisms, was in fact the spectrum of the ferrous, or reduced, forms of three distinct cytochromes—cytochrome *a*, cytochrome *b* and cytochrome *c*. Keilin obtained a soluble preparation of cytochrome *c* from baker's yeast, and together with Hartree, in 1938–1939, showed that the indophenol oxidase activity of particulate tissue preparations was simply the result of a nonenzymic reduction of cytochrome *c* by dimethyl-*p*-phenylenediamine, the reduced heme protein being oxidized by indophenol oxidase in the presence of oxygen. Having established the nature of the final steps of tissue respiration, they renamed the enzyme "cytochrome oxidase," since its only function appeared to be the oxidation of cytochrome *c*. There had been no doubt of the overwhelming physiological importance of the system ever since 1934, when Haas found that, in a number of tissues, the rate of oxygen uptake was identical to that of cytochrome *c* reduction, demonstrating that nearly all of the oxidizing equivalents of oxygen were transmitted by the cytochrome *c*-cytochrome oxidase system.

That the material in tissues reacting directly with oxygen was in fact a heme compound had been shown by the experiments of Warburg and collaborators on the effect of carbon monoxide on tissue respiration, carried out in the late 1920s. Warburg observed that carbon monoxide inhibits the uptake of oxygen by tissues and that this inhibition is reversed in bright light. Using this phenomenon, he succeeded in measuring the absorption spectrum of the carbon monoxide complex of the respiratory enzyme, a spectrum that turned out to be clearly that of a heme compound. Thus, when Keilin and Hartree in 1939 found that in the presence of carbon monoxide, cytochrome *a* showed up as two spectroscopic components, they were able to demonstrate that the new cytochrome, cytochrome a_3, was the substance responsible for the photochemical action spectrum of Warburg. Cytochrome a_3 was thus identified with the respiratory enzyme reacting directly with oxygen, and the system was considered to be composed of three entities, cytochromes *c*, *a*, and a_3, reacting consecutively, like all the other components of the respiratory chain.

Cytochrome *c* consists of a polypeptide chain, from 104 to 108 amino acid residues in length. A single heme prosthetic group is attached by thioether bonds formed between the sulfhydryl side chains of two cysteine residues in the protein and the vinyl side chains of the porphyrin ring as shown by

CYTOTOXIC CHEMICALS. Chemical agents that damage cells to which they are applied. They are poisons, to which cells respond with injury, disease, or death. There are multitudes of cytotoxic chemicals; they act by a variety of mechanisms; and they have many different kinds of effects. See also **Carcinogens**.

A simplistic classification can start with biological alkylating agents of which a great variety exists. They all possess the ability to add alkyl groups to a wide range of electronegative groups under mild aqueous conditions. It is thought that some destroy growing cells by cross-linking the adjacent guanidine molecules on DNA. Others cause breaks in chromosomes while yet others uncouple oxidative phosphorylation, which leads to a loss of ADP and ATP and accumulation of AMP.

Antimetabolites are analogs of folic acid, the purines and the pyrimidines. In the first group, the effect is to block DNA synthesis by interfering with the deoxyuridylic acid → deoxythymidilic acid step. The second interferes with DNA synthesis by blocking conversion of inosinic acid to adenylsuccinic acid and xanthylic acid. Pyridimine analogs inhibit deoxythymidilic acid syntheses which results in failure of DNA synthesis and the death of proliferating cells.

Several antibiotics are also cytotoxic and combine with DNA, blocking its template activity in directing the synthesis of messenger RNA.

Many of these cytotoxic chemicals find application in treating various forms of cancer, but it must be remembered that they all also affect normal cells and their introduction to body organs can only be treated with great care and even apprehension.

D

DACITE. The name of a somewhat variable group of extrusive igneous rocks similar to the rhyolites but richer in plagioclase feldspar. Typical dacites are felsitic to porphyritic in texture. Dacites are the extrusive equivalents of the quartz-rich varieties of diorites and are sometimes classified as quartz-bearing andesites. The porphyritic types usually occur toward the center of the thicker dacite flows, dikes and sills, as well as the marginal zones of laccoliths. Dacites are common in the Cordilleran province of North, Central and South America. The term, dacite, was proposed by G. Stache of Austria for lavas in the old Roman province of Dacia.

DALTON, JOHN (1766–1844). Dalton was an English scientist who worked in the fields of biology, chemistry, earth science, mathematics, and physics. He became a professor of mathematics at the New College in Manchester, England. His beginning research work was on meteorology. Early in his career, he also studied color blindness. This was of special interest to him since Dalton was himself color-blind.

His teaching career required teaching chemistry and he began researching chemistry and meteorology and soon he proposed that in a mixture of gases, each component acts independently of the other gases present. This proposal is known as Dalton's Law. Continued research in this field led him to consider the nature of matter and he began to develop a systematic atomic theory based on quantitative chemical principles.

See also **Dalton Law**.

J.M.I.

DALTONIDE COMPOUNDS. See **Chemical Composition**.

DALTON LAW. The law of partial pressures in mixed gases and vapors. If several gases not reacting chemically with each other are introduced into the same container, the pressure of the resulting mixture is equal to the sum of the pressures which would be observed if each gas were separately enclosed in that container. We may, for example, regard the atmospheric pressure as the sum of a nitrogen pressure, an oxygen pressure, an argon pressure, a carbon dioxide pressure, a water-vapor pressure, etc. The same principle holds for mixtures of the saturated vapors of two or more liquids evaporating in the same closed space, provided one liquid does not dissolve the vapor from the other (as water dissolves ammonia). Like other gas laws, this law is approximately valid only within limits. See also **Combustion (Fuels)**.

DANBURITE. The mineral danburite, $CaB_2Si_2O_8$, calcium-boron silicate, crystallizes in the orthorhombic system in prismatic forms somewhat resembling the mineral topaz. Its fracture is subconchoidal; brittle; hardness, 7; specific gravity, 2.97–3.02; color, colorless, yellowish-white, yellow, dark wine yellow and brownish-yellow; luster, vitreous to greasy; translucent to transparent. It is found at Danbury, Connecticut, from whence its name was derived, Saint Lawrence County, New York, Switzerland, Japan, and Madagascar.

DARCY'S LAW. The volumetric rate of flow of water through a sand filter bed is directly proportional to the cross-sectional area of the bed and the pressure difference across the bed, and inversely proportional to the thickness of the bed.

DARMSTADIUM. See **Chemical Elements**.

DATOLITE. Datolite, basic calcium boron silicate, $CaBSiO_4(OH)$, occurs in monoclinic crystals of varied habit, mostly short stout prisms, but often in highly modified forms. Datolite reveals no cleavage, its fracture is conchoidal to uneven; brittle; hardness, 5–5.5; specific gravity, 2.9–3.0; luster, vitreous to dull; color, white to gray or may be greenish, yellowish, or brownish. It has a white streak and is transparent to translucent usually, but has been observed opaque.

Datolite is a secondary mineral, being found in veins and cavities associated with zeolites and calcite, particularly in the basic igneous rocks. It has been found in the Harz Mountains, Germany; in the Trentino district, Italy; in Norway and Tasmania. In the United States it has been found in the Triassic traps of the Connecticut River Valley in Massachusetts and Connecticut, and from similar rocks in New Jersey. In Michigan, datolite has been found associated with the copper-bearing rocks of Keweenaw County. This mineral derives its name from the Greek word meaning to divide, in reference to the granular structures of some of the massive varieties.

DAVY, SIR HUMPHRY (1778–1829). Born in Cornwell, Davy was the first to isolate the alkali metals and recognize the identity of chemical and electrical energy. A pioneer in the science of electrochemistry, he carried out basic studies of electrolysis of salts and water, and his application of electricity to the decomposition of molten caustic potash led to the isolation of metallic potassium.

DEACON PROCESS. A method of converting hydrogen chloride to chlorine by oxidation of hydrogen chloride with oxygen at 400–500°C over a copper-salt catalyst, $2HCl + O \rightarrow Cl_2 + H_2O$. It is a means of producing chlorine without caustic and of utilizing the large amounts of by-product hydrogen chloride from the chlorination of organic compounds. When conducted in the presence of an organic compound that reacts with the chlorine formed, it is known as oxychlorination, e.g., $CH_2{=}CH_2 + 2HCl + O \rightarrow CH_2ClCH_2Cl + H_2O$.

DEARATION. Because water dissolves, to a greater or lesser extent, many common gases, it will contain in the natural state a certain amount of dissolved gases, such as oxygen and carbon dioxide. Deaeration is the removal of this dissolved gas. Deaeration at the present is practiced where the gas that water contains would have undesirable effects. Often dissolved oxygen is objectionable because of its corrosive action. This is true in the case of the high-pressure steam boiler, where a small amount of oxygen dissolved in the feedwater may become quite active in attacking the boiler metal under the high pressure and temperature conditions there experienced. Steam boiler operators often treat their boiler feedwater in deaerators to remove this oxygen.

These deaerators are either of the deactivating or the heating type. Deactivating types employ chemical means of deaeration. Deaerating action in a heating-type deaerator is obtained by first reducing the solubility of the gas through heating the water (under pressure); second, reducing the pressure and producing explosive boiling; and third, controlling the agitation of the water subsequent to the second action in a partially evacuated region.

DE BROGLIE, LOUIS-VICTOR (1892–1987). de Broglie was a remarkable French physicist. He studied at the Sorbonne in Paris, and although he entered as a history student, he later turned to science. He became a professor of theoretical physics at the Sorbonne in 1932. He was researching at about the same time that Arthur Compton, and de Broglie's s doctoral thesis showing the electron was demonstrated to have a wave character, made Compton's finding more significant. In 1923, de Broglie published three papers on light quanta. In his dissertation he described wave-particle duality, how matter waves should behave, and suggested it should be possible to diffract a beam of electrons using crystal. His

theory advanced the study of physics significantly. For his work, de Broglie received the Nobel Prize in 1929. He wrote forty-five books on physics in his lifetime.

Professor de Broglie's most important publications are:

Recherches sur la théorie des quanta (Researches on the quantum theory), Thesis Paris, 1924.

Ondes et mouvements (Waves and motions), Gauthier-Villars, Paris, 1926.

Rapport au 5e Conseil de Physique Solvay, Brussels, 1927.

La mécanique ondulatoire (Wave mechanics), Gauthier-Villars, Paris, 1928.

Une tentative d'interprétation causale et non linéaire de la mécanique ondulatoire: la théorie de la double solution, Gauthier-Villars, Paris, 1956.

English translation: *Non-linear Wave Mechanics: A Causal Interpretation*, Elsevier, Amsterdam, 1960.

Introduction á la nouvelle thèorie des particules de M.Jean-Pierre Vigier et de ses collaborateurs, Gauthier-Villars, Paris, 1961.

English translation: *Introduction to the Vigier Theory of elementary particles*. Elsevier, Amsterdam, 1963.

Étude critique des bases de l'interprétation actuelle de la mécanique ondulatoire, Gauthier-Villars, Paris, 1963.

English translation: *The Current Interpretation of Wave Mechanics: A Critical Study*, Elsevier, Amsterdam, 1964.

See also **de Broglie Wavelength**; **Electron Theory**; and **Quantum Number**

J.M.I.

DE BROGLIE WAVELENGTH. A wavelength ascribed to any particle having momentum. For a relativistic particle, the value of this wavelength is given by the expression:

$$\lambda = \frac{h}{mv} = \frac{h}{m_0 v}\sqrt{\frac{1 - v^2}{c^2}}$$

where λ is the de Broglie wavelength, h is the Planck constant, m_0 is the rest mass of the particle, v is its velocity, and c is the velocity of light. The observed mass of the particle is m and the momentum is mv.

As an example, the wavelength of an electron moving with a kinetic energy of 1 eV (electron volt) is 1.23×10^{-7} cm, shorter than the wavelength $\lambda = c/v = hc/hv = 1.24 \times 10^{-4}$ cm for a photon with an energy of 1 eV, but longer than the wavelength of a proton moving with a kinetic energy of 1 eV, which is $\lambda = 2.86 \times 10^{-9}$ cm.

DEBYE-FALKENHAGEN EFFECT. The variation of the conductance of an electrolytic solution with frequency. This effect, which is noted at high frequencies, is also called the dispersion of conductance.

DEBYE-HÜCKEL LIMITING LAW. The departure from ideal behavior in a given solvent is governed by the ionic strength of the medium and the valences of the ions of the electrolyte, but is independent of their chemical nature. For dilute solutions, the logarithm of the mean activity is proportional to the product of the cation valence, anion valence, and square root of ionic strength giving the equation

$$-\log f_{\pm} = Az + z - \sqrt{\mu}$$

See **Electrochemistry**.

DEBYE, PETER J. W. (1884–1966). A Dutch chemist and physicist who received the Nobel prize for chemistry in 1936 for his contributions to our knowledge of molecular structure through his investigations on dipole moments and on the diffraction of X-rays and electrons in gases. The interference patterns are still called Debye-Sherrer rings. He also made outstanding contributions to knowledge or polar molecules and to fundamental electrochemical theory.

DEBYE-SEARS EFFECT. A piezoelectric crystal vibrating in a longitudinal mode in a liquid sets up acoustic waves consisting of regions of compression and regions of rarefaction in the liquid, which alternate at distances of half a wavelength. Hence, if a parallel beam of light shines through such a crystal tank with plate-glass walls, the regions of density and rarefaction act like a plane light diffraction-grating. If the parallel beam from the cell is focused on a single spot when no sound waves are present, first and higher order diffraction-spectra will appear on either side of the zero-order spot when sound waves are present. From the spacings of the diffraction orders, the sound wavelength can be determined, which, together with the frequency, gives the velocity of sound in the liquid. See **Piezoelectric Effect**.

DEBYE THEORY OF SPECIFIC HEAT. The specific heat of solids is attributed to the excitation of thermal vibrations of the lattice, whose spectrum is taken to be similar to that of an elastic continuum, except that it is cut off at a maximum frequency in such a way that the total number of vibrational modes is equal to the total number of degrees of freedom of the lattice.

The Debye temperature is defined by the relation

$$\Theta = \frac{hv}{k}$$

where v is the maximum frequency of the thermal vibrations of the lattice, h is Planck's constant and k is the Boltzmann constant.

DECARBURIZATION. Reduction in carbon content at the surface of steel or cast iron by heating in air or other oxidizing or reducing gases. In heating for hot rolling, forging, or heat treatment, decarburization is usually objectionable, and specially prepared neutral furnace atmospheres may be used to reduce or eliminate it. Molten salt or lead baths are also effective in protecting the surface during heat treatment.

In the case of heat-treated machine parts, surface decarburization is objectionable because it reduces fatigue strength and lowers the wear-resistance of bearing surfaces. Important surfaces of hardened steel parts are often finish-ground, in which case a limited amount of decarburized skin can be removed. Tool steels for cutting tools, punches, chisels, etc., are usually ground sufficiently to remove all decarburization; however, many tools and dies are machined to finish dimensions before hardening and extreme care must be taken to protect the surface.

Decarburization is intentional in the processing of low-carbon sheet steels for electrical applications. In the production of malleable cast iron by annealing white cast iron decarburization is beneficial.

DECAY PRODUCT. A nuclide resulting from the radioactive disintegration of a radionuclide, being formed either directly or as the result of successive transformations in a radioactive series. Also called *daughter*, or *daughter element*. A decay product may be either radioactive or stable.

DECOLORIZING AGENTS. A substance that removes color by a physical or chemical action. Charcoals, carbon blacks, clays, earths, activated alumina or bauxite, or other materials of highly adsorbent character are used to remove undesirable colors (and often odors) from sugar, vegetable and animal fats and oils, and other substances. In a broad sense, decolorizing agents also embrace bleaches, which usually remove color by chemical reaction.

Activated carbon is one of the most widely used of the adsorbants. It is an amorphous form of carbon characterized by high adsorptivity. The carbon is obtained by the destructive distillation of wood, nut shells, animal bones, or other carbonaceous material. It is "activated" by heating to 800–900°C with steam or carbon dioxide, which results in a porous internal structure. The internal surface area of activated carbon averages about 10,000 square feet (929 square meters) per gram. Numerous uses include applications in the brewing and sugar refining industries.

Diatomaceous earth also finds numerous adsorbant applications in food and chemical processing, not only in decolorizing, but as a filter aid and clarifying agent as well. This is a soft, bulky solid material (88% silica) composed of skeletons of small prehistoric aquatic plants related to algae. See also **Diatomite**. They have intricate geometric forms and expose a great deal of area per unit of weight.

Fuller's earth, also used as an adsorbant, is a porous colloidal aluminum silicate (clay) which has a high natural adsorptive power. See also **Fuller's Earth**.

Silica gel is a regenerative adsorbant consisting of amorphous silica derived from sodium silicate and sulfuric acid. In addition to color

adsorbing and bleaching powers, silica gel is used as a dehumidifying and dehydrating agent and as an anticaking agent.

Prior to crystallization in the refining of sugar, bleaching of the syrup is required. This is sometimes effected through treatment of the solution with calcium hypochlorite, usually in the presence of calcium phosphate which serves as a buffer and aids in the final precipitation of calcium from the bleached solution.

The physical properties of representative adsorbants and decolorizers are given in table in entry on **Adsorption**.

DECOMPOSITION (Chemical). A chemical change in which a single chemical substance is broken up into two or more other substances, which differ from each other and from the parent substance in chemical identity. Complete decomposition refers to such a condition of the products that they are not readily decomposed further, e.g., such decomposition products as ammonia and carbon dioxide. *Degradation* refers to gradual decomposition in which the molecule is diminished in size in small steps. See also **Degradation (Chemical)**.

The *heat of decomposition* is the change of heat content when one mole of a compound is decomposed into its elements. This is equal in quantity, but opposite in sign, to the *heat of formation*.

Sensitized decomposition is a chemical decomposition that is brought about by the presence of a second substance which absorbs an exciting radiation. The essential mechanism of the reaction is the excitation of particles of the second substance by the radiation, followed by collisions between these excited particles and molecules to be decomposed. The process proceeds most effectively if the energy difference between the ground state and excited state of the sensitizer is nearly equal to the energy of the decomposition reaction.

Double decomposition is a term used to express the interaction of molecules which exchange one or more of their constituent atoms or radicals.

DEFOAMING AGENTS. Film breakers or defoaming agents are substances used to reduce foaming caused by proteins, gases, or nitrogenous materials which may interfere with processing or the desired characteristics of the end-products. Processes particularly prone to foaming conditions include the Kraft process for papermaking, where a very foamy pulp slurry is formed; phosphoric acid production from phosphate rock; beet sugar processing; several fermentation processes; and, in terms of the end-product, latex paints. See also **Paints and Coatings**.

The terms *defoamer* and *antifoam* or *antifoaming agent* are frequently used interchangeably. A *defoamer* best describes a substance that kills the foam from above, once it exists. An *antifoaming agent* stops the foam from forming in the first place. Often a defoamer will be a poor antifoaming agent, and vice versa. Defoaming agents, when used in small concentrations, can be quite effective. Where a suitable chemical substance cannot be found, physical means may be required. These may be mechanical, electrical, or thermal in nature. The mechanical devices are fundamentally simple, usually taking the form of rotating breaker arms. The presence of a hot surface near a foam tends to destroy the foam. Essentially, a portion of the foam is evaporated, causing the acceleration of its breakdown. It has also been established that electrical discharges tend to weaken or destroy films.

Mechanisms of Defoaming Agents

These agents may operate via a number of mechanisms, but the most common ones appear to be those of entry and/or spreading. The defoamer must first of all be insoluble in the foaming liquid for these mechanisms to function. Second, the surface tension of the defoamer must be as low as possible. The interfacial tension between defoamer and foamer should be low, but not so low that emulsification of the defoamer may occur. Third, the defoamer should be dispersible in the foaming liquid. It was first shown in 1948 that thermodynamically the entry of the defoamer droplet into a bubble surface occurs when the entering coefficient has a positive value. The physics of bubbles is described in entry on **Foam**.

A type of defoamer may consist of a dispersion in oil of fine particles of silica coated with silicone, the silicone surface of the particles causing them to be hydrophobic. The defoaming action of such a formulation can be explained on the basis of the entry mechanism. Hydrophobic particles can act as an emulsifying agent where the defoamer oil constitutes the continuous phase and the foam constitutes the dispersed phase. In experimental trials, it has been found that excessively hydrophobic particles, such as powdered Teflon, do not function as well as silicone-coated particles. An emulsifier particle must be wetted to some extent by the dispersed phase in order to function as an emulsifier.

The more efficient defoaming mechanism of spreading involves transport of underlying liquid so that the liquid is replaced by a film of defoamer that does not support foam. A drop of oleic acid added to water spreads at a velocity of 30 miles (48.2 kilometers) per hour. The mechanical shock to a film by such a defoamer may be considerable. In addition to the foam-destroying aspect, spreading is also of value as a defoamer-dispersion method, particularly in viscous or poorly stirred systems.

Defoaming agents are in three principal categories, but sometimes are used in combination: (1) surfactants made soluble, (2) dispersions of hard particles, and (3) dispersions of soft particles. The fatty acid-fatty alcohol combination in hydrocarbon oil is an example of a solubilized surfactant defoaming formulation. Paraffinic waxes and fatty amides may be used in soft-particle formulations. The most common of the hard-particle formulations is silica or a mineral coated with silicone dispersed in a vehicle. A particle size as small as 0.02 micrometer may be optimal.

Choice of defoaming agents in the food field is somewhat restricted because substances used obviously must be nontoxic and not produce off odors, off colors, or off tastes. Chemical defoaming agents commonly used in food processing include decanoic acid, dimethylpolysiloxane, lauric acid, mineral oil (white), myristic acid, octanoic acid, oleic acid, oxystearin, palmitic acid, petrolatum, petroleum wax (synthetic), silicon dioxide, sorbitan monostearate, and stearic acid. See also **Foam**.

An example from the brewing industry points out the importance of defoaming agents. Advantages of their use include: (1) higher production through increased fermentation capacity—up to 20% more throughout; (2) the lid of the fermentation tank can be left on, reducing oxidation and improving sanitation; (3) lower oxidation rate, which gives a better physical and chemical stability to the beer as the denatured or partially denatured protein levels remain low, and thus reducing turbidity; and (4) less yeast build-up on the sides of the tank, thus reducing cleaning requirements. Inasmuch as foam is a consideration in the final quality of the brewed product, effective foam control during processing can later affect the "head" of the final product, providing for a stable, long-lived, creamy foam. Thus, a defoaming agent for process use must be insoluble in the beer and capable of removal so that it does not detract from the head of the final product.

DEGASIFICATION. Removal of gas, as applied particularly to the removal of the last traces of gas from wires used in vacuum apparatus, from metals to be plated, and from substances to be used in other specialized applications. Untreated glass always contains water, carbon dioxide, oxygen, and traces of other gases within it and on its surface, and these are ordinarily in a state of equilibrium with the surroundings. When the pressure is reduced, however, the equilibrium is upset, and these gases, being gradually released from solution in and adsorption on the glass, spoil the vacuum. It is usual to drive the gases out of the glass by baking the glass at a temperature of about 350°–500°C, while on the vacuum pump. Degassing of metal is necessary for the same reason as in degassing of glass, but because of the larger quantities of gas present in metals, more complex methods of degassing must be employed. These include baking at high temperature, eddy-current heating, and electron bombardment.

See also **Gettering**.

DEGENERACY. In the kinetic theory of gases, a gas that does not obey the ideal gas laws is referred to as a degenerate gas. The greater the deviation of the real gas from the ideal, the greater is its degeneracy.

A *degenerate electron gas* is an electron gas that is far below its Fermi temperature, that is, which must be described by the Fermi distribution. The essential characteristic of this state is that a very large proportion of the electrons completely fill the lower energy levels, and are unable to take part in any physical processes until excited out of these levels.

DEGRADATION (Chemical). A gradual decomposition occurring in stages with well-marked intermediate products. For example, the maltose chain loses one carbon atom under certain conditions to produce a sugar with eleven carbon atoms in its skeleton. In fact, the term degradation often means specifically a reduction of the number of carbon atoms in an organic compound, usually an aliphatic compound. Among the specific methods used for this purpose are the Hoffmann reaction, treating an amide

with a hypohalite: the conversion of fatty acids to methyl ketones, followed by oxidation: and the Curtius reaction for the conversion of an acid azide to the primary amine.

Kraft Method

A method of reducing the number of carbon atoms in the molecule of an acid, especially a fatty acid by the decomposition of its calcium or barium salt in the presence of a salt of acetic acid, followed by oxidation of the resulting methyl ketone:

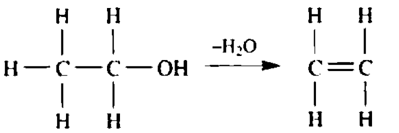
$$(RCH_2COO)_2Ca + (CH_3COO)_2Ca \longrightarrow 2RCH_2COCH_3 + 2CaCO_3.$$
$$\downarrow CrO_3$$
$$2RCOOH + 2CH_3COOH.$$

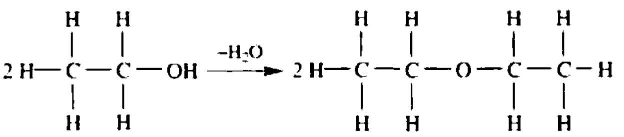
See also **Decomposition (Chemical)**.

DEHUMIDIFICATION. A process, used in air conditioning and in the process industries, in which air or other gases partially saturated with water are subjected: (1) to cooling below their dew point, so that part of the water vapor is condensed and thus separated from the gas; (2) to the action of chemical desiccants, either liquid or solid, which adsorb moisture from the gas; or (3) to a combination of both actions. The most commonly used gas in industry is compressed air. This air requires drying and conditioning for trouble-free operation of pneumatic equipment, including tools, instruments, and automatic controllers. In paint manufacture, dry inert gas is used to blanket agitation operations. Dry process gases, such as nitrogen or hydrogen, are used in metal-annealing operations. The manufacture of some transistors requires blanketing with a dry gas during assembly.

Deliquescent dryers (dissolving desiccant types) and refrigeration-type dryers are adequate for most air-comfort applications and some industrial applications. Usually, these systems only partially remove moisture from air and other gases and generally require additional drying equipment. To meet tight drying specifications, a solid, regenerable desiccant that adsorbs the moisture usually is used. Desiccant regeneration usually is accomplished by the application of heat or purging, or a combination of both procedures. Normally, dual drying towers are used for continuous service, allowing one tower to be on-line, while the other tower is being regenerated. Desiccants most frequently used are silica gel, activated alumina, and molecular sieves. Desiccant systems permit efficient dew-point performance in the range of −40 to −100°F (−40 to −73°C) and are available in a wide range of capacities and pressure ratings (from atmospheric pressure up to 340 atmospheres; 5000 psig).

DEHYDRATION (Chemical). Removal of water from a substance or system or chemical compound: or removal of the elements of water, in correct proportion, from a chemical compound or compounds. The elements of water may be removed from a single molecule, or from more than one molecule, as in the dehydration of alcohol: this may yield ethylene, by loss of the elements of water from each molecule, or ethyl ether, by loss of the elements of water from two molecules, which then join to form a new compound:

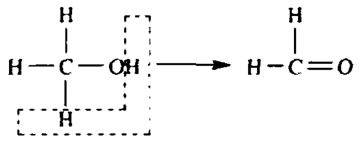




Many reactions known in chemistry under special names, such as neutralization, esterification and etherification are dehydration reactions. See also **Esterification**.

In the food processing field, dehydration is sometimes described as the removal of 95% or more of the water from a food substance, by exposure to thermal energy by various means. The aims of dehydration are reduction in volume of the product, increase in shelf life, and lower transportation costs, among other factors. There is no clearly defined line of demarcation between drying and dehydrating, the latter sometimes being considered as a supplement of drying. Usually, the direct use of solar energy, as in the drying of raisins, hay, etc., is not lumped in with dehydrating. The term dehydration also is not generally applied to situations where there is a loss of water as the result of evaporation. *Rehydration* or *reconstitution* is the restoration of a dehydrated food product to essentially its original edible condition by the simple addition of water, usually just prior to consumption or further processing. The distinction between the terms drying and dehydrating may be somewhat clarified by the fact that most substances can be dried beyond their capability of restoration. Important food products that are dehydrated include animal feedstuffs, hops, malt, oat, peanut (groundnut), potato, rice, and sweet potato. See also **Drying (Process)**.

DEHYDROGENATION. A reaction resulting in the removal of hydrogen from an organic compound or compounds. This process is brought about in several ways. Simple heating of hydrocarbons to high temperature, as in thermal cracking, causes some dehydrogenation, indicated by the presence of unsaturated compounds and free hydrogen. Catalytic processes often produce commercially practicable yields of selected dehydrogenated products. The enzyme dehydrogenase is a selective catalyst of this character. There is considerable evidence to indicate that many reactions commonly classed as oxidations, e.g., the oxidation of methanol to formaldehyde are actually dehydrogenations, i.e.,



In the chemical process industries, nickel, cobalt, platinum, palladium, and mixtures containing potassium, chromium, copper, aluminum, and other metals are used in very large-scale dehydrogenation processes. For example, acetone (6 billion pounds per year) is made from isopropyl alcohol; styrene (over 2 billion pounds per year) is made from ethylbenzene. The dehydrogenation of *n*-paraffins yields detergent alkylates and *n*-olefins. The catalytic use of rhenium for selective dehydrogenation has increased in recent years. Dehydrogenation is one of the most commonly practiced of the chemical unit processes.

See also **Organic Chemistry**.

DEIONIZING. A method for purifying water that involves two steps. First, soluble salts are converted into acids by passing through a hydrogen exchanger. Second, they are removed by an acid adsorbent or synthetic resin.

See also **Demineralization**.

DEISENHOFER, JOHANN (1943–). Awarded the Nobel prize for chemistry in 1988, along with Robert Huber and Hartmut Michel, for work that revealed the three-dimensional structure of closely linked proteins that are essential to photosynthesis. Doctorate awarded in 1974 by Max Planck Institute of Biochemistry, Germany.

DELIQUESCENCE. When a substance absorbs moisture upon exposure to the atmosphere, the substance is said to be *deliquescent*. At ordinary temperatures the vapor pressure of water varies as shown in Table 1. If the solution of a substance in water has a lower water vapor pressure than that of the atmosphere at the given temperature, water vapor condenses in the solution from the atmosphere until the water vapor pressure of the solution equals the water vapor pressure of the surrounding atmosphere.

TABLE 1. VARIATION OF WATER VAPOR PRESSURE WITH TEMPERATURE

Temperature	Water vapor pressure in mm of mercury	
°C	At saturation	At 50% humidity
0	4.6	2.3
10	9.2	4.6
20	17.5	8.8
30	31.8	15.9
40	55.3	27.7

Substances that are ordinarily deliquescent are sulfuric acid (concentrated), glycerol, calcium chloride crystals, sodium hydroxide (solid), and 100% ethyl alcohol. In an enclosed space, these substances deplete the water vapor present to a definite degree. Other substances are used to accomplish this end by chemical reaction, e.g., phosphorus pentoxide (forming phosphoric acid), and boron trioxide (forming boric acid). Water is absorbed from nonmiscible liquids by addition of such substances as anhydrous sodium sulfate, potassium carbonate, anhydrous calcium chloride, and solid sodium hydroxide. The converse phenomenon is known as *efflorescence*.

See also **Dehumidification**; and **Efflorescence**.

DEMAL SOLUTION. A solution which contains one gram-equivalent of solute per cubic decimeter of solution. It is slightly weaker than a normal solution, in the ratio of the magnitude of the liter to the cubic decimeter.

DEMINERALIZATION. Removal from water of mineral contaminants, usually present in ionized form. The methods used include ion-exchange techniques, flash distillation, or electrodialysis. Acid mine wastes may be purified in this way, thus alleviating the pollution problem.

See also **Deionizing**; and **Ion-Exchange Resins**.

DEMULSIFICATION. The process of destroying or "breaking" and unwanted emulsion, especially water-in-oil types occurring in crude petroleum. Both chemical and physical means are used. Chemical means include addition of polyvalent ions to neutralize electrical charges or of a strong acid; physical means include heating, centrifuging, or use of high-potential alternating current.

See also **Emulsions**.

DENDRITE. A tree-like crystal formed during solidification of metals or alloys. Dendrites generally grow inward from the surface of the mold, extending branches from a central trunk in a manner resembling a fir tree. In alloys, the central portions of a dendritic crystal are richer in higher melting point constituents, while the outer portions consist of lower melting point material, which is last to solidify. This form of segregation can usually be eliminated by diffusion during subsequent mechanical working and heat treatment.

The reasons for the branched growth of a crystal into a liquid that of the temperature of which falls ahead of, the solid, are easily understood. Whenever a small section of the interface is ahead of the surrounding surface, it will be in contact with liquid metal at a lower temperature. Its growth velocity will be increased relative to the surrounding surface, which is in contact with liquid at a higher temperature, and the formation of a spike is only to be expected. Associated with the formation of each spike is the release of a quantity of heat (latent heat of fusion). This heat raises the temperature of the liquid adjacent to any given spike and retards the formation of other similar projections on the general interface in its immediate vicinity. The net result is that a number of spikes of almost equal spacing are formed which grow parallel to each other in the fashion shown in Fig. 1. The *dendritic growth direction* depends upon the crystal structure of the metal.

The branches, or spikes, in Fig. 1 are primary in nature. Once they have formed growth at the general interface will be slow because here the supercooling is small and the latent heat of fusion associated with the formation of the spikes tends to further decrease its magnitude. At

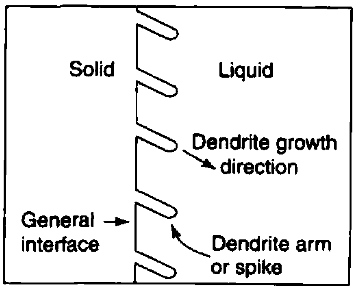


Fig. 1. Schematic representation of the first stage of dendritic growth. A temperature inversion is assumed to exist at the interface i.e., the temperature in the liquid drops in advance of the interface

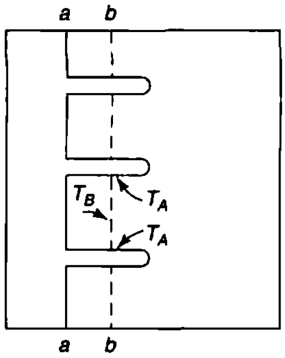

Fig. 2. Secondary dendrite arms form because there is a falling temperature gradient starting at a point close to a primary arm and moving to a point midway between the primary arms

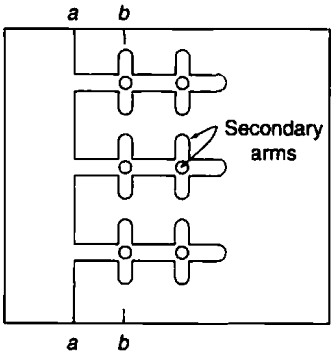

Fig. 3. In a cubic crystal, primary and secondary arms are normal to each other

section *bb* in Fig. 2 on the other hand, the average temperature of the liquid is, by definition, lower than at *aa*. However, even on this section at points in the liquid close to the spikes the temperature will be higher than midway between the spikes ($T_A > T_B$) because of the latent heat released at the spikes. There is, therefore, a decreasing temperature gradient not only in front of the primary spikes, but also in directions perpendicular to the primary branches. This temperature gradient is responsible for the formation of secondary branches, which form at more or less regular intervals along the primary branches, as shown in Fig. 3.

DENSITY. The density of a substance is its mass per unit volume, usually expressed in grams per cubic centimeter. The specific gravity of the substance is the ratio of its density to that of water, usually at 4°C, or 20°C, or 60°F, in the same units, and is therefore an abstract number independent of units. The density of a body is the ratio of its mass to its volume.

To determine the density of a given substance, it is necessary only to ascertain the volume of a specimen whose mass is known by weighing. This may be obtained from measurements on the dimensions of the specimen, or, in the case of a liquid, by the use of a pycnometer or specific gravity bottle. For solids a more precise ethod is to measure the buoyant force, upon the specimen, of a liquid of known density in which it is immersed, or by enclosing it in a gravity bottle and determining the volume by displacement. The Mohr-Westphal balance is especially designed to give densities of liquids by the buoyant force on a solid sinker of known volume. The hydrometer may also be used for quick determinations of liquid densities. The density of a gas is best obtained by weighing a specimen of it in a large, light bulb of known capacity, concurrently observing the temperature and pressure to which the gas is subjected, much as the pycnometer is used for liquids.

TABLE 1. BRIEF LIST OF DENSITIES

Substance	Density	Substance	Density
Air	0.001293	Gold	19.3
Alcohol	0.794	Hydrogen	0.0000899
Aluminum	2.70	Iron	7.86
Carbon dioxide	0.001977	Lead	11.3
Chlorine	0.003214	Mercury	13.55
Copper	8.90	Nitrogen	0.001251
Cork	0.24	Oxygen	0.001429
Gasoline	0.67	Platinum	21.45
Glass	2.4–2.8	Silver	10.5
Glycerine	1.27	Water (4°C)	0.999973

See Table 1 for a brief list of densities, all in grams per cubic centimeter. For gases the densities are at standard temperature and pressure. The term density is also applied in length-force-time systems of units, to the weight per unit volume. Other meanings of the term density are the blackness of the image on a photographic plate or film and the ratio of the number of particles or total amount of such a quantity as energy or momentum, carried by or contained in a volume, to that volume. Thus one speaks of energy density, electron density, charge density, etc.

This last usage has given rise to a number of specific applications of the term density. Thus, the *luminous density* is the luminous energy found in a unit volume of space. The *specular density* is the logarithm of the reciprocal of the specular transmittance, and so on.

DEOXIDIZING AGENT. A compound that has an affinity for oxygen—hence, chemically removes oxygen from many substances. In essence, a deoxidizing agent plays the role that is reverse that of an oxidizing agent. Thus, a deoxidizing agent is a reducing agent. Of course, at one time, oxidation meant simply a combination with oxygen and reduction meant a loss of oxygen. In their broader interpretations, oxidation now refers to the loss of one or more electrons from the outer-shell of an atom, and the reverse for reduction. Although the broader interpretation also could apply to deoxidation, the term still is interpreted generally as removal of oxygen.

Oxygen frequently is an impurity in various metallurgical processes, particularly melting and refining processes. Deoxidizing agents are commonly used to reduce or remove oxygen from molten metals. Lithium metal, for example, will preferably absorb oxygen (by combination) from copper and copper alloys. Boron carbide also is used as a deoxidizing agent for casting copper. Silicon usually in the form of ferrosilicon, and manganese in the form of ferromanganeses are widely used in the production of steel and iron alloys. Aluminum, titanium, zirconium, and vanadium also play a deoxidizing part in the production of iron alloys. Magnesium is also a powerful deoxidizer and desulfurizer and is used in the production of such metals as beryllium, hafnium, titanium, uranium, yttrium, and zirconium. Zinc is used as a deoxidant in the refinement of silver and gold.

Normally, the process of rock formation is one of oxidation. However, a greenish or yellowish area in a red rock may be developed by reduction (deoxidation) of ferric oxide in the presence of organic materials.

Deoxidation also enters into physiological reactions. For example, ascorbic acid (vitamin C) is acclaimed as an antioxidant.

DEOXYRIBONUCLEIC ACID (DNA). A complex sugar-protein polymer of nucleoprotein which contains the genetic code for enzymes in the cell. It occurs as a major component of the genes, which are located on the chromosomes in the cell nucleus. The DNA molecule is a unique and vastly intricate structure: it is comprised of from 3000 to several million nucleotide units arranged in a double helix containing phosphoric acid, 2-deoxyribose, and the nitrogenous bases adenine, guanine, cytosine, and thymine. The spiral consists of two chains of alternating phosphate and deoxyribose units in continuous linkages. The nitrogenous bases project toward the axis of the spiral and are joined to the chains by hydrogen bonds. Adenine always unites with thymine and cytosine with guanine. The complementarity of the bases on the joined chains allows each chain to act as a template for replication of the other when the chains are separated, thus producing two new strands of DNA. The sequence of the bases on the chains varies with the individual, and it is this sequence that governs the genetic code. DNA works in conjunction with ribonucleic acid (RNA).

The foregoing is a highly generalized definition. Within the last few years, considerable new knowledge has been gained concerning DNA and its genetic function. The early studies of genes concentrated on bacterial genes. In these, the bacterial genes are not spread out in pieces. More recent studies in the mid- and late 1970s concentrated on animal viruses, animals, and humans. The genes in these cases, with the possible exception of the histone genes, are found in pieces that are spread out along DNA. Thus, between gene fragments, there are long stretches of DNA, the functions of which are poorly understood as of the present. This discovery of fragmented or spaced out genes in animals raised the question as to whether such structures are exceptional or the rule. Subsequent research has indicated that they are the norm.

This discovery, while creating several new and fundamental questions, has provided at least partial answers to some former questions. For example, it has been known for some years that there are large quantities of DNA in the cells of higher organisms, that is, DNA in an amount far in excess of the DNA required if the genes were not in pieces. The spacing out of the genes into fragments accounts for all or part of the excess DNA previously noted.

As of the early 1980s, numerous hypotheses have been formulated by molecular biologists and this fundamental discovery has stimulated a whole new line of research in many laboratories throughout the world. Some scientists have observed that the extra DNA cannot be accounted for simply upon the basis of evolutionary theories. The extra DNA may play a role in controlling gene expression. The complexity and current uncertainty of these hypotheses are beyond the scope of this book at this juncture in the research program. Perhaps the topic will be better clarified at the time of the next edition. Several of the references listed shed further insights.

Studies of DNA in the human cell have suggested that the intricate DNA structure may be as much as 1.2 meters (4 feet) long—and yet it is contained within a nucleus which is less than 0.025 millimeters ($\frac{1}{1000}$ inch) in diameter. That the DNA structure is in the form of a complex tangle under these conditions is not difficult to imagine. Upon division of the cell, the DNA condenses into strands in duplicate copies, one set for each daughter cell. It follows that the copying must take place while the DNA is in the form of a tangle, but in such a manner to allow easy separation of the duplicate copies. The mechanics and time required for the copying process still remain undetermined. As early as 1974, Berezney and Coffey (Johns Hopkins University School of Medicine) estimated from electron micrographs that about 5% of the protein in a nucleus appears to be a rigid skeleton or scaffolding, a structure they termed the *nuclear matrix*. These researchers have proposed that the DNA in the nucleus is attached onto the nuclear matrix at thousands of sites, with the genetic material arrayed in thousands of loops. The loops pass through enzyme complexes located at the matrix sites and in so doing are copied. In the process, the loops are preserved and remain attached to the matrix. It is further postulated that when a cell divides, duplicate copies of loops already joined to a scaffolding are drawn apart to the daughter cells. It has been estimated that genetic material in rat liver cells consists of from 10,000 to 15,000 loops. Thus, the nuclear matrix would have a corresponding number of enzyme complexes.

DEPHLEGMATION. Partial condensation of vapor from a distillation operation to produce a liquid richer in higher-boiling constituents than the original vapor. The residual vapor is richer in the lower-boiling constituents.

See also **Distillation**.

DEPOLARIZATION. See **Batteries**.

DERIVATIVE (Chemical). A term used in organic chemistry to express the relation between certain known or hypothetical substances and the compound formed from them by simple chemical processes in which the nucleus or skeleton of the parent substance exists. Thus, phenol, aniline, and toluene are said to be derivatives of benzene; and many of the terpenes are derivatives of cymene. Or, when a paraffin such as methane is halogenated, a series of halogen-substitution products may be formed. Depending upon conditions of the reaction, CH_4 plus Cl may yield the monosubstitution product CH_3Cl (methyl chloride), or the disubstitution product CH_2Cl_2 (methylene dichloride), or the trisubstitution product $CHCl_3$ (chloroform), or the tetrasubstitution product CCl_4 (carbon tetrachloride). In essence, these compounds are derived from methane and thus are methane derivatives as the result of chlorination. Usually the term applies to those compounds where the resulting compound is formed in one step, although a chain of steps may be involved in some cases, depending essentially upon how easy it is to identify the "derivative" with the parent substance. Where a chain of steps is involved, the intervening compounds often are called intermediates rather than derivatives.

DESALINATION. As generally used, the term describes the production of water appropriate for human consumption from seawater and brackish water. Seawater averages about 35,000 ppm of total dissolved solids (TDS). Brackish waters TDS range from 2000 ppm upwards. The maximum TDS of water considered tolerable and acceptable for continued human consumption is about 500 ppm, although water containing up to 1000 ppm TDS may be consumed for short periods.

Desalination processing techniques fall into three groups:

1. *Processes based on a change of phase*—distillation and freezing.
2. *Processes based on selective transport using membranes*—electro dialysis and reverse osmosis.
3. *Processes based on chemical bonding*—ion exchange.

Distillation and freezing process have advantages for high-salinity water, such as seawater, because the energy required is independent of salt content. Electrodialysis and ion exchange are best suited for brackish waters. Reverse osmosis is competitive for desalting both seawater and brackish water. A general desalting plant schematic of the components common to all desalting systems is shown in Fig. 1. The raw saline water is treated to prepare the water for desalination and to ensure more efficient and trouble-free performance of desalination systems. The pretreated saline water enters the desalting plant, where the product water stream is the desalting plant's primary output; a brine stream is also produced. The product water is mixed with suitable chemicals in the post-treatment step, depending upon the intended use of the water. The treated product water is then transferred to a distribution system.

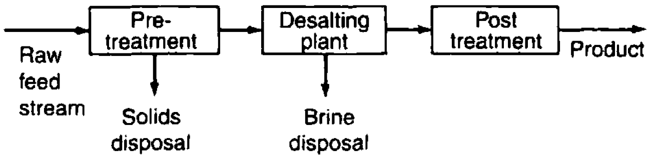

Fig. 1. Generalized schematic of a desalting plant

Distillation

In distillation, impurities from saline water or brine are removed by boiling the saline water, collecting the water vapor and then cooling the vapor until it condenses. The basic equipment used is an evaporator. Commercial evaporators operate under vacuum to utilize the maximum available temperature range for heat transfer. The three major classifications of distillation systems currently in use are: (1) multistage flash distillation (MSF); tube evaporation (VTE, HTE); and vapor compression (VC).

Multistage flash distillation is used widely by itself and also in conjunction with steam power plants to produce potable water from seawater. The MSF process is illustrated in Fig. 2. Multistage flash distillation incorporates flashing of heated brine as it enters a stage in which the vapor pressure is maintained so that the boiling point of the brine is below its incoming temperature. Flashing occurs in steps as the heated brine passes in series through a number of stages at successively lower pressures. The multistage distillation process is the most economic of the high-temperature processes in terms of energy and cooling water requirements. The optimum number of stages is determined by an economic and technical evaluation. Modern MSF designs typically have three or four heat rejection stages, plus twenty flash stages.

Tube evaporators may be designed as vertical tube evaporators (VTE) or horizontal tube evaporators (HTE). In the VTE, vapor produced in one effect is condensed in the next effect. The effect is an evaporator chamber receiving heat from an external source or from a higher effect and producing vapor and brine which may serve as a heat source for the next effect. To obtain high efficiency in the use of heat energy, the process is repeated in several evaporator effects arranged in series. See also **Evaporation**.

Vapor compression uses the reverse principle of multieffect distillation. As a vapor is compressed, its temperature and pressure increase. The compressed vapor can be used instead of fresh steam as a heat source at the high-temperature end of the distillation process.

All distillation processes are based on energy-consuming phase changes to convert seawater to potable water. Careful consideration of pretreatment requirement and materials of construction is necessary to provide a satisfactory system.

Electrodialysis

Electrodialysis (ED) is a membrane process based on the ability of semipermeable membranes to pass select ions in feedwater. A direct current electrical field transports the ions through the membranes. In the basic system, alternating cation- and anion-selective membranes are placed in an electrical field. An electrodialysis stack schematic is shown in Fig. 3. The cation-selective membranes permit only the transport of cations; anion-selective membranes allow only the transport of anions.

The transport of ions across the membranes results in ion depletion in some cells and ion concentration in alternate ones. Water exiting from the ion-depleted cells is the desalted product; water leaving the ion-concentrated cells is the brine. The cell pair consists of a cation-selective membrane, an ion-depleted cell, an anion-selective membrane, and an ion-concentrated cell. A commercial electrodialysis unit consists of hundreds of cell pairs stacked vertically and clamped between two huge oppositely charged electrodes. Electric energy is consumed in proportion to the quantity of salts to be removed. Economics usually limit the application of ED to feedwaters of less than 10,000 ppm total dissolved solids (TDS). The electrodialysis process does not remove organics, colloidal matter, or bacteria.

Reverse Osmosis

If a solution is placed on one side of a semipermeable membrane and water is placed on the other side, then there is a natural tendency (*osmosis*) for water to diffuse through the membrane to the solute side until an equilibrium osmotic pressure is reached.

If a pressure is applied to the solute side, substantially greater than the osmotic pressure, the water diffuses from the solution through the membrane to the fresh-water side. This phenomenon is called reverse

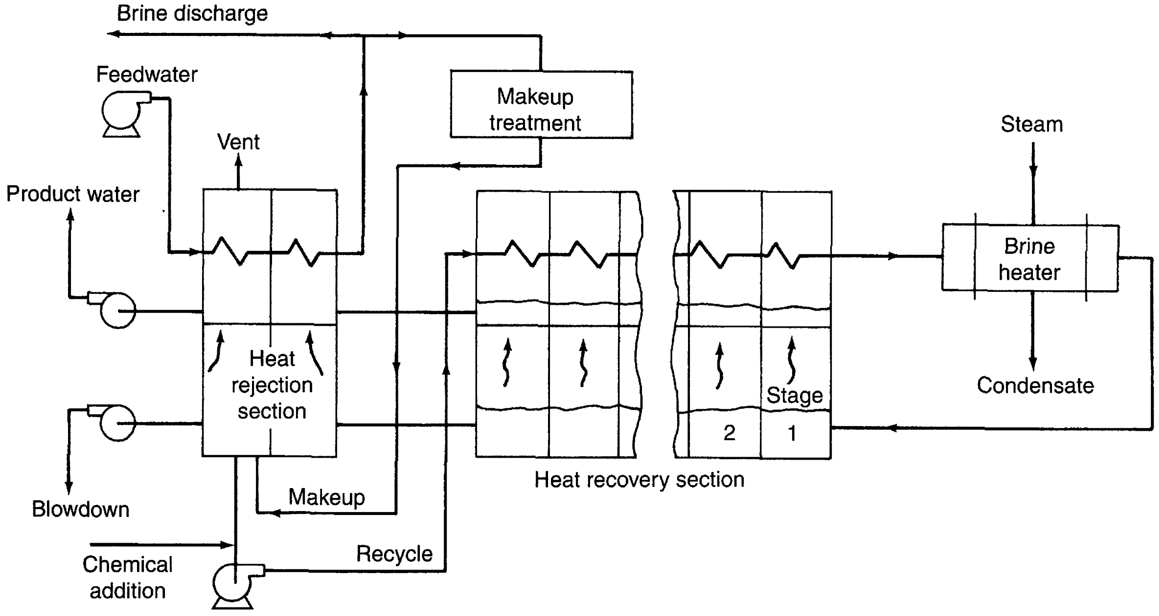

Fig. 2. Multistage flash evaporation process used in desalination

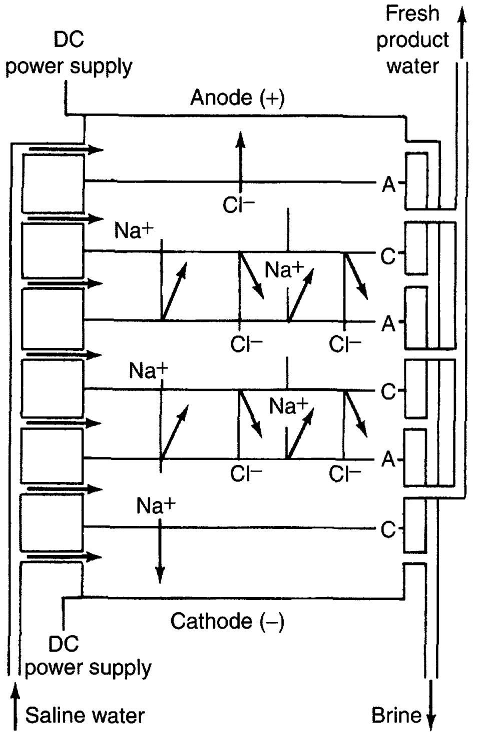

Fig. 3. Schematic of electrodialysis stack used in desalination and other separation processes

osmosis (RO). In applying this principle to desalination, hydraulic pressure is used to force pure water from saline water through a semipermeable membrane. See Fig. 4. RO membranes may be spiral wound sheets, hollow fine fibers, or tubes. In the spiral wound design, two membranes sheets are glued back to back to form an envelope. When water, under pressure, is passed over the surface of the sheet, pure water passes through the membrane, while the salts are held back on the outer surface of the envelope. The membrane envelopes are separated by mesh spacers and rolled into the spiral configuration. The hollow fiber membrane design places a large number of hairlike hollow elements in a pressure vessel. The membranes have an outside diameter of about 100 to 300 micrometers and an inside diameter of about half that dimension. Normally, the fibers are looped in a U-shape so that both ends are embedded in a plastic tube-sheet. Under pressure, desalted water passes through the fiber walls and flows down the inside of the fibers for collection. The hollow fine fiber design is shown in Fig. 5.

Reverse osmosis performs a separation without a phase change. Thus, the energy requirements are low. Typical energy consumption is 6 to 7 kWh/m^2 of product water in seawater desalination. Reverse osmosis, of course, is not only used in desalination, but also for producing high-pressure boiler feedwater, bacteria-free water, and ultrapure water for rinsing electronic components—because of its properties for rejecting colloidal matter, particle and bacteria.

Ion Exchange

Ion exchange processes use natural or synthetic granular materials that exchange one ion for another. The new (captured) ion is held for a finite period and then released to a regenerating solution. Because regeneration costs increased proportionally with the TDS reduction, the ion exchange process has not been competitive with membrane processes for desalting

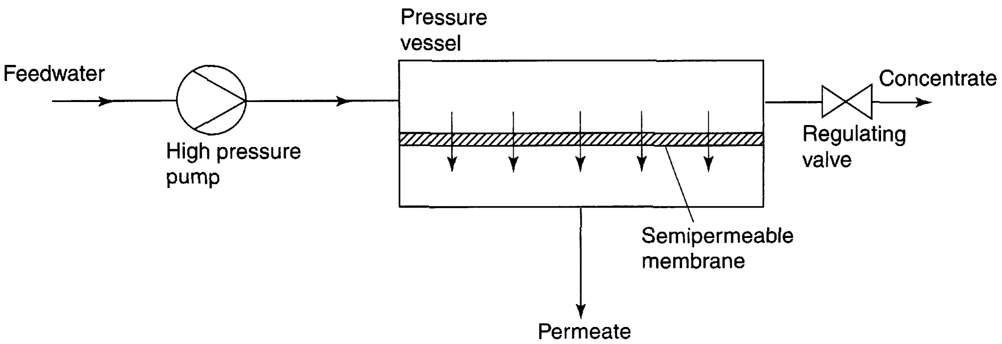

Fig. 4. Schematic of reverse osmosis process used in desalination process. (*Toyobo Co., Ltd., Osaka, Japan*)

feedwaters above 1000 ppm TDS. Ion exchange technology is used worldwide in systems ranging from domestic water softeners to large municipal and industrial demineralizers. See also **Ion-Exchange Resins**.

Other Processes

A number of other desalination processes, such as freezing, membrane distillation, and solar humidification, have been used to desalt saline waters. Based on their commercial success, these processes can be considered as minor desalination processes.

In the *freezing process*, dissolved salts are naturally excluded during the formation of ice crystals. When seawater is frozen, fresh-water ice crystals are formed and the salt is concentrated in the remaining brine solution. The ice crystals can be separated from the brine, washed, and melted, to yield fresh water.

In the *membrane distillation process*, combined use of distillation and membranes is made. Salt water is warmed to produce vapor. This vapor passes through porous membranes, which are permeable to vapor but not to the liquid phase. The vapor is condensed on a cooled surface to produce fresh water. The main advantage of this process is its simplicity and the need for only small temperature differentials to operate.

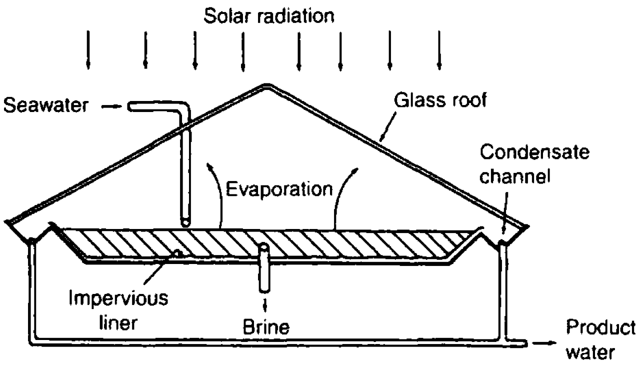

Fig. 6. Cross section of a solar still

The solar humidification process is represented schematically in Fig. 6. This process generally imitates a part of the natural hydrologic cycle in that the saline water is heated by the sun's rays to enhance vapor production.

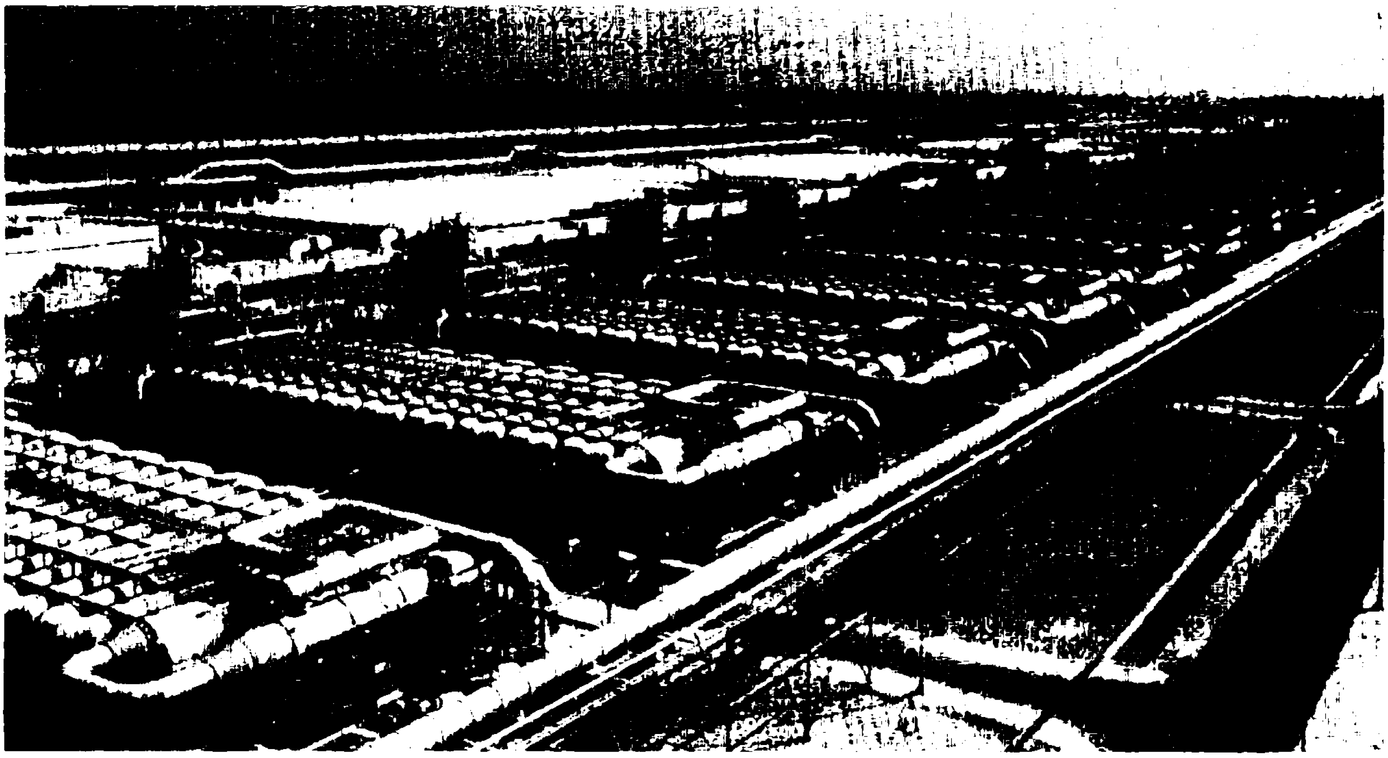

Fig. 7. Multistage flash distillation (MSF) desalination plant in Al Jubail, Saudi Arabia. Capacity/day is 23,500 tons × 20 units. (*Toyobo Co., Ltd., Osaka, Japan*)

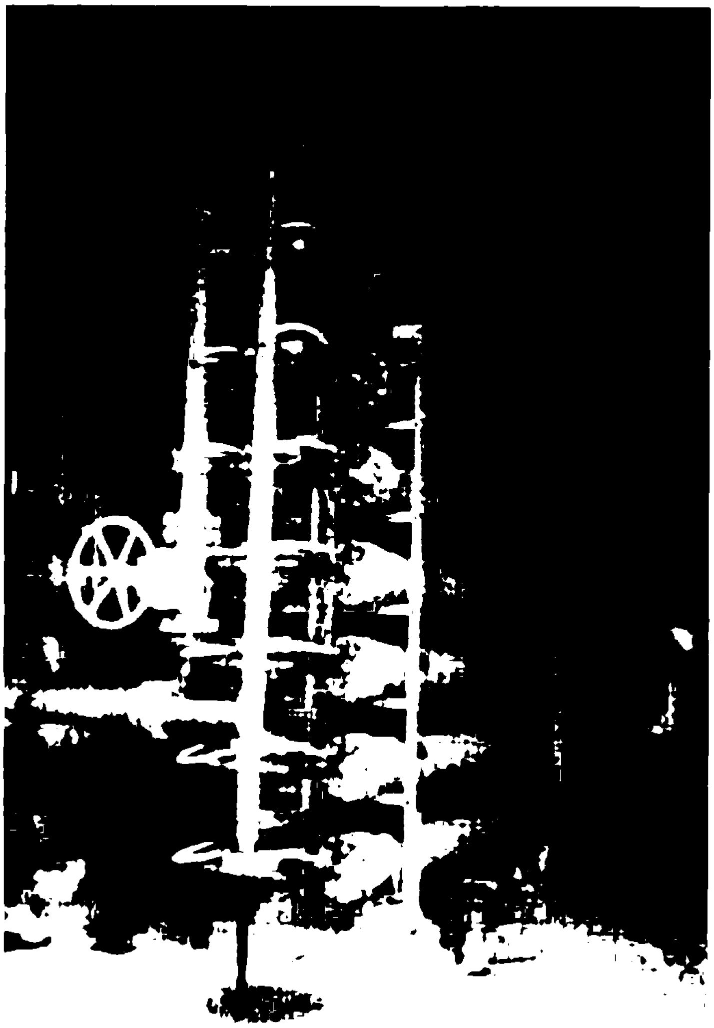

Fig. 8. Portion of reverse osmosis (RO) desalination plant in a Singapore power station. Capacity is 2,000 tons/day. *(Toyobo Co., Ltd., Osaka, Japan)*

The vapor is then condensed on a cool surface and the condensate collected as product water.

Worldwide Installations

As of 1990, the worldwide inventory of total capacity of installed desalination plants was approximately 13.2 million cubic meters (nearly 3.5 billion U.S. gallons) per day.

Two representative installations are shown in Figures 7 and 8.

DESORPTION. The reverse of absorption or adsorption, as in the release of one substance which has been "taken into" another by a physical process, or the release of a substance which has been held in concentrated form upon a surface.

DESULFURIZATION (Steel). See **Calcium**.

DETERGENTS. For purposes of this article, detergents are defined as complete washing or cleansing products, which contain among their ingredients an organic surface-active compound (*surfactant*) that has soil-removal properties. Frequently, the term *detergent* is used synonymously with *surfactant*, but common industry practice treats the surfactant as one component of a total detergent product, as is done here. See also **Surfactants**. Additionally, this article treats primarily only the so-called synthetic detergents, excluding those products in which soap is the sole or predominant surfactant. Soaps, the alkali salts of long-chain fatty acids, differ significantly in certain important performance properties from the synthetic surfactants and are described separately in this encyclopedia. See also **Soaps**.

The synthetic detergent industry is one of the largest chemical process industries. In 1984, annual U.S. production of synthetic detergents was about 7 million tons, with approximate manufacturer's value of $9 billion. The industry differs from many other chemical process industries, however, in that the bulk of its production is sold directly to individuals for household consumption, primarily as branded products, rather than to industrial or institutional users.

Detergent Ingredients and Their Functions

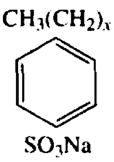
Detergent formulas vary greatly, depending upon the intended end-use application. Differentiation by surfactant type as well as selection of auxiliary ingredients is involved. Some of the ingredients most commonly used in detergent formulas and their functions are as follows.

Surfactants. By definition every detergent product contains one or more types of surfactants. Basically, every surfactant is an organic compound consisting of two parts: (1) a *hydrophobic* portion, normally including a long hydrocarbon chain, and (2) a *hydrophilic* portion, which renders the entire compound sufficiently soluble or dispersible in water or other polar solvent to serve its intended use. Together, these combined hydrophobic and hydrophilic moieties render the compound surface-active—able to concentrate at the interface between a surfactant solution and another phase, such as air, soil, and textile substrate to be cleaned.

Surfactants provide the detergent with the ability to penetrate and wet soiled surfaces, to displace, solubilize, or emulsify various soils, particularly oils and greases, and to disperse or suspend certain soils in solution to prevent their redeposition. In addition, the surfactants provide (to various degrees) whatever foaming or sudsing properties the detergent solution possesses, properties which are necessary for satisfactory use in certain industrial applications and highly desirable to many consumers in household laundry, hand-dishwashing, and personal care uses.

Surfactants in broad use may be classified into three general types: (1) *anionics*, in which the hydrophilic portion of the molecule carries a negative charge; (2) *cationics*, in which the charge of this portion is positive; and (3) nonionics, which do not dissociate but commonly derive their hydrophilic portion from polyhydroxy or polyethoxy structures. *Ampholytic* and *zwitterionic* surfactants are also known and are starting to be of commercial importance.

Of the three main types of surfactants, the anionics are by far the most commercially important class, constituting, in particular, the major surfactant type represented in laundry and hand-dishwashing detergents. Among the anionics, linear sodium alkyl benzene sulfonate (LAS), linear alkyl sulfates, and linear alkyl ethoxy sulfates are by far the most widely used compounds. (The industry converted voluntarily to linear alkyl chains in the mid-1960s to obtain improved biodegradability relative to the branched-chain alkylates formerly used.)



(x ranges from 9 to 15)

Linear alkyl benzene sulfonate (LAS)

$CH_3(CH_2)_xOSO_3Na$ (x ranges from 9 to 17)

Alkyl sulfate

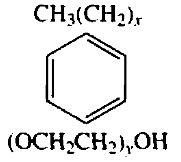
$CH_3(CH_2)_x(O-CH_2-CH_2)_y\ OSO_3Na$ (x ranges from 7 to 15) (y ranges from 0 to 6)

Alkyl ethoxy sulfate

Nonionic surfactants are also used in substantial amounts in laundry detergents and in automatic dishwashing detergents, both applications reflecting in particular their generally lower sudsing characteristics than the anionics. Commercially important examples of the nonionics include the alkyl ethoxylates, the ethoxylated alkyl phenols, the fatty acid ethanol amides, and complex polymers of ethylene oxide, propylene oxide, and alcohols.

$CH_3(CH_2)_x(O-CH_2-CH_2)_yOH$ (x ranges from 9 to 15) (y ranges from 4 to 20)

Alkyl ethoxylates



(x ranges from 7 to 13) (y ranges from 3 to 12)

Ethoxylated alkyl phenols

$CH_3(CH_2)_xCON(CH_2CH_2OH)_y(H)_z$ (x ranges from 9 to 17) (y ranges from 1 to 2) (z is 1 or 0)

Fatty acid ethanol amide

Cationic surfactants are used in only limited tonnage for specialty detergent products, such as metal cleaners for electroplating, and more commonly in ancillary textile laundering products for their fabric-softening, antistatic, and germicidal properties. A typical cationic surfactant would be tallow trimethylammonium chloride:

$$CH_3(CH_2)_{13-17}N^+(CH_3)_3Cl^-$$

In contrast with soaps, virtually all the synthetic anionic and nonionic surfactants do not form readily visible insolubles in the presence of the Ca^{++} and Mg^{++} ions present in many water supplies—the familiar scum, curd, and "lime soap" of the laundry soap era. This property, in combination with the discovery that the detergency performance of many synthetic surfactants could be greatly augmented by the addition of certain phosphate chelating agents, led to the "detergent revolution" in the laundry-product field. See also **Surfactants**.

Builders. *Builder* is the term used within the industry to designate materials in the synthetic detergent which chelate (sequester) or precipitate polyvalent metal ions present in the cleaning solution, particularly Ca^{++} and Mg^{++} ions, which are present in substantial quantities in so-called hard water supplies. Nearly 2 billion pounds (0.9 billion kg) of builders are presently used in detergent products, particularly in textile-cleaning detergents, where they may constitute one-half of the total weight of product. Laundry products containing significant quantities of builders are called *heavy-duty* or *built* detergents.

Builders perform several critical functions in present-day detergents:

1. They prevent polyvalent metal ions from combining with (many) surfactant(s) to form an adduct which is less effective than the unmodified surfactant in cleansing properties.

2. They prevent polyvalent metal ions from combining with various soils, such as lipid residues and clays, to form less dispersible residues, which adhere tenaciously to the surface to be cleaned.

The aforementioned effects combine to provide greatly enhanced removal of many soils and stains by a formula with builder compared with a formula without.

3. They prevent redeposition of soils removed from a surface back onto the surface through a dispersing action associated with chelating and charge-distribution effects.

4. They provide added and buffered alkalinity to the wash solution, which is generally helpful to cleansing in most applications.

5. They provide enhanced removal and kill of microorganisms, a critical property in many applications involving sanitation of commercial facilities.

By far, the most commonly used builders are the condensed polyphosphates, particularly pentasodium tripolyphosphate (STP) and, to a lesser extent, tetrasodium pyrophosphate. These polyphosphates chelate the polyvalent metal ions to form a soluble complex (under some conditions, the pyrophosphate complexes are sparingly soluble). In response to state and local legislation aimed at reducing the phosphate levels in lakes and rivers, detergent manufacturers began large-scale utilization of synthetic zeolites (sodium aluminosilicates) in 1978. Zeolites are insoluble in water, but act as ion exchange agents; exchanging Na^+ for Ca^{++} in the wash water. Peak usage of zeolites occurred in 1982 at 300 million pounds (136 million kg) annually.

Precipitating builders, such as sodium carbonate, Na_2CO_3, are also used, but to a much lesser extent, since the precipitate formed can itself deposit on the surface to be cleaned unless special washing procedures are followed. Other chelating builders than phosphates, such as trisodium nitrilotriacetate (NTA), tetrasodium ethylenediamine tetraacetate (EDTA), and other polycarboxylates, have also been used in small to moderate quantities, but questions concerning their safety, efficacy, or economics have to date prevented major displacement of the phosphates.

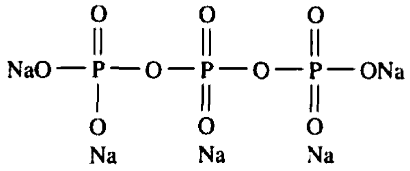
Bleaches. In many detergent applications, the action of a supplementary bleaching agent is necessary or desirable. It is frequently preferable to incorporate the bleach directly into the detergent product for reasons of convenience or performance.

Two types of bleaching agents are in common use in detergent products: (1) those based on a hypochlorite bleaching species, and (2) those based on a peroxygen species. The hypochlorite, or "chlorine," bleaches are considerably more powerful in their oxidizing action than the commonly used peroxygen bleaches under most U.S. usage conditions. Commercially important examples of hypochlorite species bleaches used in detergents include: Sodium dichloroisocyanurate dihydrate, $NaDCC \cdot 2H_2O$, and chlorinated trisodium phosphate (a physical combination of NaOCl, H_2O, and Na_3PO_4,), while sodium perborate, $NaBO_3 \cdot 4H_2O$, is by far the most commonly used of the peroxygen bleaches. All current detergent products containing bleach are dry solids since aqueous bleach solutions have not been found to be sufficiently stable in the presence of other desired detergent ingredients.

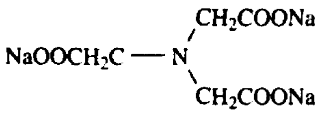
Types of detergent products to which chlorine bleaches are frequently added include hard-surface cleaners, such as the scouring cleansers and the automatic dishwashing detergents, and detergents for commercial sanitation, in which the disinfecting properties of the chlorine bleach are a critical performance attribute. In the cleaning of textiles, consideration of possible fiber and color damage prevents the universal use of a powerful oxidizing agent like hypochlorite. Consequently, a separate liquid solution of sodium hypochlorite is often used in conjunction with the detergent on those fabrics where its use is appropriate, while some textile detergents contain the milder sodium perborate bleach for more general application.

Corrosion Inhibitors. Early research indicated that unmodified alkaline detergents could be corrosive to certain hard surfaces such as aluminum, washing-machine porcelain, and the overglaze on fine china. It was quickly determined, however, that the addition of soluble silicates (silicates with varying ratios of SiO_2 to Na_2O are used, depending upon product processing and intended application) could essentially prevent this corrosive effect. Consequently, the soluble silicates are widely added in moderate amounts to alkaline detergents, and even contribute to detergency through their added alkalinity.

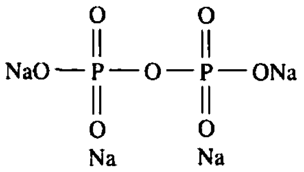
Alkalinity Boosters. It has long been known that many soils are sensitive to high pH. Fairly high levels of sodium carbonate, soluble silicates (ratio 1.6 to 3.2 SiO_2 to Na_2O) and sodium metasilicate (Na_2SiO_3) are used to supply alkalinity for improved cleaning performance.



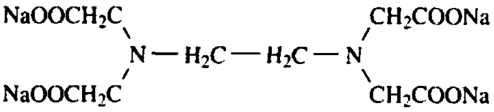
STP



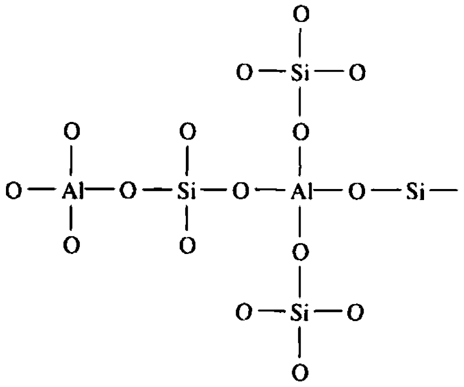
NTA



Tetrasodium pyrophosphate



EDTA



Sodium aluminosilicates
(Zeolities)

Sudsing Modifiers. In many applications, the detergent surfactants that appear to provide optimum cleansing performance do not provide satisfactory product-sudsing characteristics from a functional or aesthetic standpoint. Accordingly, materials that depress or boost the sudsing of the basic surfactant system are often added in small amounts to such products. Examples of materials which can be used to boost the sudsing of common anionic surfactant systems are the mono- and diethanol amides of C_{10-16}, fatty acids, while the long-chain, $C_{16,\ 22}$ fatty acids themselves and certain nonionics, such as the ethoxylated fatty alcohols, are commonly used as suds depressors.

Fluorescent Whitening Agents (FWA). Fluorescent whitening agents (also called *fluorescers, brighteners, optical bleaches*) are organic chromophores which absorb incident light in the ultraviolet region and reemit part of the absorbed energy as visible light, generally in the blue region of the visible spectrum. In addition, the chromophore is modified with organic substituents to make it substantive to one or more textile substrates from a laundry wash solution. Consequently, the brightness and whiteness of the fabrics on which FWA is deposited are enhanced. In effect, an added portion of the incident light is reflected from the fabric.

Enzymes. The most substantial advance in textile cleansing since the introduction of synthetic detergents has occurred through the introduction of low levels of enzymes into laundry detergent and presoak products. Both proteolytic and amylolytic enzymes are used by the industry to hydrolyze protein and starch so that the smaller soil fragments are easier to remove. They are effective on stains with protein and carbohydrate substituents (such as body soils, many food stains, grass stains, blood, and many others). Enzymes are catalytic and specific and thus must be used at low levels in products with excellent safety for fibers and textile colors (compared with a general chemical reactant, such as hypochlorite bleach).

Presently, all detergent enzymes are derived from fermentation cultures of specific strains of the ubiquitous bacilli *B. subtilis* and *B. licheniformis*. (The enzymes themselves are, of course, nonliving proteins, biochemical products of the bacilli which are used to hydrolyze exocellular proteins into small peptide fragments that can be absorbed by the bacteria as nutrient sources.) It had been recognized since early in this century that enzymatic action could be a most useful mechanism in textile cleansing, but available enzymes were rendered ineffective by the elevated temperatures and alkalinity required for satisfactory general detergency. The discovery and production of the *B. subtilis* and *B. licheniformis* mutants and their metabolites which remained active under laundering conditions was the essential step required to make enzymatic action available in textile detergency.

Antiredeposition Agents. In textile laundering, many soils once removed have a tendency to redeposit back onto the textile substrate during the remainder of the washing process. Certain agents, such as carboxymethyl cellulose and polyvinyl alcohol have been found to be effective in preventing or minimizing this effect and are consequently added in very small amounts to many laundry detergents.

Softeners and Anti-stats. A recent formulation trend is to incorporate fabric care benefits, such as softening and anti-static properties, into textile cleaning products in both powder and liquid form. The most common ingredient used is ditallow dimethyl ammonium chloride, the same material used in many liquid fabric-softener products:

$$(CH_3(CH_2)_{13-17})_2N^+(CH_3)_2Cl^-$$

Ditallow dimethylammonium chloride

Since this material is cationic, it is generally incompatible with anionic surfactants unless special proprietary formulation approaches are used. Therefore, fabric care detergents, especially liquids, often use nonionic surfactants.

Other Materials. In addition to the basic performance ingredients previously discussed, other materials are commonly added to facilitate product manufacture (for example, hydrotropes such as xylene sulfonate) and to enhance product acceptability among consumers (colorants and perfumes). A few materials are formed or carried along into the finished product by the manufacturing process (such as sodium sulfate and water).

Types of Detergent Products

Synthetic detergents are manufactured to perform a wide variety of household and industrial cleansing operations. Within the commercially more important (in terms of tonnage and dollar volume of sales) household-product category, the following major functional areas may be defined.

Textile Cleansing. Household laundry detergents and presoak products represent the largest single category of detergent use, currently accounting for over 2 million tons per year in U.S. consumption. These products are used in conjunction with individually owned or self-service washing machines to launder most of the clothing, bed and bath linens, curtains, and other textiles used in the typical household. Prior to the introduction of detergents over a half-century ago, soaps were almost exclusively used for these purposes.

Detergents in liquid, tablet, and granular powder forms are sold for household laundry use, the granules accounting for by far the major amount (75%) of product sold. A household laundry detergent powder typically contains 10–20% surfactant, 20–40% builder, 5–10% sodium silicates, low levels of suds builders or suppressors, anti-redeposition agents, fluorescent whitening agents, enzymes, peroxygen bleach, colorants, perfume as required to meet aesthetic and performance objectives, and the remainder being materials of processing (sodium sulfate, water). Powder bulk density varies among products, but most commonly is such as to provide a wash solution concentration of about 0.15% detergent at the product usage recommended. The presoak powders differ from the wash detergents in providing relatively higher wash water concentrations of enzymes, builders, and peroxygen bleach (if used), but a relatively lower concentration of surfactant. The liquid laundry detergents are currently the most rapidly growing segment of the market. They use the same type of materials present in powders, but typically have much higher levels of surfactants (20–30%) and lower levels of builders.

Hard-Surface Cleaning. Products used for hard-surface cleaning around the home include the hand- and automatic dishwashing products, the liquid and powder floor and wall cleaners, and the abrasive scouring cleansers.

Although the higher-sudsing laundry detergents may be used satisfactorily for hand dishwashing (and were so used extensively in the past), high-sudsing liquid products are predominantly used for this purpose. Relative to powders, the liquids offer superior ease and convenience of use, a product form into which surfactant types and levels better suited to the dishwashing task can be incorporated, and comparable economy of use since the builders required for superior laundry performance are not essential for hand dishwashing use. Dishwashing liquids typically consist of 25–45% anionic or semipolar surfactants, the remainder consisting of solvents, hydrotropes, buffers, colorants, perfumes, and water of processing. Surfactant types used in this application include LAS, alkyl sulfates, alkyl polyethoxy sulfates, di- or monoethanol fatty acid amides, alkyl glyceryl ether sulfonates, and alkyl dimethylamine oxides. The alkyl portions of these surfactants commonly average to a coconut or C_{12} chain length, as opposed to laundry detergents, where slightly longer alkyl chains are used.

Automatic dishwashing products are designed solely for use in household mechanical dishwashers, machines in which a moving high-velocity water spray is used to clean the tableware and cooking utensils. Performance requirements for an automatic dishwasher product differ substantially from those for laundry and hand dishwashing products; they include: (1) very low sudsing to prevent suds overflows with the high-velocity spray; (2) very complete rinsing to avoid residual deposits; (3) complete sequestration of Ca^{++} and Mg^{++} ions in water supplies by the use of relatively large amounts of builder to avoid deposits of sparingly soluble Ca and Mg salts; and (4) thorough removal of minute particles of food protein which can form nuclei for spot formation during drying. Consequently, automatic dishwashing products typically contain a low level of a nonionic surfactant (commonly polyoxy-ethylene/polyoxypropylene condensates), a low level of a dry bleach (KDCC or chlorinated trisodium phosphate), a high level of builder (STP and/or sodium carbonate), and moderate-to-high levels of auxiliary sources of alkalinity (sodium silicates and/or sodium carbonate). These products are typically dry powders for reasons of machine design and product bleach stability during the period between manufacture and eventual use. However, thixotropic automatic dishwashing liquid products containing bleach were recently introduced into the marketplace.

Abrasive cleaners are used to remove soils and stains from hard surfaces that are durable to the scouring action. Such surfaces include stainless steel and porcelain plumbing fixtures, metal and ceramic cooking utensils, and various stone, metal, and ceramic building surfaces. Typically, these products consist of a very high level of abrasive (commonly silica flour) with moderate to low levels of a dry chlorine bleach (KDCC or chlorinated trisodium phosphate) and low levels of surfactant (LAS) and builder (STP) for wetting action and improved stain removal.

Other hard-surface cleaners are formulated to clean larger surface areas which do not require or are less resistant to the action of an abrasive cleanser or from which the abrasive would be difficult to remove, such as floors, walls, woodwork, and large appliances. These products are sold in both liquid and powder form. The liquid products contain low levels of nonionic and anionic surfactants; moderate levels of a stable, highly soluble builder (commonly tetrapotassium pyrophosphate, $K_4P_2O_7$) for better stain removal; solvents; hydrotropes; and water of processing. The powdered products contain a very low level of surfactant (LAS), a moderate amount of builder (STP), and substantial amounts of sources of mild alkalinity (trisodium phosphate and mixtures of sodium carbonate and sodium bicarbonate) for improved soil removal. Low sudsing is a requirement for both types of products to aid in rinsing the surfaces after cleaning.

Personal Care Products. Within the broad definition of synthetic detergents, a variety of cleansing products are made for personal care. These include such products as cleansing bars, shampoos, bubble-bath products, cosmetic cleansers, and tooth pastes. Formulations of these products vary widely, depending upon their intended use.

Although essentially pure soap products continue to dominate the cleansing-bar field, a few products contain synthetic surfactants in addition to soap to act as scum and curd dispersants. Synthetic surfactants used in this application include alkyl sulfates, alkyl glyceryl ether sulfonates, alkyl esters of sodium isothionate, and alkylamides of N-methyl tauride. Shampoos are commonly formulated in liquid, paste, and gel form and usually consist of high-sudsing anionic surfactant(s) (such as LAS and those previously listed for bars), along with specific ingredients for improved hair health or control (such as antidandruff agents and substantive collagen proteins).

Bubble baths are provided in both liquid and powder form, and commonly provide a high sudsing surfactant(s). Cosmetic cleansers vary widely in formulation, depending upon intended use. Some provide mixtures of surfactants and heavy mineral oil (cold cream), while others provide an organic solvent (for mascara removal, for example). Tooth pastes provide a low level of an anionic surfactant (several types used) and high levels of a moderate abrasive (insoluble pyrophosphates), along with other special ingredients, such as anticaries agents.

Many other products, such as rug cleaners, automobile cleaners, scouring pads, and pet care products incorporate synthetic detergents.

Industrial and Institutional Applications. In addition to household products just described, a wide variety of products based wholly or partially on synthetic detergents are made for industrial and institutional use. Included among these are products that are essentially direct analogues of the various household products. In addition, there is a wide variety of products which have no counterparts among the household detergents. Included are detergents to scour raw yarns in the textile manufacturing process, detergents to clean metals prior to painting or electroplating, surgical preparation products, detergents to clean and disinfect poultry houses, and many more. Industrial and institutional detergent products account for about 500 million pounds (227 million kg) of product annually.

DETINNING. See **Goldschmidt Detinning Process**.

DEUTERIUM. The isotope of hydrogen with mass number 2 is termed deuterium. The symbol D is sometimes used. Using ocean water as a reference, the atomic abundance of deuterium in natural hydrogen is 0.0149%. Deuterium oxide D_2O is known as heavy water and was first identified by Harold C. Urey in 1932. Urey noted a slight shift in the spectrum of deuterium and tritium as compared with protium (ordinary hydrogen). The diameter of the electron orbit for deuterium is slightly greater than for protium, and still greater for tritium. Deuterium and

deuterium oxide gained prominence largely because of their excellent properties as moderators in nuclear reactors. See also **Uranium**.

DEUTERON. The nucleus of deuterium (heavy hydrogen) is known as deuteron. A particle that contains one proton and one neutron also is termed a deuteron.

DEVITRIFICATION. The process by which the natural rock glasses, such as obsidian and tachylyte, develop minute but definite minerals, usually quartz and feldspar.

Devitrification also applies to manufactured glasses, denoting crystallization and detected by the appearance of opaque areas. See also **Vitreous State**.

DEW POINT. The temperature to which a given parcel of air must be cooled at constant pressure and constant watervapor content in order for saturation to occur; the temperature at which the saturation vapor pressure of the parcel is equal to the actual vapor pressure of the contained water vapor. Any further cooling usually results in the formation of dew or frost. Also called *dewpoint temperature*. When this temperature is below 0°C, it is sometimes called the frost point.

DEXTROROTATORY COMPOUND. See **Asymmetry (Chemical)**; **Isomerism**.

DEZINCIFICATION. A form of electrolytic corrosion observed in some brasses where the copper-zinc alloy goes into solution with subsequent redeposition of the copper. The small red copper plugs thus formed in the brass are usually porous and of low strength. In recent years, the term dezincification has also been applied in a more general sense to signify any metallic corrosion process that dissolves one of the components from an alloy.

DIAGENESIS. A term proposed by Gumbel in 1888 for the gradual and successive chemical-physical changes that take place in sediments previous to or during their consolidation. Diagenesis may also include the numerous processes of lithification but is a useful term only when particularly applied to the more or less contemporaneous chemical alteration of sediments.

DIALLAGE. The mineral term for a calcium-iron pyroxene, similar in chemical composition to diopside but richer in iron oxide. In addition to the typical prismatic cleavage of the pyroxene group diallage has a marked "cleavage" parallel to the vertical pinacoids, known as diallage parting. Diallage is a common constituent of gabbros. The term diallagite was proposed by Cloiseaux in 1845 for rocks particularly rich in diallage. The term diallage is derived from the Greek meaning difference, and referring to the peculiar cleavages of this variety of monoclinic pyroxene. See also **Pyroxene**.

DIALYSIS. The process of separating compounds or materials by the difference in their rates of diffusion through a colloidal semipermeable membrane. Thus, sodium chloride diffuses eleven times as fast as tannin and twenty-one times as fast as albumin. When the process is conducted under the influence of a difference in electrical potential, as from electrodes on opposite sides of the semipermeable membrane, it is called electrodialysis.

An apparatus for carrying out a dialysis usually consists of two chambers separated by a semipermeable membrane of parchment paper latex, animal tissue, or other colloid. In one chamber the solution is placed, and in the other, the pure solvent. Crystalline substances diffuse from the solution through the membrane and into the solvent much more rapidly than amorphous substances, colloids or large molecules.

DIAMAGNETISM. Diamagnetism is the phenomenon in which the magnetization in a substance opposes the magnetizing force that induces it. Diamagnetism is considered to exist in all substances, although in substances exhibiting paramagnetism or ferromagnetism, it is masked by the much greater opposite effect due to the orientation of the magnetic atoms or molecules.

DIAMINES AND HIGHER AMINES, ALIPHATIC. The aliphatic diamine and polyamine family encompasses a wide range of multifunctional, multireactive compounds. This family includes ethylenediamine (EDA) and its homologues, the polyethylene polyamines (commonly referred to as ethyleneamines), the diaminopropanes and several specific alkanediamines, and analogous polyamines. The molecular structures of these compounds may be linear, branched or cyclic, or combinations of these.

The ethyleneamines have found the broadest commercial application and are the primary focus of this article. The lower molecular weight ethylenediamines, i.e., EDA, diethylenetriamine (DETA), piperazine (PIP), and *N*-(2-aminoethyl)-piperazine (AEP), are available commercially as industrially pure products. The tetramine (TETA), pentamine (TEPA), hexamine (PEHA), and higher polyamine products are commercially available as boiling point fractions consisting of natural mixtures of linear, branched, and cyclic compounds. Their compositions are largely determined by the chemical processes used in their production. The individual components in these higher ethyleneamines are generally not available in industrial quantities.

The predominant commercial diaminopropanes are 1,2-propylenediamine (1,2-PDA), 1,3-diaminopropane (1,3-PDA), iminobispropylamine (IBPA), and dimethylaminopropylamine (DMAPA). Other commercially important products include other higher alkylenediamines, such as hexamethylenediamine (HMDA); certain cyclic amines, such as triethylenediamine (TEDA); and various alkyl- and hydroxylalkyl-derivatives.

Physical Properties

Physical properties of some commercially available polyamines appear in Table 1. Generally, they are slightly to moderately viscous, water-soluble liquids with mild to strong ammoniacal odors. Although completely soluble in water initially, hydrates may form with time, particularly with the heavy ethyleneamines (TETA, TEPA, PEHA, and higher polyamines), to the point that gels may form or the total solution may solidify under ambient conditions. The amines are also completely miscible with alcohols, acetone, benzene, toluene and ethyl ether, but only slightly soluble in heptane. Piperazine, the lowest mol wt cyclic diamine, freezes above room temperature. As such, it is available commercially as either the anhydrous solid or an aqueous solution.

Chemical Properties

The aliphatic alkyleneamines are strong bases exhibiting behavior typical of simple aliphatic amines. Additionally, dependent on the location of the primary or secondary amino groups in the alkyleneamines, ring formation with various reactants can occur. This same feature allows for metal ion complexation or chelation. The alkyleneamines are somewhat weaker bases than aliphatic amines and much stronger bases than ammonia as the pK_b values indicate.

Alkylene Oxides and Aziridines. Alkyleneamines react readily with epoxides, such as ethylene oxide or propylene oxide, to form mixtures of hydroxyalkyl derivatives. Aziridines react in an analogous fashion to epoxides.

Aliphatic Alcohols and Alkylene Glycols. Simple aliphatic alcohols, such as methanol, can be used to alkylate alkyleneamines.

Organic Halides. Alkyl halides and aryl halides, activated by electron withdrawing groups (such as NO_2) in the ortho or para positions, react with alkyleneamines to form mono- or disubstituted derivatives.

Aldehydes. Alkyleneamines react exothermically with aliphatic aldehydes. The products depend on stoichiometry, reaction conditions, and structure of the alkyleneamine.

Organic Acids and Their Derivatives (Anhydrides, Nitriles, Ureas). Alkyleneamines react with acids, esters, acid anhydrides or acyl halides to form amidoamines and polyamides. Various diamides of EDA are prepared from the appropriate methyl ester or acid at moderate temperatures.

Sulfur Compounds. EDA reacts readily with two moles of CS_2 in aqueous sodium hydroxide to form the bis sodium dithiocarbamate.

Environmentally Available Reactants. Under normal conditions ethyleneamines are considered to be thermally stable molecules. However, they are sufficiently reactive that upon exposure to adventitious water, carbon dioxide, nitrogen oxides, and oxygen, trace levels or by-products can form and increased color usually results.

TABLE 1. PROPERTIES OF COMMERCIAL DIAMINES AND HIGHER AMINES

Commercial name	Molecular weight	Freezing point, °C	Bp[a], °C	ΔH^a_{vap} kJ/mol	Refractive index, $n^{20}D$	Viscosity at 20°C, mPa · s(= cP)
ethylenediamine	60.1	10.8	117.0	40.7	1.4565	1.8
diethylenetriamine	103.2	−39	206.9	54.0	1.4859	7.2
triethylenetetramine	146.2[b]	−35	277.4	56.4	1.4986	26
tetraethylenepentamine	189.3[b]	>−40	315		1.5067	76
pentaethylenehexamine[c]	232.4[b]	−30	180–280[d]			100–300
aminoethylpiperazine	129.2	−17	221	41.2	1.5003	15
piperazine	86.1	109.6	144.1			
1,2-propylenediamine	74.1	−27	120–123	38.2	1.4455	1.6
1,3-diaminopropane	74.1	−12	137–140	46.4[e]	1.4555	2.0
iminobispropylamine	131.2	−16	110–120	76.2[e]	1.4791	9.6
N-(2-aminoethyl)-1,3-propylenediamine	117.2		80			
N,N'-bis-(3-aminopropyl)-ethylenediamine	174.3		170			
dimethylaminopropylamine	102.2	−56	134.9	35.6	1.4350	1.1
menthanediamine	170.3	−45	107–126[f]		1.479	17.5[g]
triethylenediamine	112.2	158	174	61.9[h]		
hexamethylenediamine[i]	116.2	41	204.0	51.0		

[a] At 101.3 kPa = 1 atm unless otherwise noted.
[b] Linear component. Commercial product consists of a mixture of linear, branched, and cyclic structures with the same number of nitrogen atoms.
[c] Commercial higher polyamine products contain up to about 40% PEHA.
[d] At 0.67 kPa, 10–60% distills in this range.
[e] At 93.3°C.
[f] At 1.3 kPa.
[g] At 25°C.
[h] Heat of sublimation, below 78°C.
[i] For manufacture of HMDA in preparation of nylon-6,6 see **Polyamides**.

Manufacture

Ethyleneamine Processes. Present industrial processes are based on ethylene and ammonia. The sixty-year-old ethylene dichloride (EDC) process is still the most widely practiced industrial route for producing ethyleneamines.

Alternative processes for the manufacture of ethyleneamines have been actively sought since the late 1960s. The catalytic reductive amination of monoethanolamine (MEA), which was the first such process to appear, produces the lighter ethyleneamines (EDA, DETA, PIP, and AEP) and coproduct aminoethylethanolamine (AEEA), and hydroxyethylpiperazine (HEP).

The condensation of MEA with EDA over heterogeneous catalysts to form primarily DETA represents the newest commercial technology for making ethyleneamines.

A process for the production of ethylenimine, a suspected carcinogen, by the vapor phase dehydration of monoethanolamine has been developed.

Diaminopropane Processes. 1,2-Propylenediamine can be produced by the reductive amination of propylene oxide, 1,2-propylene glycol, or monoisopropanolamine. 1,3-Propanediol can be used to make 1,3-diaminopropane. Various propaneamines are produced by reducing the appropriate acrylonitrile–amine adducts. Polypropaneamines can be obtained by the oligomerization of 1,3-diaminopropane.

Economic Aspects

Worldwide growth for most ethyleneamines is expected to parallel GDP. Some regional and certain applications demands will show somewhat higher growth rates.

Of the worldwide ethyleneamines capacity, over 50% is EDC-based; the balance is monoethanolamine-derived.

Storage and Handling

By virtue of their unique combination of reactivity and basicity, the polyamines react with, or catalyze the reaction of, many chemicals, sometimes rapidly and usually exothermically. Some reactions may produce derivatives that are explosives (e.g., ethylenedinitramine). The amines can catalyze a runaway reaction with other compounds (e.g., maleic anhydride, ethylene oxide, acrolein, and acrylates), sometimes resulting in an explosion.

As commercially pure materials, the ethyleneamines exhibit good temperature stability, but at elevated temperatures noticeable product breakdown may result in the formation of ammonia and lower and higher mol wt species.

Like many other combustible liquids, self-heating of ethyleneamines may occur by slow oxidation in absorbent or high surface-area media. In some cases, this may lead to spontaneous combustion; either smoldering or a flame may be observed. These media should be washed with water to remove the ethyleneamines, or thoroughly wet prior to disposal in accordance with local and Federal regulations.

Since ethyleneamines react with many other chemicals, dedicated processing equipment is usually desirable. Amines slowly absorb water, carbon dioxide, nitrogen oxides, and oxygen from the atmosphere, which may result in the formation of low concentrations of by-products and generally increase color. Storage under an inert atmosphere minimizes this sort of degradation.

Galvanized steel, copper, and copper-bearing alloys are unacceptable for all ethyleneamine service. A 300 series stainless steel or aluminum are recommended for storage of lighter amines (particularly EDA and DETA) to maintain product quality. Carbon steel generally can be used for storage of the heavier ethyleneamines without noticeable impact on product quality if the storage temperature is modest (<60°C), nitrogen blankets are maintained to exclude air, and the material is anhydrous. A 300 series stainless steel is often specified for heating coils, transfer lines, and small agitated tanks, because carbon steel can suffer enhanced corrosion as a result of the erosion of the passive film by the product velocity. Similar logic suggests cast 316 stainless steel for pumps and valves in ethyleneamine service.

Baked phenolic-lined carbon steel is acceptable for storage of many pure ethyleneamines, except EDA. Gaskets utilized in ethyleneamine service generally are made of Grafoil flexible graphite or polytetrafluoroethylene (TFE).

Most common thermal insulating materials are acceptable for ethyleneamine service. However, porous insulation may introduce the hazard of spontaneous combustion if saturated with ethyleneamines from a leak or external spill.

Certain ethyleneamines require storage above ambient temperature to keep them above their freezing points (EDA and PIP) or to lower the viscosity (the heavy amines). As a result, the vapors "breathing" from the storage tank can contain significant concentrations of the product. Water scrubbers may be used to capture these vapors.

Solid ethyleneamine carbamates, formed by the reaction of the amines with carbon dioxide, can foul tank vents and pressure relief devices. Vent fouling can be minimized by using a nitrogen blanket that prevents atmospheric CO_2 from being drawn in, or by steam-tracing the vents (>160°C) to decompose the carbamates.

Although the ethyleneamines are water soluble, solid amine hydrates may form at certain concentrations that may plug processing equipment, vent lines, and safety devices. Hydrate formation usually can be avoided by insulating and heat tracing equipment to maintain a temperature of at least 50°C. Water cleanup of ethyleneamine equipment can result in hydrate formation even in areas where routine processing is nonaqueous. Use of warm water can reduce the extent of the problem.

Health and Safety Factors

Ethyleneamine vapors are painful and irritating to the eyes, nose, throat, and respiratory system. Extremely high vapor concentration may cause lung damage. Prolonged or repeated inhalation may lead to kidney, liver, and respiratory system injury. Contact with the liquids will severely damage the eyes and may cause serious burns to the skin. When swallowed, the concentrated liquid materials may produce considerable local injury. Both vapors and liquid can cause sensitization in some individuals, resulting in contact dermatitis and/or the development of an asthmatic respiratory response. This may occur in certain susceptible individuals following exposure to extremely low concentrations of ethyleneamines, even below the irritation threshold.

The ACGIH has adopted TLVs of 10 ppm (25 mg/m^3) and 1 ppm (4 mg/m^3) for EDA and DETA, respectively. Strict precautions should be observed to prevent direct contact with ethyleneamines, including eye, skin, and respiratory protection. If contact is made, medical treatment should be obtained immediately, in addition to flushing and washing with copious amounts of water. Vomiting is not to be induced following ingestion.

Applications

Polyalkylene polyamines find use in a wide variety of applications by virtue of their unique combination of reactivity, basicity, and surface activity. With a few significant exceptions, they are used predominantly as intermediates in the production of functional products. End-use profiles for the various ethyleneamines include fungicide, oil and fuel additives, polyamides/epoxy curing, paper resins, chelating agents, fabric softeners/surfactants, petroleum production, bleach activator, and anthelmintics/pharmaceuticals.

DIAMOND. An allotropic form of carbon, diamond over the centuries has been known best for its use by the jewelry trade as a precious stone. See also **Gemstones**. See Fig. 1. Although diamond possesses several outstanding properties as a material, its hardness largely has accounted for the industrial uses of diamond for cutting and polishing operations. Until comparatively recently, industrial diamonds were the byproducts of gem stone-mining operations. Although numerous researchers over the years have been attracted by the possibility of creating diamonds synthetically, only during the last decade or two has sufficient progress been made in diamond synthesis to forecast the production of industrial diamonds in tonnage quantities at affordable prices. In addition to the traditional use of diamond because of its hardness, other properties of this outstanding material (heat conductivity, for example) are exploited. Annual industrial diamond production, which amounted to about $200 million in 1991 is expected to exceed $1 billion by the end of the century. As of 1994, research is continuing at an aggressive pace, notably in Japan; a few firms in the United States also are quite active in the field. Over the years, Russian scientists also have been developing a position in synthetic diamond technology.

Important Properties of Diamond

Diamond has the highest atom-number density of any known material at terrestrial pressures[1]. Because of its high atom-number density and strong covalent bonding, diamond has the highest hardness and elastic modulus of any material and is the least compressible substance known.

[1] Diamond possibly may be exceeded by the superdense carbon reported by Matyusenko, et al., 1979. (See reference listed.)

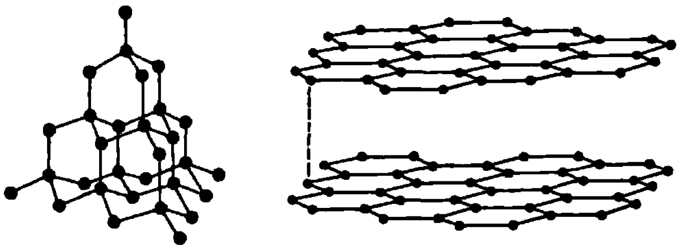

Fig. 1. A gross conceptualization of the space lattices of (a) diamond, and (b) graphite. See new spatial concept for graphite in article on **Carbon**. Diamond crystallizes in the cubic system, is the hardest of known substances (10 on the Mohs scale; 5,500–7,000 on the Knoop scale), specific gravity 3.51–3.521 (20°C), dielectric constant at 10^4 Hz, 16.5, at 10^8 Hz, 5.5, index of refraction 2.417–2.4195. Classically, a diamond crystal may be pictured as a huge polymeric molecule, very tightly packed, with a density about 1.6 times greater than the other allotropic form of carbon, graphite. The normal C–C single bond distances in the atomic lattice of diamond are all 1.54 Å, whereas in graphite the C–C bond distances are 1.42 Å. The tight packing of diamond accounts, of course, for its relatively high density and for its extreme hardness. Graphite, on the other hand, essentially is comprised of two-dimensional molecules, very laminar, and which tend to slide and thus impart lubricity to the substance

The thermal conductivity of diamond at 300 K is higher than that of any other material, and its thermal expansion coefficient at 300 K is 0.8×10^{-6}, lower than that of *Invar* (an Fe–Ni alloy). Diamond is a very wide-band gap semiconductor ($Eg = 5.5$ eV), has a high breakdown voltage (10^7V cm^{-1}), and its saturation velocity of 2.7×10^7 cm s^{-1} is considerably greater than that of silicon, gallium arsenide, or indium phosphide.

Because of these several outstanding qualities, as early as 1988, J.C. Angus and C.C. Hayman (Case Western Reserve University) observed, "There is great interest in using single-crystal diamond for heat sinks and as an active semiconductor element. Potential electronic applications of diamond include high-temperature devices, millimeter-wave traveling wave amplifiers, backward-wave oscillators, and picosecond high-voltage electro-optic switches. Some potential applications may require only polycrystalline films, for example, laser and x-ray windows, lenses, bearing surfaces, and tribological coatings." Several of these applications already have been demonstrated as of the mid 1990s.

Naturally Occurring Diamonds

Geologists observe that probably all of the known diamonds found prior to 1725 had been found in India. In that year, diamonds were discovered in Brazil, a source that has continued to present times. Most Brazilian stones, however, are comparatively small.

Diamonds were discovered in 1867 along the Orange River in South Africa, and since then Africa has been preeminent in the production of diamonds; in the seventies and eighties occurred a series of amazing discoveries of diamond fields and stones of extraordinary size. Diamonds have also been found in Australia, Borneo, British Guiana, and Arkansas.

Much as the matter has been studied there is no consensus as to the genesis of the diamond. It is found in alluvial deposits, both unconsolidated and consolidated, indicating the erosion of rocks containing diamonds not only during the present era but also in past geologic time. In Africa diamonds are mined in a dark basic rock of the general nature of peridotite called kimberlite from the town of Kimberley. The kimberlite occurs in vertical "pipes," resembling what once may have been volcanic necks or other types of igneous rock conduits. It is supposed that the diamonds have been formed in and brought to the surface by the magma, which was of the general nature of peridotite. Undoubtedly high pressures, and possibly high temperatures as well, are necessary for the development of crystallized carbon in the form of diamonds.

Expanded insight concerning the formation and occurrence of diamonds in southern Africa is provided by Boyd (Carnegie Institution of Washington) and Gurney (University of Cape Town) in a paper dealing with diamonds and the African lithosphere. In addition to gaining a better understanding of diamonds, the researchers point out that new knowledge on the structure and history of the Kaapvall craton in which diamonds occur has been gained. As pointed out by the investigators, high pressures are required for the crystallization of diamonds, corresponding to depths in the earth's mantle of at least 150 kilometers. Diamonds formed at those depths

have been brought to the surface in volcanic eruptions of kimberlite. See also **Kimberlite.** Diamonds are found in minute concentrations (+ ppm) in kimberlite that has filled the throats of ancient volcanoes, such as those at Kimberley, where igneous occurrences of diamonds were first recognized. Erosion of kimberlite pipes and transport of diamonds in streams and rivers has dispersed them beyond the boundaries of the craton, in some cases forming secondary concentrations in stream gravels and beach deposits.

In a summary of their findings, Boyd and Gurney state that the Kaapvall craton has a root composed in large part of peridotites that are strongly depleted in basaltic components. See also **Peridotite.** The asthenosphere boundary shelves from depths of 170 to 190 kilometers beneath the craton to approximately 140 kilometers beneath the mobile belts which border the craton on the south and west. The root formed earlier than 3 billion years ago, and at that time ambient temperatures in it were 900 to 1200°C. These temperatures are near those estimated from data for xenoliths erupted in the Late Cretaceous or from present-day heat-flow measurements. Many of the diamonds in southern Africa are believed to have crystallized in this root in Archean time and were xenocrysts in the kimberlites that brought them to the surface. Information about the composition and history of this root is being gathered through study of mineral inclusions in diamonds. Multiple, separate inclusions in individual diamonds are abundant. Sulfides form the most abundant inclusions, but garnet, olivine, pyroxenes, and chromite are also relatively common. For the reader who is seriously interested in South African diamond resources, reference to the full Boyd—Gurney report is suggested.

The manner in which large diamonds are cut and the weight of famous large diamonds is given under **Gemstones.** Growing interest by the jewelry trade in the so-called *pink diamond* has been demonstrated in recent years. As pointed out by P. Proddow and M. Fasel (See reference listed), "Pink diamonds became readily available only in 1984. Now they are used to surround everything from a 79-carat peridot from Burma to a starfish broach to black and white pearls in twin heart earclips."

Synthesis of Diamond

It is reasonable to assume that interest in synthesizing diamonds, driven by the scarcity of natural diamonds[2] extends back to the days of alchemy. Contemporary research involving either high-temperature, high-pressure methods or chemical vapor deposition (CVD) processes commenced in the late 1940s. Important early work was performed at Case Western Reserve University in Cleveland, Ohio and at the Institute for Physical Chemistry, Moscow, Russia. In 1949, W.G. Eversole (Union Carbide Corporation) was the first researcher to grow diamond successfully at low pressures. Conclusive proofs and repetitions of the experiments occurred in early 1953 and thus appears to predate the diamond synthesis at high pressure by investigators at General Electric Company, which was reported as accomplished in December 1954, but which was not announced publicly until 1955. Essentially contemporaneously, Liander (Allemanna Svenska Elektriska Aktiebolaget ASEA) in Sweden reported synthesis of diamond. It is interesting to note that Eversole grew new diamond on preexisting diamond nuclei, whereas the GE and ASEA syntheses commenced with nondiamond carbons.

As reported by J.C. Angus and C.C. Hayman (Case Western Reserve University), "B. Deryagin (Russia), who started work on low-pressure diamond synthesis in 1956 has had the longest sustained research effort on metastable diamond growth of any worker." Deryagin's group initiated many approaches to the problem, starting with the growth of diamond whiskers by a metal-catalyzed vapor-liquid solid (VLS) process. Later, the group researched epitaxial growth from hydrocarbons and hydrocarbon-hydrogen mixtures, using different forms of vapor transport reactions. The Deryagin group also concentrated on theoretical investigations of the relative nucleation rates of diamond and graphite. See Fig. 2.

J.C. Angus and co-researches at Case Western Reserve University (CWRU) targeted principally the CVD process, by attempting to deposit diamond on diamond seed crystals from hydrocarbons and hydrocarbon-hydrogen mixtures. The CWRU team grew P-type semiconducting diamond from $CH_4-B_2H_6$ gas mixtures and studied the rate of diamond and graphite growth in CH_4-H_2 gas mixtures and ethylene. The group was the first to report on the preferential etching of graphite compared to diamond by atomic hydrogen and noted that boron had an unusual catalytic effect on metastable diamond growth. The role of hydrogen in permitting metastable diamond growth was a constant thread throughout the early work.

[2] Proof that diamond is an allotropic form of carbon was given by the English chemist, Smithson Tennant, in 1797.

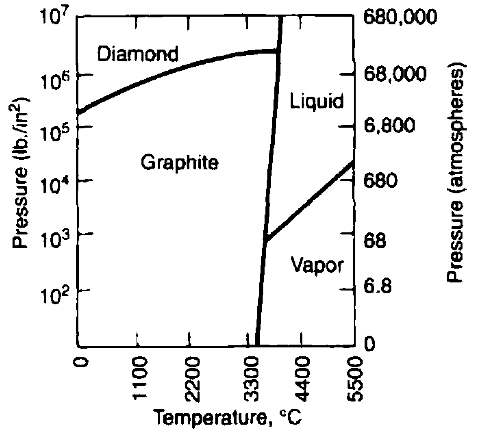

Fig. 2. Phase diagram approximation of carbon, indicating pressure-temperature parameters favoring yield of graphite and diamond. See also phase diagram in the article on **Carbon**

Numerous other groups worked on the problem, and it was demonstrated that the presence of hydrogen enhanced yields of diamond. The addition of hydrogen to the hydrocarbon gas phase was shown to suppress the growth rate of graphite more than it suppressed the growth rate of diamond, resulting in higher diamond yields. However, graphitic carbons nucleated on the surface and suppressed further diamond growth. It was necessary to remove the graphitic deposits preferentially, with atomic hydrogen or oxygen, and to repeat the sequence.

Isotopically Adjusted Diamonds

The ratio of isotopes in natural diamond is about one carbon-13 atom for every 100 atoms, the remainder being carbon-12 atoms. During the early 1970s, R. Seitz (Harvard University) became convinced, it is reported, that an isotopically pure diamond (all carbon-12 atoms) would be an excellent conductor of heat and less susceptible to damage by a laser beam. In July 1990, General Electric announced that it had made an isotopically pure carbon-12 diamond. Tests and calculations have shown that a diamond of all or nearly all carbon-12 atoms had been produced. Apparently, the methane gas used in the CVD process can be enriched with either C-12 or C-13, after which thin mosaics of tiny diamond grains serve as feedstock for a week-long process involving 1000 tons of pressure and a temperature of about 1500°C. The operation may be described as a slow diffusion process. Because of the time factor and extreme conditions, costs are high. J.C. Angus (CWRU) suggests, "An alternative route for growing the gem-sized diamonds might develop from the vapor deposition methods now used for growing diamonds." Subsequent research by various groups has indicated that an all carbon-13 diamond may be even better than the pure carbon-12 structure. Quantum mechanical calculations have indicated that slightly more atoms cause the atoms to be about .015 percent closer. This could translate into practical end-use properties, including hardness, among other property changes still unknown. It is reported that a carbon-13 diamond had been produced in 1971, but that it had not been reported officially. Some scientists now note that in the future diamonds may become commercially available on a "ready to order," isotopic ratio basis.

John Angus (CWRU) has suggested that an alternative route for growing gem-size diamonds may develop from the vapor deposition methods now used for growing diamond films.

Diamond Films

Two principal classes of diamond film deposition have been developed: (1) PACVD (plasma-assisted chemical vapor deposition) and (2) IBED (ion-beam-enhanced deposition).

A.H. Deutchman and R.J. Partyka (Beam Alloy Corporation) observe, "Characterization and classification of thin diamond films depend both on advanced surface-analysis techniques capable of analyzing elemental composition and microstructure (morphology and crystallinity), and on measurement of macroscopic mechanical, electrical, optical and thermal properties. Because diamond films are very thin (1 to 2 micrometers or less) and grain and crystal sizes are very small, scanning electron microscopy

and transmission electron-microscopy techniques must be used to examine film morphology. Crystallinity is measured by various techniques including x-ray and electron diffraction Auger electron spectroscopy, and laser Raman spectroscopy."

Analysis of chemical composition is important because large percentages of hydrogen can be incorporated in the films, especially with PACVD techniques. This can cause a wide variety of hydrogenated structures.

Diamond films, although not approaching bulk diamond, are harder than most refractory nitride and carbide thin films, which makes them attractive for tribological coatings. Transparency in the visible and infrared regions of the optical spectrum can be maintained and index-of-refraction values approaching that of bulk diamond have been measured. Electrical resistivities of diamond films have been produced within the full range of bulk diamond, and thermal conductivities equivalent to those of bulk diamond also have been achieved. As substrates for semiconductor electronic devices, diamond films can be produced by both the PACVD and IBED techniques.

Diamonds in Meteorites

The presence of diamond in extraterrestrial specimens first was detected in the late 1800s. Inasmuch as meteorites are believed to originate from relatively small bodies (only a few hundred km in diameter or less), the origination of meteorite diamond is believed to differ from the diamond-forming process on Earth—mainly because of the absence of high pressures as found on Earth. Researchers recently have observed, "There is considerable need to subject diamonds from Abee (enstatite chondrite) and, for that matter, diamonds from ureilites and iron meteorites to the kind of scrutiny being given to the nanometer-sized component Cδ. It may be that low-temperature, low-pressure (that is, nonshock) formation of diamond was an important process in the early inner solar system." See also **Extraterrestrial Materials**.

DIAMOND ANVIL HIGH PRESSURE CELL. The behavior of matter under extreme pressure is of great interest to several scientific disciplines and scientists working in the field of high pressure research are continually striving to achieve higher and higher pressure, to expand our knowledge in the field. Modern high pressure research falls under two categories—*static* and *dynamic*. Static high pressure is sustained pressure acting on a sample, while dynamic pressures last only a few millionths of a second and are generated by a shock wave. While dynamic pressures in the megabar range* (millions of atmospheres) can easily be generated, static pressures of this magnitude are hard to realize. Only recently, this has become possible through the introduction of a novel pressure generating device called the *Diamond Anvil Cell* (DAC). The DAC has practically replaced all other pressure generating devices used in high pressure research and is proving to be a versatile tool to study the high pressure behavior of matter. With the DAC, pressures of 5 megabars (5 million atmospheres) have recently been achieved.

*Pressure is usually expressed in bars, atmospheres, or pascals. One bar = 0.9868atmosphere = 10^5 pascals. One megabar = 10^6 bars = 100 GPa (giga pascals).

Why diamond works so well is because of its two most desirable properties, namely, (1) it is the hardest substance known to science, and (2) it is very transparent to optical radiation as well as to x-rays. Compared to diamond, tungsten carbide, which was used in older pressure generating devices, has a much lower compressive strength and, further, it is opaque to radiation.

The Diamond Anvil Cell

In Fig. 1 a modern DAC capable of generating megabar pressures is shown. Quite contrary to the general conception of high pressure apparatus, the DAC is such a compact device that it fits in the palm of a hand. Figure 2 shows the basic elements of the DAC. The arrangement shown consists of two flawless (gem quality) diamonds, one-third to one-half carat in weight. The pointed ends of the diamonds are ground off and polished to produce small flats of about 0.5 millimeter in size and are set in opposition to each other. When a metal gasket is compressed between these small flat faces very high pressure is generated in the gasket. To apply this pressure on a sample, a hole is drilled in the gasket for locating the sample and the pressure-transmitting medium. Because the area over which the force is concentrated is extremely small, the pressure on the sample, which is force per unit area, can be enormous. For the same reason a force that can be applied by hand is multiplied 500 to 1000 times by the mechanism, which makes the DAC a very compact apparatus. In a practical DAC such as the one shown in Fig. 1, the two diamonds are mounted inside a hardened steel mechanism, machined to high tolerances, that imparts thrust along an axis perpendicular to the diamond faces. For the successful operation of the DAC, the two diamond flats have to be set perfectly parallel to each other and further they should be accurately centered along the common axis. The mechanism carries hardened steel or tungsten carbide rockers for diamond support and alignment. The thrust and alignment mechanisms can be designed in different ways, and hence, several types of diamond cells have evolved.

The simple operation of the DAC is the hard-won result of two decades of evolution in design. High pressure devices employing diamonds were first built in 1959 by C.E. Weir, E.R. Lippincott, A. Van Valkenburg and E.N. Bunting of the National Bureau of Standards, and J.C. Jamieson, A.W. Lawson and N.D. Nachtrieb of the University of Chicago, independently and simultaneously. Since that time, the NBS Scientists and several other groups have developed the DAC as a fine tool for ultrahigh pressure research.

In a diamond cell, the sample volume is sacrificed for the sake of higher pressures, and hence, all operations connected with the cell have to be performed under a microscope. In preparing the DAC for an experiment, the first step is to indent the metal gasket (hardened stainless steel strip or Inconel strip) with the anvil diamonds to the correct thickness (50 to 100 micrometers) and then drill a 100- to 200-micrometer hole as close to the center of the indentation as possible. The gasket is seated on the face of one of the diamonds in the same orientation as it had when the indentation was made. The sample material and a small chip of ruby for pressure calibration are then placed in the hole. Finally, to maintain hydrostatic pressure the hole is filled with a tiny drop of fluid from a syringe and then the hole is quickly sealed by the diamond faces before the fluid evaporates.

When thrust is applied, the metal gasket is compressed, and along with it the pressure medium and the sample. Because of the greater compressibility of the pressure medium, the pressure on the gasket is always greater than the pressure on the contents in the hole, and this ensures perfect sealing of the pressure chamber. The optimum hardness for the gasket is an important element in diamond cell work, for too soft a gasket would simply flow like butter, and too hard a gasket would not compress. The purpose of the

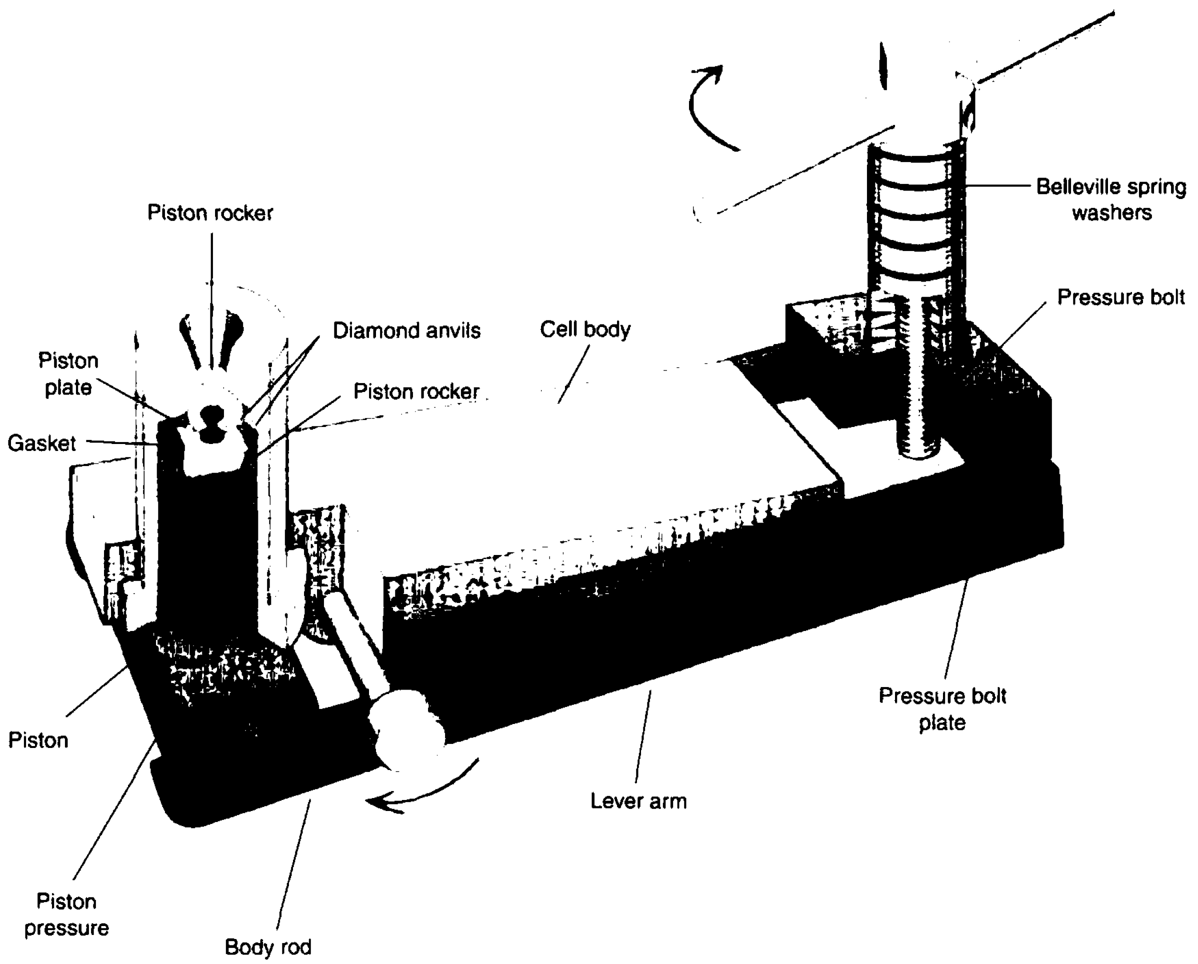

Fig. 1. Modern diamond anvil cell of the type developed at the Geophysical Laboratory of the Carnegie Institution in Washington, DC. It is about 20 cm long and weighs about 3 kg. The piston and cylinder are machined to very high tolerances. The anvil diamond on the piston is fixed on a half-cylindrical rocker mount recessed into the piston. The other anvil diamond is inside the cylinder and sits on a similar rocker mount. The two rocker mounts are set at right angles and can be moved laterally with screws to center the diamond flats. Parallel alignment of the diamond flats is accomplished by tilting the two half-cylindrical rockers until the optical interference fringe pattern appearing in between the two flats is reduced to a uniform gray color, and then locking the rockers in position with set screws. Thrust is generated by turning the handle on the spring-loaded pressure bolt clockwise. The thrust is transmitted by the long lever arms and is delivered to the movable piston as a vertical upward force through the action of the fulcrum (the rod on the side goes into the body of the cell and acts as the fulcrum) and a swiveling piston pressure plate (not seen in the figure). The lever arm mechanism magnifies the thrust and delivers it to the piston plate which, in turn, pushes the piston diamond against the stationary diamond attached to the cylinder. One of the finest features of the diamond anvil apparatus is that pressurized samples can be viewed directly with an optical microscope. (*From "The Diamond-Anvil High-Pressure Cell" by A. Jayaraman. Copyright © April 1984 by Scientific American, Inc. All rights reserved*)

gasket is to provide containment for the pressure medium as well as to give support to the diamond flats. The higher the pressure, the harder the gasket material should be.

Megabar Pressures. To reach megabar pressures, the diamond flats have to be modified to what is known as beveled geometry. This is shown in Fig. 3. In this a part of the flat has been beveled: the bevel angle is typically 5°. The flat region B and dimension A are variable, and for megabar pressures they are usually 50 micrometers and 300 micrometers, respectively. The beveling seems to smooth out the pressure gradients, with beneficial effects on the diamond. At megabar pressures, gradients over the active area dictate the use of a very small sample and this makes experimentation at these pressures a challenge. However, these challenges are being met by using ingenious methods.

Pressure Calibration. Pressure is determined in a remarkably simple way using ruby fluorescence. Indeed, without the ruby the small size of the high-pressure cell would make the pressure quite difficult to calibrate and the scientific value of the instrument would be far less than it is. When ruby is excited by light, it fluoresces strongly with a deep red color. The fluorescent emission can be resolved by a spectrograph into two peaks, called R_1 and R_2, whose wavelengths are accurately known at atmospheric pressure. When the pressure on the ruby is increased, the fluorescence peaks shift to a higher wavelength. This shift has been calibrated for pressures known on independent grounds, and hence, the measured shift of the peaks is an indirect measure of the pressure on the ruby. Usually the stronger of the two peaks, the R_1 peak, is used in pressure calibration. The spectral shift can be quickly and accurately measured with a simple grating spectrometer. The shift is almost exactly proportional to the pressure up to 300 thousand atmospheres (0.037 nanometer per atmosphere). For higher pressures the spectral shift is somewhat smaller for a given increment in pressure, but the shift has now been calibrated up to 2 megabars (nearly 2 million atmospheres) using gold as standard. The ruby seems to work quite satisfactorily to the highest pressures reached with the DAC, namely, 5 megabars, and an extrapolation of the above scale is used to measure these very high pressures.

Pressure Media

There are several materials currently employed as hydrostatic media in the cell. The most convenient material to load into the cell is a mixture of four parts methanol to one part ethanol, but at pressures of more than 105,000 atmospheres the mixture solidifies at room temperature and the pressure is no longer hydrostatic. For higher hydrostatic pressures, noble gases, viz. argon, xenon, or even hydrogen and helium are used. These gases can be trapped in the tiny hole in the gasket either by cooling the diamond cell to low temperatures and filling with the liquefied gas or by the high pressure gas loading technique. In the latter method, the diamond cell is enclosed in a large pressure vessel and charged with the gas at about 2000 atmospheres. The high pressure gas, filling the gasket hole, is trapped by applying pressure to the gasket with the diamonds, from outside. After the release of pressure in the large pressure vessel, the diamond cell with

the trapped high pressure gas is taken out and loaded into the lever-arm mechanism for further pressurization when running an experiment. The trapped gas can serve as a pressure medium, or it can be a sample for high pressure studies.

High Pressure-High Temperature. High pressure-high temperature conditions are particularly desirable for geophysical studies. In the diamond anvil cell such conditions can be produced by internal heating of the sample with a high power laser beam (such as a neodymium glass laser) or externally by surrounding the diamond anvil region with a heater element. In the first method, only the sample gets heated and not the diamond, because of its transparency to the laser radiation. Sample temperatures of 5000°C have been attained at pressures of one megabar with laser heating. The temperature is measured either by optical pyrometry or by a radiometric technique. In the external heating method, the entire diamond anvil region is heated. The temperature attainable is limited to about 1000°C because of the damage to the diamond and loss of mechanical support at high temperatures.

Low Temperature. It is also possible to operate the DAC at liquid helium temperatures (−270°C) for high pressure-low temperature studies. For low temperature studies the diamond cell is placed inside a low temperature Cryostat provided with optical windows, and is pressurized by a suitably designed tightening mechanism.

Ultrahigh Pressure Research

The diamond anvil cell is a tool par excellence for optical, infrared and Raman spectroscopy and enables the researcher to study the changes in the electronic structure and chemical binding caused by the application of high pressure. Phase transitions, which involve changes in the atomic architecture can be determined with the diamond cell using the x-ray diffraction technique. The diamond cell has been successfully interfaced with synchrotron sources, which generate powerful x-ray beams, for x-ray diffraction studies. In geophysics, the high pressure-high temperature

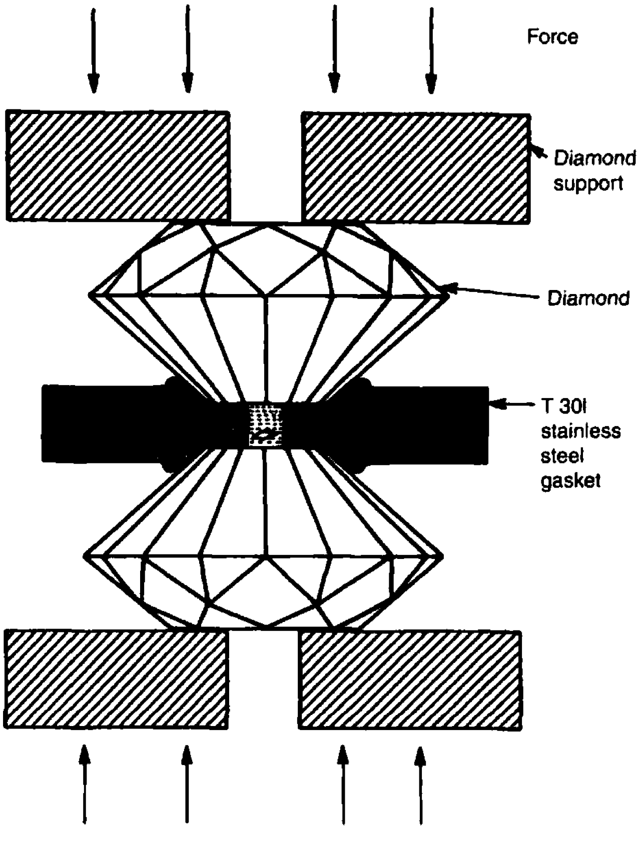

Fig. 2. Basic principle of the diamond cell. Pressure is generated in the gasket hole when the diamonds are pushed against one another. The sample and a small chip of ruby for pressure calibration are placed in the hole and the latter is filled with a pressure-transmitting medium. The purpose of the gasket is to provide containment for the pressure medium as well as support the diamond flats. Suitable apertures in the diamond support blocks provide access to optical, x-ray, and other radiation

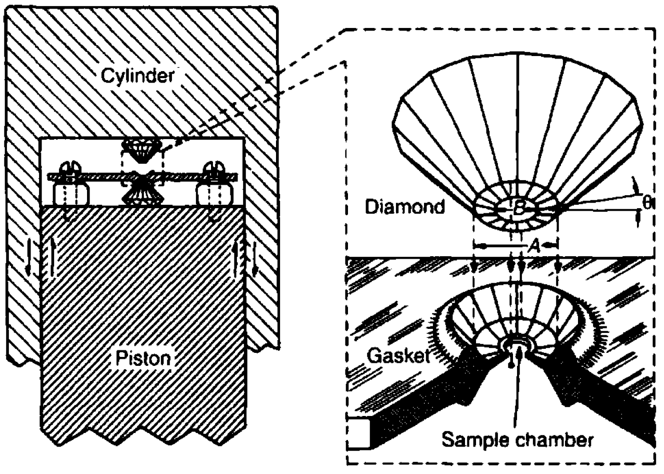

Fig. 3. For megabar pressures, the piston and cylinder assembly should be perfectly fitting, to maintain the alignment of the diamond anvils. The diamonds are beveled to smooth out the pressure gradients. The *A* dimension varies from 0.6 mm to 0.3 mm and the *B* dimension from 0.3 mm to 0.1 mm. The gasket hole varies from 0.1 mm to 0.025 mm. The bevel angle *θ* is usually around five degrees. After an experiment at megabar pressures, the diamonds develop ring cracks, but they can be reground and repolished for further use. (*After Mao and Bell*)

capabilities of the diamond cell is like a window to the interior of the earth. High pressure-high temperature studies give information on the state of silicate minerals and oxides in the mantle region right up to the core-mantle boundary and provide us with a view of the earth's interior, where high pressure and high temperature conditions exist. In solid state physics, one of the most fascinating problems is the possibility of making metallic hydrogen under ultrahigh pressure. This extraordinary change from a very good insulating to a metallic state in hydrogen is predicted to occur near 3 to 4 million atmospheres. High pressure scientists are trying hard to make metallic hydrogen with the DAC.

The limit of pressure attainable with the DAC could be much higher than 5 million atmospheres. Theoretical calculations reveal that diamond is stable up to 23 million atmospheres with respect to any phase transitions. Plastic deformation would limit its capability, but this limit could be much higher than the presently reported maximum pressure of 5 million atmospheres.

Since the introduction of the diamond anvil high pressure cell in the early 1980s, it has found wide usage in a variety of research fields. Possibly, the greatest pressure achieved to date was 4.16 megabars by researchers (Cornell Univ.) when "squeezing" a microscopic sample of molybdenum powder. By comparison, the pressure at the center of the Earth is estimated at about 3.6 megabars. Other extremely high pressures have been achieved at the Lawrence National Laboratory (Livermore, California).

In 1988, J.M. Brown and L.J. Slutsky (Univ. of Washington) and K.A. Nelson and L.T. Cheng (Massachusetts Institute of Technology) took advantage of the adaptability of laser-induced phonon spectroscopy and diamond anvil techniques to determine acoustic velocities and equations of state (methanol and ethanol). As pointed out by the researchers, "Acoustic velocities are directly related to interatomic force constants and these velocities of sound are a matter of considerable importance to the earth sciences." By knowing these properties, proceeding from a seismological image of the Earth's interior, a geophysical model in terms of density, temperature, and chemical composition can be created.

Godward (Univ. of California, Berkeley) and a team of researchers used a laser-heated diamond cell (modified Mao-Bel type) in their research on the ultrahigh-pressure melting of lead. This study is part of a project to *characterize* materials at ultrahigh pressures. Such data can be useful for a wide range of applications in the planetary sciences and the physics of condensed matter.

DIAPHRAGM CELL. A type of electrolytic cell for the production of sodium hydroxide and chlorine from sodium chloride brine. The cell contains anode and cathode compartments separated by a porous diaphragm or membrane to prevent mixing of the solutions. Asbestos fibers are usually used for this diaphragm, though a recent development is a plastic material made from perfluorosulfonic acid. The brine is fed continuously to the anode compartment, where chlorine is released at the graphite anode and flows through the diaphragm to the steel cathode, where hydrogen is liberated. Sodium hydroxide accumulates in the liquid and is continuously drained from the cathode compartment. The Hooker cell and the Vorce cell are two widely used types of diaphragm cell.

See also **Chlorine**.

DIASPORE. The mineral diaspore is a hydrous oxide of aluminum corresponding to the formula AlO(OH) occurring in prismatic orthorhombic crystals, usually somewhat flattened, or massive. It displays good cleavage; conchoidal fracture; is brittle; hardness, 6.5–7; specific gravity, 3.3–3.5; luster, vitreous to pearly; color, white, grayish, greenish, yellowish, brownish or colorless; transparent to translucent. Diaspore is found associated with corundum, emery and bauxite, being probably an alteration product of the oxide. It has been made artificially. Diaspore has been found associated with emery in the Ural Mountains, in the Middle East, in the Island of Naxos, Greece, and in the United States at Chester, Massachusetts. Its name is derived from the Greek word meaning to scatter, because of its decrepitation upon heating.

DIATOMACEOUS EARTH. See **Diatomite**.

DIATOMITE. Diatomite is a naturally occurring, porous, high surface area form of hydrous silica that is used as a filter aid and as a mineral filler. Diatomite products may be classified according to manufacturing method into three categories: natural diatomite, calcined diatomite, and flux-calcined diatomite. Products from all three categories find widespread use in industrial filtration applications as a filter aid for achieving higher clarity, longer filter cycles, and removing high solids concentrations (Table 1). Products from all three categories are also used as functional fillers where diatomite properties add to the performance of paints, plastics, rubber, catalysts, agricultural chemicals, pharmaceuticals, toothpastes, polishes, and other chemicals.

Diatomite, also known as diatomaceous earth, or kieselguhr, consists mainly of accumulated shells or frustules of intricately structured amorphous hydrous silica secreted by diatoms, which are microscopic, one-celled golden brown algae of the class Bacillariophyceae. Diatoms exist in many different environments and are abundant in regions of oceanic upwelling.

Origins of Deposits

Most commercial marine diatomite deposits exploit accumulations resulting from large blooms of diatoms that occurred in the oceans during the Miocene geological epoch. Marine deposits must have been formed on the bottom of protected basins or other bodies of quiet water, undisturbed by strong currents, in an environment similar to the existing Santa Barbara Channel or Gulf of California.

The main deposits of freshwater diatomite were laid down in large lakes. Many of these deposits in the western United States formed during glacial times, when the local climate was wetter. Several tens of square kilometers in Nevada west of Tonopah are covered with diatomite as are other large areas in the Great Basin.

Location of Deposits. Deposits of diatomite are known to exist on every continent and in nearly every country. Most of the deposits are not large enough or sufficiently pure to have commercial value. Production figures show the location of the deposits that meet commercial standards in both respects.

In the United States the most extensive commercial deposits are located in California, Nevada, Oregon, and Washington. The U.S. Bureau of Mines also reports the commercial operation of diatomite deposits in Arizona.

TABLE 1. PROPERTY RANGES OF DIATOMITE PRODUCTS[a]

Property	Filter aids			Fillers,
	Natural	Calcined	Flux-calcined	all types
permeability range, μm^2 [b]	0.06	0.5–2.0	1.0–29.6

[d] To convert from kPa to psi, multiply by 0.145.
[e] Hegman gauge readings, useful for paint manufacture, run from 0–55.

Physical and Chemical Properties

Chemically, diatomite consists primarily of silicon dioxide, $SiO_2 \cdot nH_2O$, and is essentially inert. It is attacked by strong alkalies and by hydrofluoric acid but is virtually unaffected by other acids. The silicon dioxide has a unique structure, resulting from the intricate form of the diatom skeletons. The chemically combined water content varies from 2 to 10%. Impurities that are often found mixed with the diatomite are other aquatic fossils such as sponge residues, Radiolaria, silicoflagellata, sand, clay, volcanic ash, mineral aerosols, calcium carbonate, magnesium carbonate, soluble salts, and organic matter.

The color of pure diatomite is white, or near white, but impurities such as carbonaceous matter, clay, iron oxide, volcanic ash, etc may darken it.

Individual diatom frustules are porous. The diatoms are highly variable in shape and size, having particles that range in effective diameter from 0.75 to 1000 μm, but most are 50 to 100 μm in diameter. Diatom shapes can range from simple cylinders and disks to complex, highly variable, but always punctate, forms.

The bulk density of powdered diatomite varies from 112 to 320 kg/m^3. The true specific gravity of diatomite is 2.1 to 2.2, the same as for opaline silica, or opal. The thermal conductivity of bulk quantities of diatomite is low but increases with higher percentages of impurities and a higher density. The fusion point depends on the purity but averages about 1430°C for pure material, which is slightly less than for pure silica. The addition of chemical agents, such as soda ash, reduces the fusion point.

Diatomite has only weak adsorption powers but shows excellent absorption because of its structure and high surface area. Acids, liquid fertilizers, alcohol, water, oils, and other fluids are absorbed by diatomite.

Mining and Processing

Diatomite deposits are usually discovered by observation of outcrop, and the value of the deposits is determined by geological prospecting and exploration.

Mining. Most diatomite is mined by open-pit methods.

Economic Aspects. Owing to the low bulk density of diatomite, freight and trucking rates (on a weight basis) are high. Domestic finished products are packed and shipped in laminated kraft-paper bags, usually containing 22.5 kg, or the product is shipped in bulk or semibulk bags. Bagged products are shipped by truck or rail boxcar.

Domestic Producers. A principal company mining diatomite and processing it into finished products is Celite Corp. (Lompoc, California), which has wholly owned mines and processing facilities in Lompoc, California; Quincy, Washington; Jalisco, Mexico; Murat, France; Alicante, Spain; and a joint venture mine in Iceland.

Production. After the United States, Romania, the former USSR, and France are the largest producers of diatomite. Combined with the United States, these countries account for more than 75% of the world's production.

DICARBOXYLIC ACIDS. The diacids are characterized by two carboxylic acid groups attached to a linear or branched hydrocarbon chain. Aliphatic, linear dicarboxylic acids of the general formula $HOOC(CH_2)_nCOOH$ and branched dicarboxylic acids are the subject of this article. The bifunctionality of the diacids makes them versatile materials, ideally suited for a variety of condensation polymerization reactions. Several diacids are commercially important chemicals that are produced in multimillion-kg quantities and find application in a myriad of uses.

Nomenclature

Unsubstituted aliphatic dicarboxylic acids, $HOOC(CH_2)_nCOOH$, are most often referred to by their trivial names for $n = 2$ to 10 (Table 1). Higher homologues are named using the IUPAC system by adding the suffix dioic to the parent hydrocarbon.

Physical Properties

Detailed summaries of physical properties are given. The diacids are colorless, crystalline solids that melt somewhat higher than monoacids of the same molecular weight. For diacids of even carbon number, melting points decrease sharply for numbers 2–10 and remain relatively constant for numbers 12–20 (see Table 1). There is a marked alternation in melting point and other physical properties with changes in carbon number from even to odd within the series. Odd members exhibit lower melting points, and higher solubility. Theoretical treatments have been developed to correlate these physical properties. The alternating effects are the result of the inability of odd carbon number compounds to assume an in-plane orientation of both carboxyl groups with respect to the hydrocarbon chain. Other properties showing these alternations are decarboxylation temperature and index of refraction. These effects have practical consequences in the selection of material for a given preparation because acid melting point, decarboxylation temperature, and solubility are often key considerations. The effects persist in derivatives based on the diacids, particularly polyamides, polyurethanes, and polyesters.

TABLE 1. PHYSICAL PROPERTIES OF C_2–C_{21} ALIPHATIC DICARBOXYLIC ACIDS

IUPAC name	Mp, °C	Bp, °C[a]	Water solubility,[b] g/100 mL	Density, g/mL
ethanedioic	187 (dec)		9.5	
propanedioic	134–136 (dec)		152	1.619
butanedioic	187.6–187.9		8.35	1.572
pentanedioic	98–99	200[c]	130	1.424
hexanedioic	153.0–153.1	265	3.08[d]	1.345
heptanedioic	105.7–105.8	272	5.0	1.287
octanedioic	143.0–143.4	279	0.16	1.270
nonanedioic	107–108	286.5	0.214	1.235
decanedioic	134.0–134.4	294.5	0.10	1.231
undecanedioic	110.5–112		0.003	
dodecanedioic	128.7–129.0	254[e]	0.004	1.16
tridecanedioic	114			
tetradecanedioic	126.5

hexadecanedioic	125			
heptadecanedioic	117–118			
octadecanedioic	124.6–124.8			
nonadecanedioic	118–119.5			
eicosanedioic	124–125			
heneicosanedioic	118–120			

[a] At 13.3 kPa = 100 mm Hg unless otherwise noted.
[b] At 20–25°C unless otherwise noted.
[c] At 2.7 kPa = 20 mm Hg.
[d] At 34.1°C.
[e] At 2.0 kPa = 15 mm Hg.

The temperature at which decarboxylation occurs is of particular interest in manufacturing processes based on polymerization in the molten state where reaction temperatures may be near the point at which decomposition of the diacid occurs. The diacids become more heat stable at carbon number four, with even-numbered acids always more stable. Thermal decomposition is strongly influenced by trace constituents, surface effects, and other environmental factors.

Lower members of the series are water soluble; solubility falls off sharply above adipic acid. Alternating effects are again expressed with acids of odd carbon numbers being the most soluble (see Table 1). Dibasic acids are ionized in aqueous solution to varying degree depending upon the proximity of the carboxyl groups within the individual structures. The carboxyl group, being electron-withdrawing, causes the neighboring carboxyl hydrogen to be more readily dissociated.

Chemical Properties

The dibasic acids undergo the reactions typical of monocarboxylic acids.

Manufacture, Preparation, and Processes

Glutaric Acid. Until 1990–1991 glutaric acid was available commercially from DuPont as a by-product in the production of adipic acid. It is no longer available, but DuPont produces dimethyl glutarate and mixtures of dimethyl succinate and dimethyl glutarate, as well as mixtures of dimethyl glutarate and dimethyl adipate.

Several procedures for making glutaric acid have been described in *Organic Syntheses* starting with trimethylene cyanide, methylene bis (malonic acid), γ-butyrolactone, and dihydropyran.

Pimelic Acid. This acid is manufactured by Tateyama Chemical Company in Japan in quantities of about 1000–2000 kg/yr, and by Heinrich Mock Nachf in Germany. The method or process they are using has not been disclosed. Pimelic acid is available in small quantities with purities of 98% from laboratory chemical supply companies. The preparation of pimelic acid has been described in *Organic Syntheses;* cyclohexanone condenses with diethyl oxalate, followed by decarboxylation to ethyl 2-keto-hexahydrobenzoate, and then cleavage of the β-keto ester with strong alkali.

Suberic Acid. This acid is not produced commercially at this time. However, small quantities of high purity (98%) can be obtained from chemical supply houses. If a demand developed for suberic acid, the most economical method for its preparation would probably be based on one analogous to that developed for adipic and dodecanedioic acids: air oxidation of cyclooctane to a mixture of cyclooctanone and cyclooctanol. This mixture is then further oxidized with nitric acid to give suberic acid.

Azelaic Acid. This acid is produces by the Emery Group of Henkel Corporation in Cincinnati, Ohio, in multimillion kg quantities. The process that is currently used is based on the ozonolysis of oleic acid (from grease or tallow) followed by the decomposition of the ozonide with oxygen.

Sebacic Acid. This acid is produced commercially by Union Camp in Dover, Ohio, by Hokoku Oil Company in Japan, and by a state enterprise in the People's Republic of China. The process used in each case is based on the caustic oxidation of castor oil or ricinoleic acid in either a batch or continuous process.

Dodecanedioic Acid. Dodecanedioic acid (DDDA) is produced commercially by Du Pont in Victoria, Texas, and by Chemische Werke Hüls in Germany. The starting material is butadiene which is converted to cyclododecatriene using a nickel catalyst. Hydrogenation of the triene gives cyclododecane, which is air oxidized to give cyclododecanone and cyclododecanol. Oxidation of this mixture with nitric acid gives dodecanedioic acid.

Brassylic Acid. This acid is commercially available from Nippon Mining Company (Tokyo, Japan). It is made by a fermentation process.

C-19 Dicarboxylic Acids. The C-19 dicarboxylic acids are generally mixtures of isomers formed by the reaction of carbon monoxide on oleic acid. Because the reaction produces a mixture of isomers, no single chemical name can be used to describe them. There are currently no commercial producers of C-19 dicarboxylic acids.

C-20 Dicarboxylic Acids. These acids have been prepared from cyclohexanone via conversion to cyclohexanone peroxide followed by decomposition by ferrous ions in the presence of butadiene. Okamura Oil Mill (Japan) produces a series of commercial acids based on a modification of this reaction.

C-21 Dicarboxylic Acids. C-21 dicarboxylic acids are a mixture of predominately 5-(6)-carboxy-4-hexyl-2-cyclohexene-1-octanoic acid, 5-isomer and 6-isomer. C-21 dicarboxylic acids are produced by Westvaco Corporation in Charleston, South Carolina in multimillion-kg quantities. The process involves reaction of tall oil fatty acids (TOFA) (containing about 50% oleic acid and 50% linoleic acid) with acrylic acid and iodine at 220–250°C for about 2 h.

Dicarboxylic Acids via Microorganisms

During the 1980s a number of patents were issued describing the preparation of dicarboxylic acids or esters using microorganisms. The α,ω-*n*-alkanedioic acids that have been prepared generally have 5–25 carbons. One of the first methods described the preparation of dimethyl 1,16-hexadecanedioate using a nutrient solution, *n*-hexadecyl bromide, and certain strains of *Torulopsis*. Other methods have been described to give dibasic acid of 8–22 carbons using *n*-alkanes or *n*-alcohols and various organisms.

Derivatives and Uses

Diacids, owing to their ready incorporation into polymers, are components in a wide variety of materials. The diacids are important industrial intermediates for the manufacture of diesters, polyesters, and polyamides. These derivatives find application as plasticizing agents, lubricants, heat transfer fluids, dielectric fluids, fibers, copolymers, inks and coatings resins, surfactants, fungicides, insecticides, hot-melt coatings, and adhesives. Of the higher diacids, azelaic, sebacic, and dodecanoic find the greatest application. Derivatives of glutaric and C-21 diacids also enjoy significant commercial applications.

Economic Aspects

In addition to azelaic, sebacic, dodecanedioic, eicosanedioic (C_{20} diacids), and C_{21} diacids, undecanedioic, brassylic, tetradecanedioic, hexadecanedioic, docosanedioic, and tetracosanedioic acids are available, expensive, and in limited quantity from research chemical supply houses.

Health and Safety Factors

In general, the higher diacids are essentially nontoxic. There are no indications that the dicarboxylic acids detailed here are carcinogenic or teratogenic in animals or humans. It is generally recognized that these diacids are ocular irritants and that the inhalation of the dust of these diacids is irritating to the mucous membranes and the respiratory tract. The water solubility of glutaric acid fosters its toxicity. Glutaric acid is a known nephrotoxin.

Environmental Effects. In general, the higher diacids do not pose substantial environmental risk; however, releases of significant quantities into surface or ground waters may be reportable under the Clean Water Act. The low biotoxicity of the higher diacids results, in part, from their limited water solubility. Glutaric acid is significantly more water soluble than the other diacids described herein, and the aquatic biotoxicity of glutaric acid and dimethyl glutarate is established.

DICHLOROBENZENES. See **Chlorinated Organics**.

DIE. A device, usually of steel, having a specific shape or design that it imparts to such materials as metals and plastics either by impact (stamping), by the contour of a negative cavity (casting), or by passing the material through it (extrusion). Diamond dies may be used for wiredrawing. The terms "die" and "mold" are virtually synonymous in the sense of a negative cavity into which a molten metal or plastic is introduced under pressure, the former being used in reference to metals, and the latter for plastics, rubber, etc.

See also **Die Casting**; and **Extrusion**.

DIE CASTING. Die castings are produced by forcing molten metal under pressure into a steel die. The pressure is maintained until solidification is complete. The process is essentially a further development of gravity-feed casting, but the pressure function entails finer detail and better finish. While gravity-feed casting tonnage is greater than that of pressure casting, the latter has a wider field of application and is more important in the quantity production of precision parts. Zinc alloys are generally used for die castings, although aluminum alloys, brass alloys and other non-ferrous metals are used to a considerable extent.

The process of die casting is entirely automatic and requires the following elements: a die-casting machine to hold the molten metal under pressure; a metallic mold or die capable of receiving the molten metal, and designed to permit easy and economical ejection of the solidified product; and a casting alloy that will produce a satisfactory product with suitable physical characteristics.

There are two types of die-casting machines. The first, or air-operated machine, forces the material into the die by high pressure on the surface of the molten metal in a special ladle or goose; the second, or plunger type machine, forces the material into the die by means of a cylinder and piston which are submerged in the molten metal.

Die-casting dies are constructed in different styles for various production requirements. A single die contains an impression of only one part; a multiple die contains two or more impressions of any one part; a combination die contains one impression only of two or more parts; and a combination-multiple die contains a number of impressions of each of two or more parts. Single dies are comparatively cheap and are used for small-lot production, since they reduce the tool investment to a minimum for any one part. Combination dies, when properly planned, will reduce the total die cost for a given set of castings to a minimum. They are applicable to parts that will always be used in the same quantities and of the same alloy. These parts should be of the same general character and weight. Multiple dies are usually slower to operate than single dies but will give higher production rates for the same labor costs.

Die-casting dies are often vented by permitting air to escape through the clearance in the ejector and core pin bearings. The problem of venting is considerably more important than in sand casting because the mold has no porosity. Sometimes dies are vented by grinding shallow grooves on the parting surfaces of the dies; in other instances plugs with suitable vent grooves are added to the die.

In 1986, direct injection zinc die casting reached commercial status with the production of gear casings for fractional horsepower electric motors. The process features use of a heated manifold and mini-nozzles to feed molten zinc directly into the die. The Zinc Institute (New York) reports that direct injection eliminates traditional runner and gating pathways and the scrap associated with them. The process is netting a 10% saving in scrap, remelt, and processing costs. Since the molten zinc is injected directly into the die, it can fill the cavity without any chilling before contacting cavity walls. The result is a more uniform structure in the cast part and fewer rejects. Also, cast surface finish is smooth so that preplate finishing operations can often be eliminated.

DIELECTRIC HEATING. The heating of a dielectric material by molecular friction in it as a result of the application of a high-frequency, alternating electric field. Dielectric heating is applicable to nearly all nonconducting materials, such as plastics, wood, and certain liquids. The method is extensively used for the preheating of plastic materials because the materials must be heated uniformly. Prior conventional methods required hours instead of a few minutes with dielectric heating. The method also is used in the printing and dyeing industry, and in the lumber and associated industries for speeding and perfecting the drying of glued joints.

Normally the power required for dielectric heating is provided by some form of oscillator, although the power can be obtained from an amplifier driven by an oscillator. The principal engineering is involved in the design of an oscillator circuit that will provide the proper energy level and in the design of the configuration whereby the energy can be most efficiently imparted to the workpiece.

DIELECTRIC THEORY. A dielectric is a material having electrical conductivity low in comparison to that of a metal. It is characterized by its dielectric constant and dielectric loss, both of which are functions of frequency and temperature. The dielectric constant is the ratio of the strength of an electric field in a vacuum to that in the dielectric for the same distribution of charge. It may also be defined and measured as the ratio of the capacitance C of an electrical condenser filled with the dielectric to the capacitance C_0 of the evacuated condenser:

$$\varepsilon = C/C_0$$

The increase in the capacitance of the condenser is due to the polarization of the dielectric material by the applied electric field. The terms "specific inductive capacity" and "permittivity" are occasionally used instead of *dielectric constant.* The constant ε appearing in the Coulomb law of force is called the permittivity, but it is also commonly called the dielectric constant. The relative permittivity or dielectric constant is the ratio $\varepsilon/\varepsilon_0$, where ε_0 is the permittivity or dielectric constant of free space. In the mks system of units, the dielectric constant of free space is 8.854×10^{-12} farad/m, while in the esu system the relative and the absolute dielectric constants are the same. The relative dielectric constant, which is dimensionless, is the one commonly used. When variation of the dielectric constant with frequency may occur, the symbol is commonly primed. When a condenser is charged with an alternating current, loss may occur because of dissipation of part of the energy as heat. In vector notation, the angle d between the vector for the amplitude of the charging current and that for the amplitude of the total current is the loss angle, and the loss tangent, or dissipation factor, is

$$\tan\delta = \frac{\text{Loss current}}{\text{Charging current}} = \frac{\varepsilon''}{\varepsilon'}$$

where ε'' is the loss factor, or dielectric loss, of the dielectric in the condenser and ε' is the measured dielectric constant of the material.

At low frequencies of the alternating field, the dielectric loss is normally zero and ε' is indistinguishable from the dielectric constant edc measured with a static field. Debye has shown that

$$\frac{\varepsilon_{dc} - 1}{\varepsilon_{dc} + 2} = \frac{4\pi N_1}{3}\left(\alpha_0 + \frac{\mu^2}{3kT}\right) \tag{1}$$

where N_1 is the number of molecules or ions per cubic centimeter; α_0 is the molecular or ionic polarizability, i.e., the dipole moment induced per molecule or ion by unit electric field (1 esu = 300 volts/cm); μ is the permanent dipole moment possessed by molecule; k is the molecular gas constant, 1.38×10^{-16}, and T is the absolute temperature. An electric dipole is a pair of electric charges, equal in size, opposite in sign, and very close together. The dipole moment is the product of one of the two charges by the distance between them.

In Equation (1), $\mu^2/3kT$ is the average component in the direction of the field of the permanent dipole moment of the molecule. In order that this average contribution should exist, the molecules must be able to rotate into equilibrium with the field. When the frequency of the alternating electric field used in the measurement is so high that dipolar molecules cannot respond to it, the second term on the right of the above equation decreases to zero, and we have what may be termed the optical dielectric constant ε_∞ defined by the expression

$$\frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2} = \frac{4\pi N_1}{3}\alpha_0 \tag{2}$$

ε_∞ differs from n^2, the square of the optical refractive index for visible light, only by the small amount due to infrared absorption and to the small dependence of n on frequency, as given by dispersion formulas. It is usually not a bad approximation to use $\varepsilon_\infty = n^2$. The general Maxwell relation $\varepsilon' = n^2$ holds when ε' and n are measured at the same frequency. The Debye equation may be written in the form

$$\frac{\varepsilon_{dc} - 1}{\varepsilon_{dc} + 2} - \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2} = \frac{4\pi N_1}{9kT}\mu^2 \tag{3}$$

A much better representation of the dielectric behavior of polar liquids is given by the Onsager equation

$$\frac{\varepsilon_{dc} - 1}{\varepsilon_{dc} + 2} - \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2} = \frac{3\varepsilon_{dc}(\varepsilon_\infty + 2)}{(2\varepsilon_{dc} + \varepsilon_\infty)(\varepsilon_{dc} + 2)}\frac{4\pi N_1 \mu^2}{9kT} \tag{4}$$

Anomalous dielectric dispersion occurs when the frequency of the field is so high that the molecules do not have time to attain equilibrium with it. One may then use a complex dielectric constant

$$\varepsilon^* = \varepsilon' - j\varepsilon'' \tag{5}$$

where $j = \sqrt{-1}$. Debye's theory of dielectric behavior gives

$$\varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_{dc} - \varepsilon_\infty}{1 + j\omega\tau} \tag{6}$$

where ω is the angular frequency (2π times the number of cycles per second) and τ is the dielectric relaxation time. Dielectric relaxation is the decay with time of the polarization when the applied field is removed. The relaxation time is the time in which the polarization is reduced to $1/e$ times its value at the instant the field is removed, e being the natural logarithmic base.

Combination of the two equations for the complex dielectric constant and separation of real and imaginary parts gives

$$\varepsilon' = \varepsilon_\infty + \frac{\varepsilon_{dc} - \varepsilon_\infty}{1 + \omega^2\tau^2} \tag{7}$$

$$\varepsilon = \frac{(\varepsilon_{dc} - \varepsilon_\infty)\omega\tau}{1 + \omega^2\tau^2} \tag{8}$$

These equations require that the dielectric constant decrease from the static to the optical dielectric constant with increasing frequency, while the dielectric loss changes from zero to a maximum value ε''_m and back to zero. These changes are the phenomenon of anomalous dielectric dispersion. From the above equations, it follows that

$$\varepsilon''_m = (\varepsilon_{dc} - \varepsilon_\infty)/2 \tag{9}$$

and that the corresponding values of ω and ε' are

$$\omega_m = 1/\tau \tag{10}$$

and

$$\varepsilon''_m = (\varepsilon_{dc} + \varepsilon_\infty)/2 \tag{11}$$

The symmetrical loss-frequency curve predicted by this simple theory is commonly observed for simple substances, but its maximum is usually lower and broader because of the existence of more than one relaxation time. Various functions have been proposed to represent the distribution of relaxation times. A convenient representation of dielectric behavior is obtained, according to the method of Cole and Cole, by writing the complex dielectric constant as

$$\varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_{dc} - \varepsilon_\infty}{1 + (j\omega\tau_0)^{1-\alpha}} \tag{12}$$

where τ_0 is the most probable relaxation time and α is an empirical constant with a value between 0 and 1, usually less than 0.2. When the values of ε'' are plotted as ordinates against those of ε' as abscissas, a semicircular arc is obtained intersecting the abscissa axis at $\varepsilon' = \varepsilon_\infty$ and $\varepsilon' = \varepsilon_{dc}$. The center of the circle of which this arc is a part lies below the abscissa axis, and the diameter of the circle drawn through the center from the intersection at ε_∞ makes an angle $\alpha\pi/2$ with the abscissa axis. When a is zero, the diameter lies in the abscissa axis, there is but one relaxation time, and the behavior of the material conforms to the simple Debye theory. When, as may arise from intramolecular rotation, a substance has more than one relaxation mechanism, or, when the material is a mixture, the observed loss-frequency curve is the resultant of two or more different curves and, therefore, departs from the simple Debye or Cole-Cole curve.

If the dielectric material is not a perfect dielectric, and has a specific dc conductance k'(ohms^{-1} cm^{-1}), there is an additional dielectric loss

$$\varepsilon''_{dc} = \frac{3.6 \times 10^{12}\pi k'}{\omega} \tag{13}$$

The effective specific conductance is given by

$$k' = \frac{1}{4\pi}\frac{(\varepsilon_{dc} - \varepsilon_\infty)\omega^2\tau}{1 + \omega^2\tau^2} \tag{14}$$

It is evident from this equation that k' increases with ω, approaching a limiting value, k_∞, the infinite-frequency conductivity, which is attained when 1 can be neglected in comparison with $\omega^2\tau^2$, so that

$$k_\infty = \frac{\varepsilon_{dc} - \varepsilon_\infty}{4\pi\tau} \quad (15)$$

In a heterogeneous material, interfacial polarization may arise from the accumulation of charge at the interfaces between phases. This occurs only when two phases differ considerably from each other in dielectric constant and conductivity. It is usually observed only at very low frequencies, but, if one phase has a much higher conductivity than the other, the effect may increase the measured dielectric constant and loss at frequencies as high as those of the radio region. This so-called Maxwell-Wagner effect depends on the form and distribution of the phases as well as upon their real dielectric constants and conductances. Each type of form and distribution requires special treatment. For a commercial rubber, for example, the observed loss may be

$$\varepsilon''(\text{observed}) = \varepsilon''_{dc} + \varepsilon''(\text{Maxwell} - \text{Wagner}) + \varepsilon''(\text{Debye}) \quad (16)$$

DIELS-ALDER REACTION. An important organic reaction for the synthesis of six-membered rings, discovered in 1928. It involves the addition of an ethylenic double bond to a conjugated diene, i.e., a compound containing two double bonds separated by one single bond, as in 1,3-butadiene ($CH_2{=}CH{-}CH{=}CH_2$) or cyclopentadiene. The ease of addition of the ethylenic compound is greatly enhanced by adjacent carbonyl groups; hence maleic anhydride reacts quantitatively with hexachlorocyclopentadiene to form chlorendic anhydride.

DIELS, OTTO P. H. (1876–1954). A German chemist who won the Nobel prize in chemistry with Kurt Alder in 1950. He was awarded the prize for diene synthesis work, which led to improved methods of analyzing and synthesizing organic compounds. His research resulted in the discovery of carbon suboxide, methods of dehydrating cyclical hydrocarbons using selenium, and determination of the structure of steroids. A student of Fischer", he graduated from the University of Berlin.

DIESEL FUELS. See **Petroleum**.

DIFFRACTION. In any wave disturbance, the interference pattern resulting from the rays passing through different parts of an opening, or coming from different points around an opaque object, as they unite at each point. Diffraction and interference effects are characteristic of all wave phenomena no matter of what type. They are thus found in electromagnetic waves (light, x-rays, etc.), sound waves, water waves, and in matter waves. Diffraction occurs whenever a wave passes through a restricted aperture, such as a small hole or slit, or around an edge or particle. An example in optics is the case in which light from a point source passes the edge of a postcard and falls upon a white screen; the shadow of the edge is not sharply defined, but deepens to darkness gradually on one side, and is bordered by very narrow alternate bright and dark interference fringes (*diffraction bands*) on the other. Again, the image of a minute opaque speck under magnification against a bright background is surrounded by concentric diffraction rings. The image of a bright object, such as a star, as formed in the focal plane of a converging lens, is also surrounded by diffraction rings. If two such images are close together the fringe systems will overlap and no matter how much magnification is applied it will never be possible to obtain clear, well-separated, images of the points. The resolving power of an optical instrument may be defined as a measure of the sharpness with which small images very close together may be distinguished. It is directly proportional to the diameter of the objective aperture and inversely proportional to the wavelength of the light. Diffraction thus limits the resolving power, and hence the practicable magnification, of optical instruments.

Diffraction always results in energy being carried into regions that it could not reach if the propagation of the wave were strictly rectilinear. The patterns produced are geometrically similar whenever the ratio of the wavelength to the dimensions of the aperture is the same. Thus a radio wave in the AM broadcast range will be diffracted in passing through a hole 15 meters in diameter to the same extent as blue light passing through a pin-hole of 0.001 millimeter diameter.

For a single slit of width a and light of wavelength λ, falling on the slit at normal incidence, the intensity of light at an angle θ from the normal to the slit is given by

$$I = R_0^2 \frac{\sin^2\left(\dfrac{\pi a \sin\theta}{\lambda}\right)}{\left(\dfrac{\pi a \sin\theta}{\lambda}\right)^2}$$

Fresnel diffraction. The intensity at any point is the resultant of disturbances coming directly to that point from all parts of the exposed wave front. In general, the wave front is spherical or cylindrical, resulting from a source at finite distance, and the point of observation is also at finite distance.

Fraunhofer diffraction phenomena are observed when both the source and the point of observation are effectively at infinite distance from the diffracting object, obstacle, or aperture. This condition is sometimes brought about by passing the light from the source through a collimator before it is diffracted, and then focusing the parallel diffracted rays at the point of observation.

For material particles, according to the de Broglie hypothesis and quantum mechanics, a material particle having a momentum of magnitude p behaves as though it were associated with a wave of wavelength $\lambda = h/p$, where h is the Planck constant. In any physical process in which a particle interacts simultaneously with two or more scattering centers, the waves associated with the scattering from the various centers will undergo interference with one another to produce diffraction analogous to that which would be observed with light of the same wavelength. According to the principles of quantum mechanics, the wave which is associated with the particle is described by the quantum mechanical wave function $\psi(r, t)$ which contains all of the information concerning the state of the particle which one is physically allowed to have. Born showed that $\psi^*(r, t)\psi(r, t)d\tau$ should be interpreted as the probability that the particle will be found in the volume element dt. Thus in regions where the wave functions representing the scattering from the different scattering centers give complete destructive interference, the probability of finding the particle will be zero. In regions where constructive interference occurs, the probability of finding the particle will be enhanced.

The analogy between the diffraction of light, x-rays, etc., on one hand and that of material articles on the other becomes clear if we remember that in the former phenomena it is the probability of finding a photon in a given location that is determined by the square of the absolute value of the wave amplitude. Because it is relatively easy to use electrons or neutrons having wavelengths of the order of one angstrom, electron and neutron diffraction may be used to study crystal structure in a manner very similar to x-ray diffraction. Electrons do not penetrate as deeply into matter as do x-rays, hence electron diffraction reveals structure near the surface; neutrons do penetrate easily and have the advantage that they possess an intrinsic magnetic moment that causes them to interact differently with atoms having different alignments of their magnetic moments.

DIFFRACTION GRATING. A series of very fine, closely spaced parallel slits, or of very narrow, parallel reflecting surfaces, which, when light is incident upon it at a definite angle, produces a succession of spectra. The complete optical theory is somewhat complicated, but the action of a plane transmission grating may be explained approximately as follows.

A plane, monochromatic light wave W, incident at angle i Fig. 1, reaches the slits at different times. A lens L receives the waves emerging from any two adjacent slits, A and B (among many others), after they have traveled paths differing by $CA + AD$; that is, by $S \sin i + S \sin \delta$, in which $S = AB$. If the lens is so placed that this path difference is a whole number of wavelengths, $n\lambda$, the successive wave-trains will reach it in the same phase, so that when they are brought to the focus F, they will be in synchronism and will produce a bright image of the distant source. Therefore any angle δ for which this result is possible is subject to the condition

$$S \sin i + S \sin \delta = n\lambda$$

or

$$\sin \delta = \frac{n\lambda}{S} - \sin i$$

Bright images will be produced for those angles δ which correspond to $n = 1, 2, 3, 4, \ldots$; the numbers denote the "orders" of the images. It is easily shown that for any order the total deviation $(i + \delta)$ is least when $\delta = i$ and therefore when

$$\sin \delta = \frac{n\lambda}{2S}$$

If the incident light is composed of various wavelengths, the corresponding images of any order will appear at different points, since δ varies with λ; and the result is a spectrum. In short, the grating acts as a dispersion piece, and as such is of great value in spectroscopes.

For high dispersion the slits must be very fine and very close together (S small), and for high resolving power (sharpness of spectral lines) the total number of slits must be large. Gratings having several thousand slits to the inch of width are common. They may be made by ruling fine scratches with a diamond point on glass, or, with reflecting gratings, on polished metal. If the rulings are not spaced with absolute regularity, false lines, called ghosts appear in the spectrum.

Rowland was the first to rule reflection gratings on concave metal surfaces. Such gratings eliminate the necessity of the spectroscope collimator or focusing lenses, as they take light direct from the spectroscope slit and form the spectral-line images like a concave mirror. The echelon is another special type of grating.

For a constant angle of incidence, the angular dispersion is given by

$$\frac{d\delta}{d\lambda} = \frac{n}{S \cos \delta}$$

and for small angles from the normal to the grating, $\cos \delta$ may be replaced by unity. At the point of focus, usually a photographic plate, the so-called normal spectrum will have a constant linear dispersion, often expressed in mm per angstrom. The resolving power of a grating equals nN, where N is the total number of slits. It, too, is there a constant. For a prism spectroscope both dispersion and resolving power depend on the wavelength of the incident light. The constancy of these two quantities is thus an advantage for a grating instrument.

Typical gratings for the visible and the ultraviolet regions have 6,000–18,000 lines per centimeter, for the infrared, 700–3,000 lines per centimeter. These numbers are roughly equal to the wave number of the light to be dispersed.

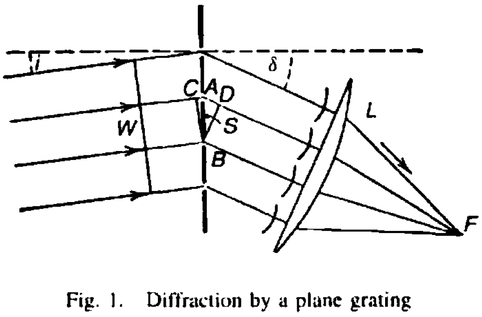

Fig. 1. Diffraction by a plane grating

DIFFUSION. This term denotes the process by which molecules or other particles intermingle as a result of their random thermal motion. The molecules of a gas or of a liquid wander about rapidly, colliding frequently and exchanging kinetic energy, but maintaining a certain aimless progress. If an enclosure contains two gases, the lighter initially above and the heavier below, the gases at once begin to mingle because of their molecular motion. The same is true of a dense solution (as of sugar) and pure water; both the sugar and the water molecules wander across the boundary, so that in the course of time the whole body of liquid attains nearly uniform concentration. The process whereby this is effected is called diffusion. In the case of fluids of different color, its progress may be easily watched.

The rates at which different gases diffuse at a given temperature are inversely proportional to the square roots of their molecular weights. Thus, hydrogen diffuses four times as fast as oxygen. This follows, according to the kinetic theory, from the fact that the molecules of various kinds have the same mean kinetic energy and hence their mean square speeds are in the inverse ratio of their masses. In the case of a solution of non-uniform concentration, the diffusion of the solute from the more to the less concentrated regions takes place in accordance with *Fick's law*, expressed by the equation

$$\frac{dm}{dt} = -DS\frac{dc}{dx}$$

This gives the mass of solute diffused per unit time through a cross-section S, in terms of the concentration gradient dc/dx in the direction x perpendicular to the cross section. D is a constant for the given solute and solvent at a given temperature, and is called the diffusion coefficient. For any one pair of substances, D is found to be proportional to the absolute temperature. It should be stated that these statements apply only to nonelectrolytic solutions.

Diffusion in solids is a phenomenon that occurs rather slowly, but can be observed. Three basic processes may be responsible: (a) direct exchange of atoms on neighboring sites; (b) migration of interstitial atoms; (c) diffusion of vacancies. The first process requires very large energy. The energy to make an interstitial migration is rather large, but many atoms migrate easily. Vacancies are fairly readily formed, and diffuse fairly easily. From the Kirkendall effect it appears that (b) and (c) are the usual processes. The diffusion coefficient is related to the ionic mobility by the Einstein relation.

Another use of the term diffusion is to denote the passage of particles through matter in such circumstances that the probability of scattering is large compared with that of leakage or absorption. It is often limited to phenomena described by a member of the class of differential equations known as *diffusion equations*.

Diffusion operations are of large importance in chemical and process engineering. Both gaseous and thermal diffusion are used to separate one gas from another. In the case of *gaseous diffusion*, if a binary gaseous mixture at a high pressure is passed over a microporous barrier, a fraction of the gas will diffuse through the barrier into a low-pressure discharge chamber and will be found to be richer in the content of one gas than of the other gas. This is termed *Knudsen diffusion*. The passage of gas mixtures through the barrier is governed by the unequal collision frequency of each molecular species upon the walls of the pores. Fast, so-called light molecules separate from slower, heavier molecules within the barrier. The Oak Ridge, Tennessee plant designed for the enrichment of $^{235}UF_6$ from the naturally occurring uranium hexafluoride that contained 99.3% $^{238}UF_6$ represented the first major application of gaseous diffusion on a large scale. The molecular weight of the hexafluoride of ^{235}U is 349, whereas that of the hexafluoride of ^{238}U is 352. Inasmuch as the rate of diffusion of a gas is inversely proportional to the square root of density, the greatest separation factor for one stage of separation is the square root of 352/349, or 1.0043. Inasmuch as only part of the gas can diffuse through a given barrier, the separation factor is less. Thus, the number of diffusion stages for the Oak Ridge plant was approximately 4,000, requiring a plant that covered several acres of ground. Polymeric barriers also are under study and with scientific improvements, gaseous diffusion may become a widely used means for the recovery of carbon dioxide, helium, and nitrogen from natural gas.

In *thermal diffusion*, a thermal gradient is applied to a homogeneous solution (gas or liquid). This causes a concentration gradient and thus affords a means of separating materials. The logic of thermal diffusion is derived from the kinetic theory of gases and the cage model of liquids. If there is no marked size difference, heavier species tend to concentrate in the cold region. Where materials of identical molecular weight are involved, the larger molecules go to the cold region by virtue of their

greater momentum. In the static mode, differential concentration can be established by eliminating convection currents that otherwise would tend to negate the effects of the applied thermal gradient. In the reflux method, hot and cold materials are flowed countercurrently. The reflux usually is provided using the density gradient that results from the imposition of the temperature gradient. Equipment of this latter type usually is referred to as a *thermogravitational column*, or a *Clausius-Dickel* column. Limited applications of thermal diffusion separations include those for concentrating dilute mixtures of isotopic gases. However, equipment costs tend to be high and efficiencies low.

Because chemical processing involves both the mingling and separating of fluids (gases and liquids), an understanding of diffusion processes is fundamental to process design.

DIFFUSION CURRENT. The limiting current reached by electrolytic migration of the ions in a solution under the application of a potential difference to the electrodes. As the potential difference is increased the ion current to the electrodes increases rapidly at first but soon reaches a limiting value (the diffusion current value) as the potential difference is increased. If the potential difference is increased still further, a point is ultimately reached at which a new ion species begins to discharge.

The current limit is set by the rate of diffusion (of the ion being discharged) through the depleted layer surrounding the electrode. This diffusion rate is proportional to the ion concentration. For application of this effect, see **Polarographic Analyzers**.

DIFFUSION POTENTIAL. When liquid junctions exist where two electrolytic solutions are in contact, as in the case of two solutions of different concentrations of the same electrolyte, diffusion of ions occurs between the solutions, and the differences in rates of diffusion of different ions set up an electrical double layer, having a difference of potential, known as the diffusion potential or liquid junction potential.

DIGESTER (Process). In the process industries, the term *digester* is used in two principal connections: (1) the digestion of wood chips in the production of pulp prior to the manufacture of paper, and (2) the digestion of sewage sludge in waste-treatment operations. The term also appears in a number of other operations operating under varying conditions and hence a generalized definition is difficult to formulate. In chip digestion (also termed cooking), the chip digester is a large vessel provided with suitable raw-chip feed and cooked-chip discharge ports and equipped with means for heating and maintaining its contents at a specified temperature for a specific time. Batch digesters are vertical, stationary cylindrical pressure vessels into which chips and cooking liquor are charged and in which liquor is constantly moved, either by percolation within the digesters aided by direct addition of steam for heating purposes, or by continual withdrawal of liquor through screened ports and reintroduction of the liquor, after further heating. Modern batch digesters are typically 4,000 to 6,000 cubic feet (113.3 to 170 cubic meters) in volume with pulp capacities of 10 to 20 tons (9 to 18 metric tons).

By contrast in terms of operating parameters, sewage sludge is digested by aerating a lagoon or pond under normal outdoor temperatures, except that below about 40°F (4.5°C), the activity of the bio-organisms which aid in the digestion falls off considerably.

Autoclaves used in the chemical industry also are sometimes referred to as digesters.

DIGESTER (Pulp). See **Pulp (Wood) Production and Processing**.

DIGESTION. (1) The physiological processes involved in the assimilation of nutrients from ingested foods by the animal organism. Hydrochloric acid in the gastric juice plays a prominent part, aided by the saliva which initiates carbohydrate breakdown, and bile and pancreatic secretions in the intestine. Numerous types of enzymes catalyze these processes. (2) In chemical engineering, the term refers to several processes: (a) the preferential dissolution of certain mineral constituents in some ore concentrates, (b) the liquefaction of organic waste materials by microbiological action as the activated sludge, (c) the removal of lignin from wood by hot chemical solutions in the manufacture of chemical cellulose and paper pulp, (d) the separation of fabric from scrap tires by hot sodium hydroxide solution in the reclaiming of rubber. The equipment for (c) and (d) is called a digester.

DIGITALIS *(Digitalis purpurea; Foxglove, Scrophulariaceae)*. The foxglove is a biennial often grown as an ornamental plant. The first year of growth produces only the long basal leaves, while in the second year the erect leafy stem 2–5 feet (0.6–1.5 meters) tall is developed. The flowers are borne in a raceme, which, through the bending of the peduncles or individual flower stalks, becomes one-sided. The purple flowers have a five-parted calyx, a tubular bell-shaped corolla obscurely five-lobed, five stamens and a single pistil. They are pollinated mainly by bees. The fruit is a two-celled capsule.

The drug digitalis is prepared mostly from leaves of the second year's growth. These are rather coarse ovate leaves covered with glandular hairs. Decoctions of the leaves have been used in Europe for many years.

Digitalis is a valued drug in medicine and is used in certain kinds of heart disease. The chief effects it has on the heart are the regulation of its rate, rhythm, tone, contraction, and conduction of impulses.

As a crop plant, digitalis is grown in England, Germany, and in the United States, especially in Michigan. Propagation is by seeds, which are sown under glass and later transplanted.

DILATANCY. The property of certain colloidal solutions of becoming solid, or setting, under pressure. Also known as "inverse plasticity" since there is an increase in the resistance to deformation with increase in the rate of shear.

DILATANT SUBSTANCES. See **Rheology**.

DILATION NUMBER. Ratio of the volume of a liquid to the volume of a solid of the same composition at the same temperature.

DILATOMETER. 1. An instrument used to measure small increments in the volume of liquids, as a solid phase separates.

2. An instrument for measuring very small length changes in a solid metal specimen such as occur during thermal expansion or phase transformations.

DILUENT. (1) An ingredient used to reduce the concentration of an active material to achieve a desirable and beneficial effect. Examples are combination of diatomaceous earth with nitroglycerin to form the much less shock-sensitive dynamite; addition of sand to cement mixes to improve workability with no serious loss of strength; addition of an organic liquid having no solvent power to a paint or lacquer to reduce viscosity and achieve suitable application properties.

(2) Low-gravity materials used primarily to reduce cost, e.g., blown asphalt, wood floc, etc., in rubber and plastic mixes. In this sense, there is no clear distinction between a diluent and an extender.

(3) An ingredient of rocket fuels, such as helium, hydrazine, or hydrogen.

DIMER ACIDS. The dimer acids, 9- and 10-carboxystearic acids, and C-21 dicarboxylic acids are products resulting from three different reactions of C-18 unsaturated fatty acids. These reactions are, respectively, self-condensation, reaction with carbon monoxide followed by oxidation of the resulting 9- or 10-formylstearic acid (or, alternatively, by hydrocarboxylation of the unsaturated fatty acid), and Diels-Alder reaction

with acrylic acid. The starting materials for these reactions have been almost exclusively tall oil fatty acids or, to a lesser degree, oleic acid, although other unsaturated fatty acid feedstocks can be used.

Physical Properties

The physical properties of polymerized fatty acids are influenced by the basestock, by the dimerization conditions and catalysis, and by the degree to which monomer, dimer, and higher oligomers are separated following the dimerization.

Dimer acids are relatively high mol wt (ca 560) and yet are liquid at 25°C. This liquidity is a consequence of the many isomers present, most with branching or cyclic structures.

Most of the products listed in Tables 1 and 2 are based on manufacture from tall oil fatty acids. Dimer acids based on other feedstocks (e.g., oleic acid) may have different properties.

Chemical Properties

Structure and Mechanism of Formation. Thermal dimerization of unsaturated fatty acids has been explained both by a Diels-Alder mechanism and by a free-radical route involving hydrogen transfer. The Diels-Alder reaction appears to apply to starting materials high in linoleic acid content satisfactorily, but oleic acid oligomerization seems better rationalized by a free-radical reaction.

Chemical Reactions. The reactions of dimer acids were reviewed fully in 1975. The most important is polymerization; the greatest quantities of dimer acids are incorporated into the non-nylon polyamides. Other reactions of dimer acids that are applied commercially include polyesterification, hydrogenation, esterification, and conversion of the carboxy groups to various nitrogen-containing functional groups.

Manufacture

Clay-catalyzed oligomerization and thermal oligomerization are the two commercial processes used to manufacture dimer acids.

Process Modification. Dimer acid process modifications have fallen into three categories; those claiming higher dimer:trimer ratios, those utilizing varying types of clays, and those purporting to result in improved yields. Another aspect of process improvement is color improvement.

Other Polymerization Methods. Experimental alternatives include the use of peroxides, hydrogen fluoride, a sulfonic acid ion-exchange resin, and corona discharge.

TABLE 1. PROPERTIES OF DIMER AND DISTILLED DIMER ACID[a]

Physical property	Distilled dimer acid: Hydrogenated[b]	Distilled dimer acid: Unhydrogenated[c]	Dimer acid
composition %			
dimer acids	97	95	82–83
trimer acids (and higher)	3	4	14–16
monobasic acids	trace	1	1–5
acid number	191–197	190–196	189–197
viscosity at 25°C, mm²/s (= cSt)	~5200	7000–8000	7500–9000
specific gravity, 25/25°C	0.94	0.9	~0.95

TABLE 2. PROPERTIES OF TRIMER ACIDS[a]

Physical property	Value
composition, %	
dimer	40
trimer	60
monobasic acids	trace
acid number	170–190
viscosity at 25°C, mm²/s (= cSt)	~30,000

[a] Hystrene 5460, Humko Chemical Div. of Witco Corp.

Energy Requirements. The production of dimer acids is quite energy-intensive. A standard operation sequence normally results in the expenditure of about 18.6 MJ (17,600 Btu) (equivalent to 0.67 kg coal or 0.33 kg natural gas of fuel oil) to produce each kg of crude dimer and to separate it into monomer, dimer, and trimer.

Storage and Handling

Since dimer acids, monomer acids, and trimer acids are unsaturated, they are susceptible to oxidative and thermal attack, and under certain conditions they are slightly corrosive to metals. Special precautions are necessary, therefore, to prevent product color development and equipment deterioration.

Economic and Market Aspects

According to one estimate, the current capacity for manufacturing dimer acids in the U.S. is around 55,000 t per year. Current demand is estimated at about 33,600 t per year, and is expected to grow at about 2–3% per year to 35,000 t in 1993.

The current market situation for dimer acids includes relatively high raw material costs, high energy costs, slow growth, and relatively low prices. It is generally recognized as a mature market, with hopes for future growth hinging on factors such as increased polyamide use and a resurgence of oil drilling, where dimers are used for corrosion inhibition.

Health and Safety Aspects

The acute oral toxicity and the primary skin and acute eye irritative potentials of dimer acids, distilled dimer acids, trimer acids, and monomer acids have been evaluated based on the techniques specified in the *Code of Federal Regulations* (CFR). Based on these evaluations, monomer acids, distilled dimer acids, dimer acids, and trimer acids are classified as nontoxic by ingestion, are not primary skin irritants or corrosive materials, and are not eye irritants as these terms are defined in the federal regulations.

Uses

Nonreactive Polyamide Resins. Dimer-based polyamide resin markets are divided into those for reactive polyamides and those for nonreactive polyamides. The largest-volume commercial application of dimer acids is in nonreactive polyamide resins. Dimer acids impart flexibility, corrosion resistance, chemical resistance, moisture resistance, and adhesion to nonreactive polyamides. Hot-melt adhesives, the largest commercial application of nonreactive polyamide resins, are thermoplastics that have fairly sharp melting ranges. Flexographic *printing inks* utilize nonreactive polyamides from dimer acids as resin binders. The most important coating application for the nonreactive polyamide resins is in producing thixotropy.

Reactive Polyamide Resins. Reactive polyamide resins are used extensively to react with epoxy or phenolic resins. The amount used in epoxy applications far exceeds the use with phenolic resins.

DIOPSIDE. The mineral diopside is a monoclinic pyroxene corresponding to the chemical formula $CaMgSi_2O_6$, calcium magnesium silicate. Its crystals, like those of other pyroxenes, tend to be short stout prisms of square or octagonal cross-section. Compact, granular, lamellar and fibrous varieties are often found. The prismatic cleavage is characteristic, cleavage planes intersecting at angles of 87° and 93°. A basal parting is often noted, but should not be confused with the cleavage. The hardness of diopside is 5–6; specific gravity, 3.2–3.3; uneven fracture tending toward conchoidal; luster, vitreous to dull; sometimes pearly on the base; color, light or dark greens, but may be colorless, gray, yellow or blue, although the latter color is rare.

Diopside is a primary mineral in rocks like diorites, gabbros and the like, but is also found in schists, and, as the result of contact metamorphism, in such rocks as crystalline limestones and dolomites. Diopside is found in association with vesuvianite, garnet, spinel, scapolite, tremolite, tourmaline and similar minerals. It is a rather widespread mineral, important localities being found in the following European countries: Finland, Sweden, Switzerland, Italy; it is found in eastern Siberia near Lake Baikal. In Canada diopside localities are in Lanark and Hastings Counties, Province of Ontario, and in the United States in Lewis and St. Lawrence Counties, New York, and in Maine.

ELMER B. ROWLEY
Union College
Schenectady, New York

DIOPTASE. The mineral dioptase is a rather rare copper silicate corresponding to the formula $CuSiO_2(OH)_2$, occurring in prismatic crystals of the hexagonal system, tri-rhombohedral in form. It may be found in crystalline aggregates or simply massive. Dioptase displays a conchoidal to uneven fracture; hardness, 5; specific gravity, 3.28–3.35; luster, vitreous; color, a beautiful emerald green. It has been found in the former U.S.S.R., Congo, Central African Republic, South West Africa, Chile, and in the United States in Arizona. The name is derived from the Greek words meaning through and to see, because cleavage was observed by looking through the crystals.

DIORITE. Diorite is a deep-seated igneous rock composed dominantly of sodiaplagioclase feldspar with hornblende, biotite, and (or) augite. Orthoclase may be present in small amounts, also quartz. Any considerable proportion of the latter mineral produces a quartz-diorite. With increasing amount of orthoclase, we have granodiorite, which is generally understood to be a rock intermediate in character between quartz-diorite and granite. If quartz is absent and there are essentially equal amounts of orthoclase and plagioclase the rock is then known as a monzonite from the type locality, Monzoni, in the Tyrol. There are quartz monzonites and, where the deficiency of silica is great enough, nephelite monzonites. Rocks of the latter sort have been reported from Madagascar. A variety of quartz, diorite, containing both hornblende and biotite, is called tonalite from the Tonale Alps, although the rock found there is more nearly a granodiorite.

DIOXIN. Although 75 variations of dioxins are known, the compound considered to possess the greatest toxicity and the subject of a continuing debate among industrial and environmental scientists specifically is 2,3,7,8-tetracholor dibenzo-*p*-dioxin and generally referred to as TCDD or, in much of the literature, simply as *dioxin*.

Attention to dioxin was propelled into scientific and public scrutiny as the result of the use of the herbicide 2,3,5-T (Agent Orange) during the Vietnam conflict. Also, a major localized contamination resulted from an accident in a chemical plant in Seveso, Italy, in 1976.

Minute amounts of dioxin are created in certain combustion processes and by a few chemical manufacturing processes, including the use of chlorine in paper bleaching.

In late 1991, a group of investigators, Sutter, et al. (Chemical Industry Institute of Toxicology, Research Triangle Park, North Carolina), reported of their studies on the effects of dioxin at the genetic and molecular level. It appears that dioxin may elicit its effects by altering gene expression in susceptible cells. In brief detail, the introduction of the Sutter, et al. paper (reference listed) summarizes: "Five TCDD-responsive complementary DNA clones were isolated from a human keratinocyte cell line. One of these clones encodes plasminogen activator inhibitor-2, a factor that influences growth and differentiation by regulating proteolysis of the extracellular matrix. Another encodes the cytokine interleukin-1β. Thus, TCDD alters the expression of growth regulatory genes and has effects similar to those of other tumor-promoting agents that affect both inflammation and differentiation."

As of early to mid 1990s, studies of dioxin continued. Epidemiological studies have shown an increase in the occurrence of soft-tissue sarcoma and non-Hodgkin's lymphoma, but these findings have been challenged by other studies. Some research has indicated that a given dosage of TCCD may kill a guinea pig and leave a hamster unaffected, or that female rats will develop liver cancer, while male rats will not from the same dosage. One effect that has pretty well risen above debate is that TCCD can cause chloracne (a disfiguring skin condition) among some humans who have been exposed to dioxin.

DIPOLE MOMENT. In the simplest case, let two electric charges $+q$ and $-q$ be separated by the distance **d**. Then the permanent electric dipole moment is the vector $\mathbf{p} = q\mathbf{d}$. More generally, if discrete charges q_i are located at points x_i, y_i, z_i the magnitude of dipole moment is given by $p_\alpha = \sum q_i\alpha_i, \alpha = x, y, z$. If the charge distribution is continuous, the summations are replaced by integrals. An induced dipole moment can be produced by an electric or magnetic field (see also **Magnetism**). Atomic or molecular dipole moments, permanent or induced, are of considerable value in the study of atomic or molecular structure. The magnitude of such moments is usually reported in Debye units. The magnetic dipole moment produced by a current i flowing in a loop area A has magnitude $m = iA$. It is a vector with directional normal to the plane of the loop and sense taken as the direction of progression of a right-handed screw rotating with the current.

DISACCHARIDES. See **Carbohydrates**.

DISINFECTANT. A substance used on inanimate objects to destroy harmful microorganisms or inhibit their activity. Disinfectants are either complete of incomplete. Complete disinfectants destroy spores as well as vegetable forms of microorganisms; incomplete disinfectants destroy vegetable forms of the organism, but do not injure spores.

Some representative disinfectants are (1) mercury compounds (mercuric chloride, phenylmercuric borate); (2) halogens and halogen compounds (chlorine, iodine, fluorine, bromine, calcium and sodium hypochlorite); (3) phenols, including cresol from coal tar, *o*-phenylphenol; (4) synthetic detergents (anionic, such as sodium alklbenzene sulfonates, and cationic, such as quaternary ammonium compounds); (5) alcohols of low molecular weight, except methanol; (6) natural products (pine oil); (7) gases (sulfur dioxide, formaldehyde, ethylene oxide). Heat and electromagnetic waves are used as disinfectants.

A number of compounds (mercurous and mercuric chlorides, copper sulfate and carbonate, and a mixture of zinc oxide and zinc hydroxide) have been employed as seed disinfectants.

Effectiveness of disinfectants is rated by the phenol coefficient.

DISLOCATION. In crystallography, a type of lattice imperfection whose existence in metals is postulated in order to account for the phenomenon of crystal growth and of slip, particularly for the low value of shear stress required to initiate slip. One section of the crystal adjacent to the slip plane is assumed to contain one more atomic plane that the section on the opposite side of the slip plane. Motion of the dislocation results in displacement of one of the sections with respect to another.

DISOLVED OXYGEN (DO). One of the most important indicators of the condition of a water supply for biological, chemical, and sanitary investigations. Adequate dissolved oxygen is necessary for the life of fish and other aquatic organisms, and is an indicator of corrosivity or water, photosynthetic activity, septicity, etc.

DISPERSANTS. Dispersants are materials that help maintain fine solid particles in a state of suspension, and inhibit their agglomeration or settling in a fluid medium. With the help of mechanical agitation, dispersants can also break up agglomerates of particles to form particle suspensions. Another use of dispersants is to inhibit the growth of crystallites in a supersaturated solution. This characteristic is also known as precipitation

inhibition, threshold inhibition, or antinucleation. Overall, dispersants are useful in preventing settling, deposition, precipitation, agglomeration, flocculation, coagulation, adherence, or caking of solid particles in a fluid medium.

Physical Chemistry of Dispersants

A convenient way to understand particle dispersion is to consider the process in four successive parts: the nature of particles and surfaces, adsorption onto particles, interface properties, and forces of attraction and repulsion.

Particles and Surfaces. Dispersants are primarily used to increase stability (prevent settling) of solid particles in liquid media, whereas surfactants are used more frequently to stabilize liquid (including polymer latex) surfaces within liquids. When the surface of a liquid is increased (stressed), molecules of the liquid flow to the surface to lower its energy, "healing" it. In contrast, solids exhibit no significant flow to the surface. Any stresses applied therefore remain in the form of a higher energy surface. Thus the history of a particle is important to its surface properties. Treatments that alter particle surface properties include freshly cleaving a surface along lowest energy crystal faces, adsorption of molecules and ions, heating or cooling, friction, corrosion, and grinding or polishing. The process by which a particle is formed also affects its surface properties. Examples of this include screw and spiral dislocations, missing layers, and other defects due to contamination or stress during formation.

Adsorption onto Particles. The Gibbs Adsorption law relates how adsorption onto surfaces affects interfacial tension, $d\gamma = -RT\Gamma d\ln c$, where γ = interfacial or surface tension, in N/m (1 N/m = 1000 dyn/cm); R = gas constant; T = absolute temperature; Γ = interfacial or surface concentration, in mol/unit area (i.e., adsorption); and c = dimensionless concentration ($d\ln c = dc/c$, thus units cancel).

If adsorption occurs ($\Gamma > 0$), then increasing the concentration of dispersant in the bulk water reduces interfacial tension.

Most adsorption processes are exothermic (ΔH is negative). Adsorption processes involving nonspecific interactions are referred to as physical adsorption, a relatively weak, reversible interaction. Processes with stronger interactions (electron transfer) are termed chemisorption. Chemisorption is often irreversible and has higher heat of adsorption than physical adsorption. Most dispersants function by chemisorption, in contrast to surfactants, which tend to physically adsorb.

Interface Properties. A polymeric dispersant may have segments extended into the solution, or the segments may be coiled, depending on whether the solvent is good (polymer–solvent interactions energetically favored) or poor (polymer–polymer and solvent–solvent contacts favored). Between these two solvent–polymer interactions is a θ (theta) solvent, in which neither condition is favored. If the polymer–solvent interaction is better than θ conditions, the extending chains or segments will repel chains adsorbed on other particles, as well as making the distance between two particles greater and enhancing steric repulsion. If the interaction is worse than θ conditions, the particles may flocculate due to mutual attraction of the polymer layers. On the other hand, if the polymer–solvent interaction is too strong, the polymeric dispersant may be adsorbed only weakly or not at all. This can lead to depletion flocculation, which is due to desorbed chains that are squeezed out from between two approaching particles. The desorbed chains can cause solvent to flow from between the particles by osmotic forces, leaving a bare area so that attraction between the particles is increased.

Attractive and Repulsive Forces. The force that causes small particles to stick together after colliding is van der Waals attraction. There are three van der Waals forces: *(1)* Keesom-van der Waals, due to dipole–dipole interactions that have higher probability of attractive orientations than nonattractive; *(2)* Debye-van der Waals, due to dipole-induced dipole interactions (i.e., uneven charge distribution is induced in a nonpolar material); and *(3)* London dispersion forces, which occur between two nonpolar substances.

As the distance between two approaching particles decreases, their electrical double layers begin to overlap. As a first approximation, the potential energy of the two overlapping double layers is additive, which is a repulsive term since the process increases total energy. Electrostatic repulsion can also be considered as an osmotic force, due to the compression of ions between particles and the tendency of water to flow in to counteract the increased ion concentration.

The overall stability of a particle dispersion depends on the sum of the attractive and repulsive forces as a function of the distance separating the particles. DLVO theory, named for Derjaguin and Landau and Verwey and Overbeek, encompasses van der Waals attraction and electrostatic repulsion between particles, but does not consider steric stabilization. The net energy, ΔG_T, between two particles at a given distance is the sum of the repulsive and attractive forces: ΔG_T = (electrostatic repulsive forces) − (van der Waals attractive forces). The electrostatic repulsive forces are a function of particle kinetic energy (kT), ionic strength, zeta potential, and separation distance. The van der Waals attractive forces are a function of the Hamaker constant and separation distance.

Although some progress has been made in calculating steric repulsive forces, the theory concerning them is not as completely developed as DLVO theory. The adsorbed polymer layers of two particles (in a good solvent) begin to interpenetrate as the particles approach each other. The interaction between these polymer layers can have an osmotic effect due to an increase in the local concentration of the adsorbed polymer layers, and can have an entropic or volume restriction effect due to crowding of the interacting chains. In both cases, entropy decreases, which is unfavorable. Moreover, the osmotic effect can create unfavorable enthalpic changes due to desolvation of closely packed chains. To regain lost entropy, the particles must separate to allow the chains more freedom of movement, while the solvent moves in to resolvate the polymer layer. As with electrostatic repulsion, an energy barrier is created. A common approximation used is that the strength of the energy barrier rises steeply at slightly less than the adsorbed layer thickness. Some of the practical differences between sterically and electrostatically stabilized dispersions may be summarized as follows:

Steric stabilization	Electrostatic stabilization
insensitive to electrolyte	coagulation occurs with increased electrolyte
effective in aqueous and nonaqueous media	more effective in aqueous media
effective at high and low concentrations	more effective at low concentrations
reversible flocculation common	coagulation often irreversible
good freeze–thaw stability	freezing often induces irreversible coagulation

Dispersant Materials

Dispersant materials include condensed phosphates, organic polymeric dispersants, poly(meth)acrylates, polymaleates, condensed phosphates, polysulfonates, sulfonated polycondensates, and tannins, lignins, glucosides, and alginates.

Uses

Dispersants are used in recirculating cooling water, boiler water, geothermal fluids, seawater distillation, reverse osmosis, sugar processing, oilfields, drilling muds, cement, paints and pigments, mineral processing, caulks, sealants, roof coatings, pesticides, animal feeds, detergents, and cleaners.

Environmental Considerations

Biodegradability of Dispersants. Most reviews on biodegradable polymers suggest that, with the exception of poly(vinyl alcohol) and poly(ethylene glycol)s, most synthetic organic dispersants are recalcitrant in the environment. More recently developed dispersants displaying biodegradability are polymers containing ester linkages and ether linkages. There is currently a great deal of research activity to develop dispersants that are both effective and biodegradable. Consequently, developments in this area should be rapid.

DISPERSION. (1) A two-phase system where one phase consists of finely divided particles (often in the colloidal size range) distributed throughout a bulk substance, the particles being the disperse or internal phase, and the bulk substance the continuous or external phase. Under

natural conditions, the distribution is seldom uniform; but under controlled conditions, the uniformity can be increased by addition of wetting or dispersing agents (surfactants) such as fatty acid. The various possible systems are: gas-liquid (foam), solid-gas (aerosol), gas-solid (foamed plastic), liquid-gas (fog), liquid-liquid (emulsions), solid-liquid (paint), and solid-solid (carbon black in rubber). Some types, such as milk and rubber latex, are stabilized by protective colloid that prevents agglomeration of the dispersed particles by an abherent coating. Solid-in-liquid colloidal dispersions (loosely called solutions) can be precipitated by adding electrolytes that neutralize the electrical charges on the particles. Larger particles will gradually coalesce and either rise to the top or settle out, depending upon their specific gravity.

See also **Colloid Systems**; **Surfactants**; and **Suspension**.

(2) In the field of optics, dispersion denotes the retardation of a light ray, usually resulting in a change of direction as it passes into or out of a substance, to an extent depending on the frequency. Dispersion is a critically important property of optical glass.

See also **Refraction**.

DISPOSAL (Radioactive Wastes). See **Nuclear Reactor**.

DISSOCIATION. This can be broadly defined as the separation from union or as the process of disuniting. In chemistry, dissociation is the process by which a chemical combination breaks up into simpler constituents due, for example, to added energy as in the case of the dissociation of gaseous molecules by heat, or to the effect of a solvent upon a dissolved substance, as in the action of water upon dissolved hydrogen chloride. Dissociation may occur in the gaseous, liquid or solid state or in solution.

Elementary substances, if polyatomic in the molecule, will dissociate under conditions of sufficient energy. Chlorine and iodine, which are diatomic, are half dissociated at 1700°C and 1200°C, respectively. Just above the boiling point the molecule of sulfur is S_8. Its molecular weight decreases from 250 at 450°C to 50 at 2070°C. Thus there are some monatomic sulfur molecules at 2070°C. The dissociation probably takes place in reversible steps and can be represented by the equation:

$$S_8 \rightleftharpoons 4S_2 \rightleftharpoons 8S. \tag{1}$$

Many chemical compounds dissociate readily upon heating or otherwise supplying them with energy. Acetic acid vapor consists of double molecules just above the normal boiling point, but dissociates completely into single molecules at 250°C. Nitrogen tetroxide (N_2O_4) is a pale reddish brown gas at temperatures near its normal boiling point of 21.3°C. On heating the density of the gas becomes less and the color becomes darker until it is almost black. At 140°C the molecular weight is 46 which is that of NO_2 molecules. The dissociation can be written:

$$N_2O_4 \rightleftharpoons 2NO_2. \tag{2}$$

If one mole of gas yields ν moles of gaseous products, and α is the fraction of the one mole which dissociates, then the total number of moles present is:

$$1 - \alpha + \nu\alpha = 1 + \alpha(\nu - 1). \tag{3}$$

Now the density of a given weight of gas at constant pressure is inversely proportional to the number of moles, and if d_1 is taken as the density of the undissociated gas and d_2 that of the partially dissociated gas, then:

$$\frac{d_1}{d_2} = \frac{1 + \alpha(\nu - 1)}{1} \tag{4}$$

or

$$\alpha = \frac{d_1 - d_2}{d_2(\nu - 1)} \tag{5}$$

Therefore the *degree of dissociation* of a substance can be found by measuring the densities of the undissociated and partially (or completely) dissociated substance in the gaseous state. Molecular weights may be substituted for densities giving

$$\alpha = \frac{M_1 - M_2}{M_2(\nu - 1)} \tag{6}$$

The degree of dissociation can be used to calculate the *equilibrium constant* for dissociation. The equilibrium constant may be expressed in terms of concentrations, for example, moles per liter (K_c), or in terms of partial pressures (K_p). The degree of dissociation and equilibrium constants are important theoretically and practically, e.g., the latter can be used to ascertain the extent of a chemical process.

The temperature dependence of dissociation is expressed in terms of the equilibrium constant and is

$$\frac{d \ln K_p}{dT} = \frac{\Delta H}{RT^2} \quad \text{or} \quad \frac{d \ln K_c}{dT} = \frac{\Delta H}{RT^2} \tag{7}$$

where ΔH is the heat of dissociation. Integrating between the limits T_1 and T_2 one obtains

$$\ln \frac{K_{p_2}}{K_{p_1}} = \frac{\Delta H}{R}\left(\frac{T_2 - T_1}{T_1 T_2}\right) \tag{8}$$

$$\ln \frac{K_{c_2}}{K_{c_1}} = \frac{\Delta H}{R}\left(\frac{T_2 - T_1}{T_1 T_2}\right)$$

Electrolytes, depending upon their strength, dissociate to a greater or less extent in polar solvents. The extent to which a weak electrolyte dissociates may be determined by electrical conductance, electromotive force, and freezing point depression methods. The electrical conductance method is the most used because of its accuracy and simplicity. Arrhenius proposed that the degree of dissociation, α, of a weak electrolyte at any concentration in solution could be found from the ratio of the equivalent conductance, Λ, of the electrolyte at the concentration in question to the equivalent conductance at infinite dilution Λ_0 of the electrolyte. Thus

$$\alpha = \frac{\Lambda}{\Lambda_0} \tag{9}$$

This equation involves the assumption that mobilities of the ions coming from the electrolyte are constant from infinite dilution to the concentration in question. From the degree of dissociation and the concentration, the ionization constant or protolysis constant of a weak electrolyte can be obtained.

Water is a weak electrolyte, ionizing according to the equation:

$$H_2O + H_2O \rightleftharpoons H_3O^+ + OH^- \tag{10}$$

The specific conductance L, of water at 25° is 5.5×10^{-8} mho cm^{-1}, and the equivalent conductance of water at infinite dilution is found from the equivalent conductance of its constituent ions (H_3O^+ and OH^-) to be 547.8 mhos. The equivalent conductance Λ of water at 25°C is LV, where V is the volume of water (18 ml) containing 1 gram equivalent of water. Hence $\Lambda = LV = 5.5 \times 10^{-8} \times 18 = 9.9 \times 10^{-7}$. Therefore $\alpha = \Lambda/\Lambda_0 = 9.9 \times 10^{-7}/547.8 = 1.81 \times 10^{-9}$. Now $C_{H_3O^+} = C_{OH^-} = 55.5 \times 1.81 \times 10^{-9} = 1.00 \times 10^{-7}$ and

$$K = \frac{C_{H_3O^+} \times C_{OH^-}}{C^2_{H_2O}} \tag{11}$$

but C_{H_2O} is a constant, namely 55.5 moles/l and therefore

$$K_w = (55.5)^2 K = C_{H_3O^+} \times C_{OH^-}$$

$$= 1.00 \times 10^{-7} \times 1.00 \times 10^{-7}$$

$$= 1.00 \times 10^{-14}$$

The ionization constant of pure water varies with temperature as shown below.

Temperature°C	0	10	25	40	50
$K_w \times 10^{14}$	0.113	0.292	1.008	2.917	5.474

Inserting corresponding values of K_w and absolute temperature into Eq. (8) and solving for ΔH one finds the heat of ionization per mole of water to be 13.8 kilocalories.

Ionization or dissociation in general can be repressed by adding an excess of a product of the dissociation process.

The acid formed when a base accepts a proton is called the conjugate acid of the base and the base formed when an acid donates a proton is the conjugate base of the acid. Thus in the reaction

$$HA + H_2O \rightleftharpoons H_3O^+ + A^- \tag{12}$$

HA and A^- are conjugate acid and base and H_2O and H_3O^+ are conjugate base and acid, respectively.

The common ion effect then can be found as the following example shows. When using ammonium hydroxide to which the common ammonium ion in the form of ammonium chloride has been added, the ionization can be represented by the equation

$$NH_3 + HOH \rightleftharpoons NH_4^+ + OH^- \quad (13)$$

Ammonium ion NH_4^+ is the conjugate acid of the ammonia molecule. The ionization constant can be written

$$K = \frac{C_{NH_4^+} \times C_{OH}}{C_{NH_3}} \quad (14)$$

and

$$C_{OH} = K\frac{C_{NH_3}}{C_{NH_4}} \quad (15)$$

Now the base NH_3 is such a weak base that in the presence of NH_4Cl the concentration of unionized base, C_{NH_3}, is equal to the total concentration of base represented by C_{base}, and $C_{NH_4^-}$ coming from the weak base is so small as to be negligible. Hence the NH_4^+ ions can be considered as coming exclusively from the NH_4Cl. Therefore Eq. (15) can be written

$$C_{OH^-} = K\frac{C_{base}}{C_{salt}} \quad (16)$$

or

$$pOH = pK + \log\frac{C_{salt}}{C_{base}} \quad (17)$$

Thus C_{OH} and hence the degree of ionization of the base NH_3 is decreased with increasing concentration of salt. The salt effect of adding electrolytes with no common ion to a solution of incompletely ionizable substance can be seen from the following considerations and using the equilibriums represented by Eq. (14) which in terms of activities becomes:

$$K = \frac{a_{NH_4^+} \times a_{OH}}{a_{NH_3}} = \frac{C_{NH_4^+} \times C_{OH}}{C_{NH_3}} \cdot \frac{f_{H_3O^+} \times f_{OH^-}}{f_{NH_3}} \quad (18)$$

This ionization constant in terms of activities is called the true or thermodynamic ionization constant. It does not differ too much from the K in Eq. (14) for sufficiently low ionic strengths. The two differ more markedly for appreciable ionic strengths. Now suppose a salt with no common ion is added to the solution. The ionic strength of the solution will be increased. This increase in ionic strength causes a decrease in the activity coefficients of the ions except in very concentrated solutions. Thus for K of Eq. (18) to stay constant the concentrations of the ions must increase to offset the decrease in their activity coefficients. The ammonia must therefore increase in ionization and K as defined by Eq. (14) must increase. This is known as a salt effect.

Ampholytes in solution give equal concentrations of a weak acid and a non-conjugate weak base. The amino acids are ampholytes which contain within their molecules equal amounts of a weak acid, the COOH group and a weak non-conjugate base, the NH_2 group.

According to Arrhenius those substances which yield the hydrogen ion in solution are acids, whereas bases produce the hydroxyl ion. As long as water was considered the only "ionizing" solvent these definitions were relatively simple. In the case of nonaqueous solvent chemistry at least three other concepts have been advanced. These are: (1) Franklin's *solvent system concept*, first limited to water and ammonia but since extended to nonprotonic media and defining an acid as a substance yielding a positive ion identical with that coming from auto-ionization of the solvent and a base as a substance yielding a negative ion identical with that coming from auto-ionization of the solvent; (2) the *protonic concept* of acids as proton donors and bases as proton acceptors advanced by Brønsted and by Lowry; and (3) Lewis' electronic theory according to which an acid is a molecule, radical or ion which can accept a pair of electrons from some other atom or group to complete its stable quota of electrons, usually an octet, and forming a covalent bond, and a base is a substance which donates a pair of electrons for the formation of such a bond.

In liquid ammonia as in water auto-ionization takes place. Ammonium and amide ions are formed by the dissociation or protolysis according to the following equation

$$2NH_3 \rightleftharpoons NH_4^+ + NH_2^- \quad (19)$$

The acid and base analogs of ammonia as a solvent is specified by this equilibrium as NH_4^+ and NH_2^- ions. All substances which undergo ammonolysis and hence bring about an increase in the ammonium ion concentration yield acid solutions. Thus P_2S_5 dissolves in liquid ammonia to give an acid solution as follows.

$$P_2O_5 + 12NH_3 \longrightarrow 2PS(NH_2)_3 + 3(NH_4)_2S. \quad (20)$$

The solution is acid since an ammonium salt is formed and also because a solvo acid is obtained.

Many substances dissolve in liquid sulfur dioxide to yield ionic, conducting solutions. It has been found that such conductance data extrapolated to very high dilution yield the limiting conductance of sulfur dioxide. Both the Ostwald dilution law and the law of independent mobility of ions hold for "strong" electrolytes in highly dilute solutions.

The order of increasing dissociation and conductivity of salts in liquid sulfur dioxide apparently parallel the order of increasing cationic size. Probably because of solvation effects a similar relationship does not hold with respect to anion size. The mobilities of various ions in liquid sulfur dioxide have been studied. The van't Hoff i factors or mole numbers have been obtained by the ebullioscopic method for a wide variety of solutes in liquid sulfur dioxide. For non-electrolytes the mole number is one within experimental error. In liquid sulfur dioxide, univalent electrolytes give mole numbers which indicate large effects of ion-association of some kind. As would be expected the mole numbers of these electrolytes approach two in very dilute solutions. See Jander and Mesech, Z. physik. Chem., *A183*, 277 (1939). The mole number in general can be found from the ratio of the value of a colligative property of the solute is solution to the value of the same colligative property for a normal solute such as sugar, both solutes being at the same molal concentration.

The protonic concept of acid and bases is applicable to many of these high temperatures solvent systems such as the fused ammonium salts which possess the "onium" ion or solvated proton, and the fused anionic acids which are salts possessing a metallic ion and a hydrogen containing anion. One of the most useful of the anionic acids is KHF which is used to dissolve ore minerals containing silica, titania and other refractory oxides.

In many high temperature reactions there is an absence of hydrogen-containing ions. The Lewis electron pair concept of acid and bases can be used to advantage in such systems. In such systems strong anion bases such as the $O^=$ ion coming from basic compounds such as metallic oxides, hydroxides, carbonates or sulfates react with acidic oxides such as silica through the intermediate formation of polyanionic silicate complexes. The average ionic size of these complexes depend no doubt upon the temperature and the amount of added base.

Anion bases include the sulfide and fluoride ions coming from the corresponding alkali metal compounds. Likewise, metaphosphate and metaborate melts are acid in nature. Also proton-like character can be ascribed to any positive ion. The smaller the positive particle and the higher its charge, the greater is its polarizing tendency in bringing about deformation of negative ions, and the more reasonably can such an ion be looked upon as an acid analog.

When the potential energy of a diatomic molecule is plotted versus the distance separating the nuclei in the molecule, the potential-energy curve shows a minimum of zero in the energy at the distance separating the nuclei where the molecule is most stable, that is, where the nuclei are at the equilibrium internuclear separation. Energy is required to force them closer together or to pull them farther apart. The energy required to separate the nuclei to an infinite distance is D', the dissociation energy measured from the minimum of the potential energy curve. The spectroscopic dissociation energy D is smaller than D' by the zero point energy $\frac{1}{2}h\nu_0$. This results in the relationship.

$$D' = D + \tfrac{1}{2}h\nu_0 \quad (21)$$

The spectroscopic dissociation energy D is the dissociation energy of an ideal gas molecule at absolute zero, where all the gas molecules are in the zero potential energy level. h is Planck's constant (6.62×10^{-27}erg second), and ν_0 is the frequency of vibration of the nuclei at the lowest vibrational level, which is above the point of zero potential energy at the equilibrium internuclear separation. Thus, for the hydrogen molecule, $D = 4.476$ electron volts, $\nu_0 = 1.3185 \times 10^{14}\,sec^{-1}$, and since 1 electron volt = 23.06 kilocalories per mole we calculate D' using Eq. (21) as

follows:

$$D' = (4.47 \text{ eV})(23.06 \text{ kcal mole}^{-1} \text{ eV}^{-1}) + \frac{6.023 \times 10^{23}\text{mole}^{-1} \times 6.62\times10^{-27} \text{ erg sec} \times 1.3185 \times 10^{14} \text{ sec}^{-1}}{(2)(4.184 \times 10^{10} \text{ ergs kcal}^{-1})}$$

$$= 109.5 \text{ kcal mole}^{-1}$$

DISTILLATION. This is one of the most important and widely used of the chemical unit operations, both in the laboratory and on a large industrial scale, for separating the components of a liquid mixture. Distillation provides a means for partially vaporizing the mixture and separately recovering the vapor and residue. Consequently, the method is dependent upon the vapor pressures of the components making up the mixture. The vapor pressure of a pure substance is a constant, but varying with temperature. In distillation, the lighter, more volatile components of the original mixture (*distilland*) concentrate in the vapor when heat is applied. Advantage is taken of the fact that the ratios of the component substances in the vapor and liquid phases, except for special situations, are different. The less volatile components concentrate in the liquid residue (*bottoms*). The vapors evolved by distillation are condensed and are termed the *distillate*.

Distillation should be contrasted with evaporation wherein the vapor (frequently water) is not usually condensed (except where it is desired to conserve water). The principal product desired in evaporation is the solid material which remains in the evaporator vessel. Thus distillation would be used to separate two or more miscible liquids, such as glycol and water, whereas evaporation would be used to separate solid sodium chloride from brine.

The effectiveness of separation by distillation is largely determined by differences in the boiling points of the starting components. Where these are widely separated, as in the case of water (100°C) and ethylene glycol (197.6°C), the separation is relatively easy and redistillation is not required. Closer-boiling mixtures, such as the isomers of xylene, are much more difficult to separate by distillation. As the boiling points of the components approach each other, effective separation by distillation becomes more difficult.

Boiling-point diagrams or what also are termed boiling and condensation curves, usually experimentally determined, are useful guides in the design of distillation equipment. Fig. 1 is the phase diagram of a binary system forming a liquid and a vapor phase at constant pressure. Curve I is the boiling curve, which gives the coexistence temperature as a function of liquid composition; and curve II is the condensation curve, which gives the coexistence temperature as a function of the composition of the vapor phase. If the temperature is increased, vaporization begins when the boiling curve is crossed. Inversely, condensation begins when the temperature is decreased below the condensation curve. The use of boiling-point diagrams in still design will be discussed later.

Major Types of Distillation

Distillation can be a batch or a continuous operation. Batch distillation is frequently used in the laboratory for determining the chemical composition of mixed liquids, such as hydrocarbons. In the majority of industrial processes, distillation is continuous. In a batch operation, the charge material is boiled and vapors are removed continuously, condensed, and collected until such point is reached where there is the desired average composition. The separation is not sharp. This type of operation is also termed *simple* or *differential distillation*. In another approach, the mixture may be heated until a definite fraction of the liquid batch is vaporized, during which time the liquid and vapor are kept in intimate contact, i.e., with no vapors being removed. At the prescribed temperature and after the liquid and vapor have had opportunity to reach full equilibrium, the vapor is suddenly withdrawn and condensed. This approach is known as *equilibrium* or *flash distillation*. The method finds wider application in connection with multicomponent systems than with simple binary systems.

In the majority of industrial distillation systems, some of the distillate will be continuously returned to the distillation column. The returned condensate is contacted countercurrently with the rising vapors, thus bringing about an enrichment of the vapor in the more volatile components than otherwise would be accomplished with a single distillation and most often obviates the need for one or more redistillations to obtain the degree of purity desired. This approach is known as *rectification* or *fractional distillation*. The material returned is termed *reflux*. In most rectifying columns, the raw feed to the column is introduced at about the mid-level of the tower or column. The portion of the column above the point of feed is called the *rectifying section*; the portion below, the *stripping section*. Where the feed may be introduced at the top of the column, the entire column then is usually referred to as a *stripping column*, with no reflux used.

Dephlegmation is a means for increasing the efficiency of fractional distillation by forcing the vapors from the still to bubble through shallow layers of condensate in a column or dephelgmator. Thereby, the amount of low-boiling component in the vapor is increased and a substantial portion of the higher-boiling components is retained in the condensate.

Steam distillation is a process whereby compounds that are sparingly soluble in water may be distilled by heating with water or by blowing steam through the mixture. Compounds of relatively high boiling point may be distilled at lower temperatures by this method and thus prevent degradation.

A representative fractional distillation column of which there are thousands in use in the process industries, notably in the petroleum and petrochemical industries, is shown in Fig. 2. The material balance of the column is:

$$F = W + D$$

$$Fx_F = Wx_F + Dx_D$$

where F = feed rate, weight-moles/unit of time
W = bottom product, weight-moles/unit of time
D = distillate, weight-moles/unit of time
x_F = mole fraction of low boiler in feed
x_D = mole fraction of low boiler in distillate
x_W = mole fraction of low boiler in bottom product

In this balance, the assumption is made that the molar heat capacities and the latent heats of vaporization of all components are identical. It is also assumed that heat losses from the column and heats of mixing are negligible. With these assumptions, the upward vapor flow and the

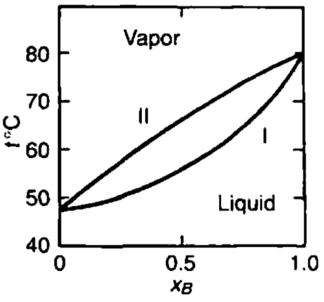

Fig. 1. Temperature-composition of a liquid-vapor system at constant pressure

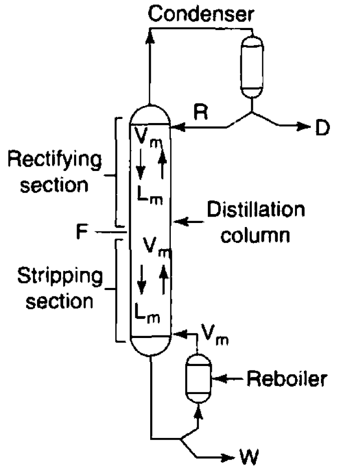

Fig. 2. Typical distillation column

downward liquid flow in both the rectifying and stripping sections will be invariant within the sections. It is also assumed that accounting for the column heat balance is independent of the compositions of the product streams. Within these qualifications, the internal material balance is:

$$L_n = (1 + b)R$$

$$V_n = D + (1 + b)R$$

$$L_m = L_n + qF$$

$$V_m = L_m - W$$

$$x_W = f\left(\frac{L_m}{V_m}\right)$$

$$x_D = g\left(\frac{L_n}{V_n}\right)$$

where V_n = vapor rate in rectifying section, weight-moles/unit of time
V_m = vapor rate in stripping section, weight-moles/unit of time
L_n = liquid rate in rectifying section, weight-moles/unit of time
D = distillate rate, weight-moles/unit of time
R = external reflux, weight-moles/unit of time
b = a numerical factor, depending upon the reflux enthalpy or temperature. (It should be noted that b is greater than zero whenever the reflux temperature is below that at the top of the column.)
q = a numerical factor, depending on the feed enthalpy whose value satisfies certain constraints
$q < 0$, when feed temperature is below feed plate temperature.
$q = 1$, when feed temperature and composition are identical with those of feed plate.
$1 > q > 0$, when feed enters column partially vaporized.
$q = 0$, when feed is fully vaporized and is at saturated temperature.
$q < 0$, when feed is superheated vapor.

f and g are factors which account for several functional relationships which depend upon such column design criteria as the number of plates in column, location of control plates, location of feed plate, and temperature and other conditions specified for control plates.

The foregoing type of material balance is of large value in determining the best form of automatic control to apply to the column in order to maximize yields.

Distillation Calculations. In determining the type of packing or trays to be used in a fractionating column, the diameter, height, location of feed, location of reflux return, vapor and liquid rates, and all other specifications for a column to effect a given separation, equilibrium diagrams of the type shown in Fig. 3 are important. Prior to the availability of high-speed computers, distillation column designers depended heavily upon graphical solutions, notably McCabe-Thiele diagrams, named after the early developers of this concept. A typical diagram of this type for a simple binary distillation is shown in Fig. 4. Oversimplifying the method, first an equilibrium curve of the type of Fig. 3 is constructed. Next a 45° diagonal line is drawn. With knowledge of desired final composition, i.e., composition of the liquid received by the top plate from the condenser, X_p, calculate the intercept of an *operating line* with the Y-axis of the chart. This is indicated as #1 on Fig. 4. The term $X_p/O + 1$ is this Y-intercept of the operating line. O is the reflux ratio. Next, the intersection of the diagonal line with the ordinate X_p is marked. This is indicated as #2 on Fig. 4. The operating line is then drawn in by joining #1 and #2. Now, commencing at #2, rectangular steps between the operating line and the equilibrium curve are drawn in until it crosses the line $X = X_s$. X_s is the starting composition of the mixture. The number of horizontal steps counted (in this case, five) indicates the number of *theoretical plates* required to accomplish the separation desired. A theoretical plate may be defined as a plate wherein complete equilibrium is reached between the vapor rising from the plate and passing to the plate above—with the liquid leaving the plate and passing to the plate below. An actual plate, of course, will not perform with this efficiency. Thus, the designer, depending upon past experience with plates of certain designs, will include an appropriate margin in specifying the number of actual plates needed.

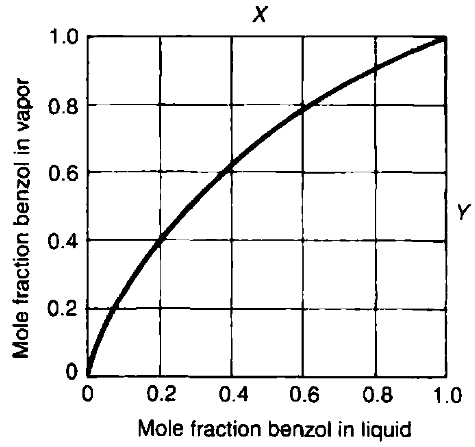

Fig. 3. Equilibrium diagram for the benzol-toluol system

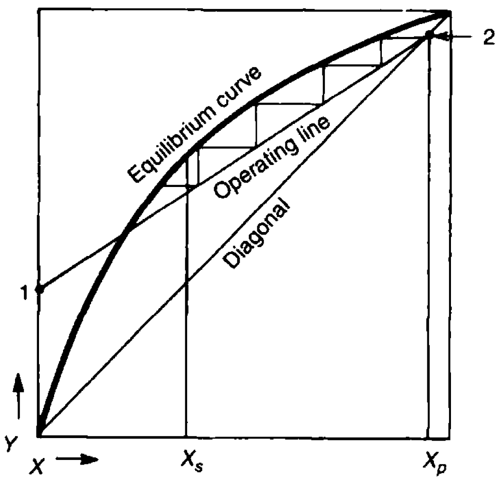

Fig. 4. Representative solution for theoretical plates in rectifying part of a distillation column

Numerous computer software programs are available today to streamline design calculations. Of course, such software can be structured only after very careful analysis is made of the chemical dynamics of a given application. Calculations are particularly complex and difficult in the instances of azeotropic and reactive distillation. Software programs are described in some detail in the Kumana, Morris, and Venkataramkan references listed.

Azeotropic Systems. An azeotropic system is one wherein two or more components have a constant boiling point at a particular composition. Such mixtures cannot be separated by conventional distillation methods. If the constant boiling point is a minimum, the system is said to exhibit *negative azeotropy*; if it is a maximum, *positive azeotropy*. Consider a mixture of water and alcohol in the presence of the vapor. This system of two phases and two components is divariant. Now choose some fixed pressure and study the composition of the system at equilibrium as a function of temperature. The experimental results are shown schematically in Fig. 5.

The vapor curve *KLMNP* gives the composition of the vapor as a function of the temperature T, and the liquid curve *KRMSP* gives the composition of the liquid as a function of temperature. These two curves have a common point M, where the curves are tangent. Because of the special properties associated with systems in this state, the point M is called an *azeotropic point*. In an azeotropic system, one phase may be transformed to the other at constant temperature, pressure and composition without affecting the equilibrium state. This property justifies the name azeotropy, which means a system that boils unchanged.

Because a number of industrially important liquid mixtures are azeotropic systems, means had to be found whereby they may be separated by distillation. Two approaches, *extractive distillation* and *azeotropic distillation*, are used. In either case, a *separating agent* is added to the column so as to alter favorably the relative volatilities of the

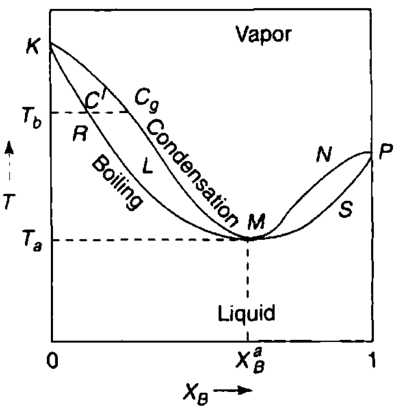

Fig. 5. Boiling-point diagram of an azeotropic system exhibiting negative azeotropy

feed components. Usually, water or polar organic compounds are found most effective. They increase the liquid-phase non-ideality of one feed component more than another.

In extractive distillation, the agent (sometimes termed solvent) is significantly less volatile than the regular feed components. The agent will be added near the top of the column. The agent behaves as a *heavier-than-heavy* key component. It is also conveniently separated from the product streams. Because the agent usually must be added in fairly substantial amounts, this means that column diameters and heat loads are increased, while plate efficiencies are lowered.

In azeotropic distillation, an agent is selected that will form an azeotrope with one of the feed components. In essence, separation is accomplished between this "new" azeotrope (as an overhead product) and the other feed component as bottoms product. An agent will be selected preferably that will permit easy separation after distillation.

Agrada, et al. (see reference listed), describes the manufacture of high-purity methyl acetate via *reactive distillation*. This operation is difficult because of reaction equilibrium limitations and formation of methyl acetate-methanol and methyl acetate-water minimum-boiling azeotropes. The researchers point out, "Conventional processes use schemes with multiple reactors in which a large excess of one of the reactants is used to achieve the high conversion of the other reactant. Some use a series of vacuum and atmospheric distillation columns to change the composition of the methyl acetate-water azeotrope. The refined methyl acetate is separated from the unconverted reactants, and the methyl acetate-methanol azeotrope is then recycled to the reactors. Other schemes use several atmospheric distillation columns and a column with an extractive agent, such as ethylene glycol monomethyl ether, to act as an entrainer to separate the methyl acetate from methanol."

In the process described by Agrada, et al., the concept of a countercurrent reactive distillation column (Fig. 6) is used.

Trays and Packing. Trays with bubble caps or other suitable configurations for enhancing a maximum intermingling of rising vapors with falling liquid in a column are usually used where efficiency and close separations are major considerations. Packed columns, filled with ceramic shapes of various types, such as Berl saddles and Raschig rings, are used primarily where cost and acid-resistance are factors. The sectional view of a form of bubble cap is shown in Fig. 7. A tunnel cap is much more shallow and replete with peripheral performations through which vapor and liquid flow. One column tray, incorporating several hundred tunnel caps, is shown in Fig. 8. In some very tight separations, several trays separated a few feet apart up the vertical length of the column may be required.

A petroleum crude atmospheric distillation column is illustrated in Fig. 9. This unit separates the crude into three major fractions which then are subjected to later separations: (1) a light straight-run fraction, consisting primarily of C_5 and C_6 hydrocarbons, but also containing any C_4 and lighter gaseous hydrocarbons dissolved in the crude; (2) a naphtha fraction having a nominal boiling range of 200–400°F (93–204°C); and (3) a light distillate with boiling range of 400–650°F (204–343°C).

Parastillation. This relatively new approach to distillation, as proposed by A.E.O. Jenkins in 1983, is a method for multistage, counter-current contact between vapor and liquid and is reputed to provide 33% more ideal stages than traditional factional distillation at the same tray spacing. The

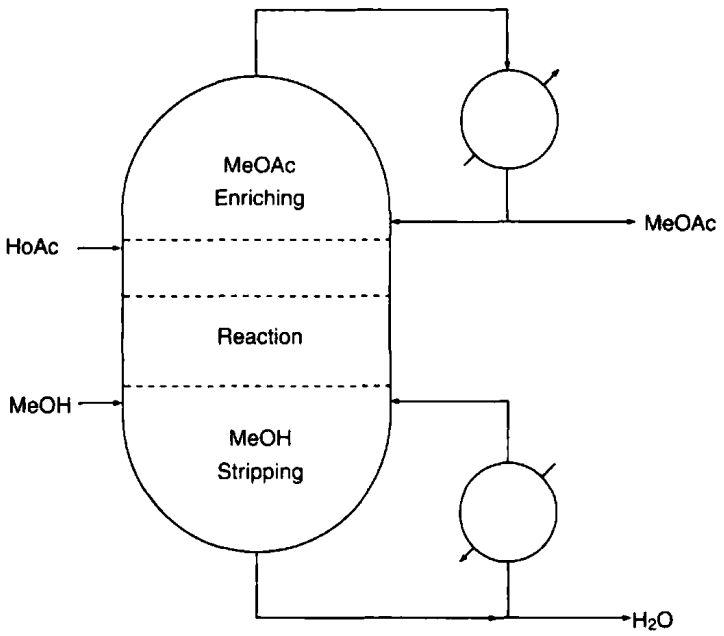

Fig. 6. General principle of reactive distillation (*After Agrada*)

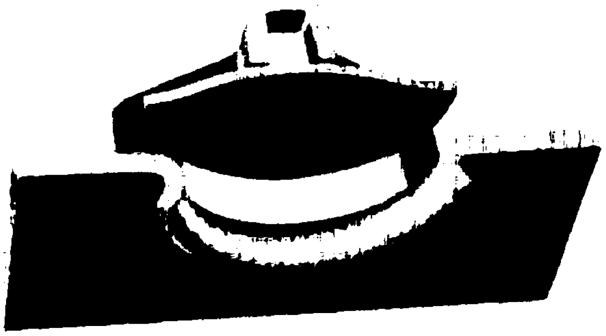

Fig. 7. Cross section of a form of bubble cap. View is from underneath plate or trap upon which cap is mounted

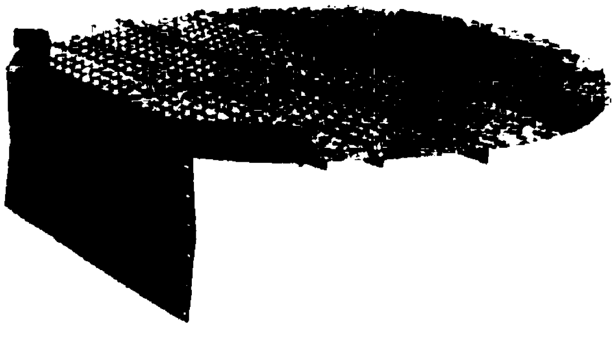

Fig. 8. Distillation tray incorporating several hundred shallow, tunnel-type caps

differences between the old and the proposed methodologies are shown in Fig. 10. This is a schematic of the vapor and liquid flows in the distillation column. In parastillation, the vapor is divided into two parts by a partition running the full height of the column; liquid entering the top of the column flows from one vapor side to the other. As pointed out by Canfield, a secondary advantage of the parastillation process over traditional distillation is that the liquid on a given vapor side of the column always flows in the same direction. Analysis of other advantages of the Jenkins system is outlined in the Canfield reference.

DIURETIC AGENTS. Diuretics are agents that increase urine output or flow. The term is generally used to describe all drugs that act on the kidney to increase the production of urine. More specifically, the terms saliuretic

or natriuretic are used to describe those agents that exert diuretic effects by primarily increasing the excretion of sodium chloride. Aquaretics are agents that increase urine output by producing a water diuresis but do not promote the urinary excretion of electrolytes. Both the use of diuretics in the treatment of hypertension, and the effects of diuretics on the kidney to promote the excretion of urine to normalize derangements in body fluid distribution leading to edematous states are discussed herein.

Disturbances in body fluid distribution may occur at three principal sites: *(1)* within the interstitial space, as occurs in peritonitis or cirrhosis with ascites; *(2)* between the interstitial space and the vascular tree, as in the nephrotic syndrome; or *(3)* within the vascular tree, as in congestive heart failure. Thus, the underlying disease may be of cardiac, hepatic, or renal origin. These derangements provide what amounts to a low blood volume signal to the kidneys that activates renal mechanisms to retain salt and water. If the retained salt and water do not terminate the low volume signal, the kidneys continuously retain salt and water, resulting in edema. The clinical outcome of excessive accumulation of salt and water depends on the particular sector of the extracellular space to which the retained fluid is relegated. Clinical signs of edema appear when the volume of the extracellular space is exceeded by several liters. Diuretics are used in the treatment of edematous states because, in most cases, they produce satisfactory mobilization and subsequent prevention of fluid accumulation in the interstitial space, the abdominal cavity, the lungs, and/or thoracic cavity. However, diuretic therapy is symptomatic in nature, and unless the underlying pathology is corrected, the kidneys continue to retain salt and water and the retained fluid and electrolytes are redistributed to the various compartments described. The principal indications of diuretics in the treatment of edema are in congestive heart failure; renal disease; hepatic cirrhosis with ascites; obesity, where salt and water retention are prominent; premenstrual tension; edema of pregnancy, including toxemia; and steroid administration. Edema may also be associated with other clinical conditions such as inflammation or hypersensitivity reactions.

Pharmacology and Mechanism of Action

Low Ceiling Diuretics. The designation of low ceiling diuretics denotes that the total excretion of the filtered sodium ion load is less than 10% compared to about 30% for the high ceiling diuretics. There are many chemical classes in this category, i.e., thiazides, quinazoline sulfonamides, chlorthalidone, indapamide, etc, but their site of action in the kidney is similar, and they are grouped as thiazide-type diuretics for general discussion.

The most popular diuretics in this class are hydrochlorothiazide and chlorthalidone; there are more potent low ceiling diuretics available. The long duration of action of chlorthalidone, 24 to 72 h, makes once a day dosing possible, and achieves good patient compliance. Cyclothiazide, polythiazide, and trichlormethiazide are about 15 to 30 times more potent than hydrochlorothiazide, and about 500 to 1000 times more potent than chlorothiazide, the first member of the thiazide family marketed.

The low ceiling diuretics increase urinary sodium excretion by acting directly on the $Na^+ - Cl^-$ transport mechanism in the convoluted distal tubules of the kidney.

Indapamide has been shown to possess diuretic and independent vasodilatory effects. It lowers the elevated blood pressure and reduces total peripheral resistance without an increase in heart rate. Indapamide antagonizes the vasoconstricting effects of the catecholamines and angiotensin II, a property not shared by other thiazide-type diuretics. Tripamide is also reported to have direct vasodilatory effects.

Weight loss is a good indicator of fluid loss and excretion. The first wave of fluid mobilized is from the periphery. The excretion of chloride and water is considered passive, and the excretion of potassium and magnesium is increased. In long-term use, the excretion of calcium is decreased.

In long-term treatment, the thiazides may produce hypokalemia, hyperglycemia, hyperuricemia, and a 5% increase in plasma cholesterol; indapamide has been shown not to increase plasma cholesterol or lipids at therapeutic doses. Thiazides can cause hyponatremia in patients with large water intake while on the drug; hyponatremia may be associated with nausea, vomiting, and headaches.

Paradoxically, the thiazides are efficacious, especially if combined with a prostaglandin synthetase inhibitor such as indomethacin or aspirin, in the treatment of nephrogenic diabetes insidipus, in which the patient's renal tubules fail to reabsorb water despite the excessive production of ADH. Thiazides can decrease the urine volume up to 50% in these patients.

High Ceiling (Loop) Diuretics. The principal action of the loop diuretics is inhibition of sodium and chloride reabsorption in the thick ascending limb of the loop of Henle. They can produce an excretion of 20 to 30% of the filtered sodium ion load. Most loop diuretics have a rapid onset of action, steep diuretic dose-response curves, and usually are short acting.

The most commonly used loop diuretics are furosemide, bumetanide, and ethacrynic acid. Newer agents available in some countries include torasemide and piretanide. The potency ratio for furosemide:ethacrynic acid:torasemide:piretanide:bumetanide is 1:1:2:4:40.

After long-term use of a loop diuretic, the extracellular fluid volume contracts and water reabsorption in the proximal and distal tubules increases, thus overriding and diminishing the diuretic's effects. A second high ceiling diuretic may sometimes induce diuresis again. This may be due to additional mechanisms. The loop diuretics increase urinary excretion of potassium and magnesium, as do the thiazides, but loop diuretics also increase urinary excretion of calcium; the excretion of chloride ion is greater than that of sodium ion, suggesting the inhibition of active chloride transport by the high ceiling diuretics in the loop of Henle. Alkalosis may develop in patients treated with the loop diuretics, and plasma renin activity (PRA) is markedly elevated. The high ceiling diuretics inhibit the ability of the kidney to concentrate urine even in the presence of high concentrations of vasopressin.

Ototoxicity, as evidenced by transient or permanent hearing loss, is a serious side effect of ethacrynic acid, and occurs less frequently with furosemide. Bumetanide is claimed to have only 20% of the ototoxic potential of furosemide. It has been reported that patients treated with torasemide at high doses for four weeks did not suffer hearing loss.

Potassium-Sparing Diuretics. Potassium-sparing diuretics act on the aldosterone-sensitive portion of cortical collecting tubules, and partially in the distal convoluted tubules of the nephron. The commonly used potassium-sparing diuretics are triamterene, amiloride, and spironolactone. Spironolactone is a competitive aldosterone receptor antagonist, whereas triamterene and amiloride are not.

Amiloride is far more soluble than triamterene, and is the most widely studied potassium-sparing diuretic. Its natriuretic effect is minimal because only 2 to 3% of the filtered sodium ion load reaches the collecting tubules of the nephron. Etozolin is a newer, long-lasting agent that has a gradual onset of action.

Spironolactone antagonizes the effects of aldosterone by binding at the aldosterone receptor in the cytosol of the late distal tubules and renal collecting ducts. Side effects of spironolactone are gynecomastia, decreased libido, and impotency.

Potassium-sparing by diuretic agents, particularly spironolactone, enhances the effectiveness of other diuretics because the secondary hyperaldosteronism is blocked. This class of diuretics decreases magnesium excretion. The most important and dangerous adverse effect of all potassium-sparing diuretics is hyperkalemia, which can be potentially fatal; the incidence is about 0.5%. Therefore, blood potassium concentrations should be monitored carefully.

Natriuretic Peptide Diuretics. Atrial natriuretic peptide (ANP), an endogenous diuretic, natriuretic, and vasodilator, is a peptide hormone primarily synthesized and stored by atrial cardiocytes, and secreted by the atria in response to mechanical stretch of the atria. ANP is also known as anaritide, $C_{112}H_{175}N_{39}O_{35}S_3$; atrial natriuretic factor (ANF); auriculin; cardionatrin; and atriopeptide. Its primary action is in the kidney and the vascular system.

It has been suggested that both the increased glomerular filtration rate (GFR) caused by ANP and the direct epithelial action in the collecting ducts by ANP are necessary to explain the diuretic effects of ANP. It appears that ANP may increase GFR by relaxing the glomerular mesangial cells resulting in increased surface area for filtration. Due to the augmented GFR, ANP increases the delivery of sodium and water to the renal tubules beyond the distal convoluted tubule. In the collecting ducts, ANP reduces sodium and free-water reabsorption by antagonizing the action of vasopressin. Therefore, the increased loads of sodium and water passing through the collecting ducts without the increased compensatory reabsorption result in profound diuresis and natriuresis.

Atrial Natriuretic Peptide Potentiator Diuretics. Neural endopeptidase inhibitors or atrial peptidase inhibitors are compounds that inhibit the enzyme that degrades ANP, resulting in higher plasma concentrations, and longer duration of action, of ANP. The diuretic effects of this class

of compounds resemble those resulting from administration of ANP. Compounds such as thiorphan, candoxatril, SCH-34826, and SCH-39370 have been studied in hypertension and congestive heart failure in humans with only limited success.

Osmotic Diuretics. An effective osmotic diuretic is a nonionic compound, freely filterable at the glomerulus, not reabsorbed by the tubules of the nephron, and biologically inert except for its osmotic properties. One of the best examples of an osmotic diuretic is mannitol, used to prevent acute renal failure in many major surgeries and traumatic injuries. An osmotic diuretic increases urine flow, rather than the excretion of sodium, by maintaining a high osmotic gradient resulting from the presence of large amounts of nonreabsorbable solutes in the luminal side of the proximal tubules. Under such conditions, the reabsorption of water is impaired along the descending loop of Henle as well as the collecting ducts, and urine flow increases. At high concentrations of an osmotic diuretic, the urinary excretion of sodium is also increased. This is due to the reduced reabsorption of sodium in the proximal tubules.

Carbonic Anhydrase Inhibitor Diuretics. Carbonic anhydrase accelerates the hydration of carbon dioxide to carbonic acid in aqueous solution, up to 7500-fold as compared to the nonenzymatic reaction. The hydrogen ions liberated from carbonic acid in the epithelial cells of the proximal tubules of the nephron are exchanged for sodium ions in the renal tubular lumen. When the generation of hydrogen ions is inhibited by a carbonic anhydrase inhibitor, the exchange of hydrogen for sodium ions is greatly diminished and the diuretic effect ensues. The site of action of carbonic anhydrase inhibitors is in the proximal tubules. In addition to sodium, the excretion of bicarbonate and potassium is also increased. Owing to the increased urinary bicarbonate excretion, the urine becomes alkaline and the blood becomes acidotic. The diuretic effect ceases once metabolic acidosis occurs.

Acetazolamide, the best example of this class of diuretics, is rarely used as a diuretic since the introduction of the thiazides. Its main use is for the treatment of glaucoma and some minor uses, e.g., for the alkalinization of the urine to accelerate the renal excretion of some weak acidic drugs, and for the prevention of acute high altitude mountain sickness.

Methylxanthine Diuretics. The methylxanthines are of very limited efficacy when used as diuretics. The excretion of sodium and chloride ions are increased, but the potassium excretion is normal. Even though the methylxanthines have been demonstrated to have minor direct effects in the renal tubules, it is believed that they exert their diuretic effects through increased renal blood flow and GFR.

Organomercurial Diuretics. Before the advent of the thiazide diuretics, mercurial and organomercurial diuretics were the mainstay therapy for the treatment of edema. They have become obsolete and are of historical value only.

Water Diuretics (Aquaretics). A water diuretic, i.e., aquaretic, decreases urinary osmolality by influencing the kidney to excrete water selectively without a concomitant proportionally increased excretion of sodium ions. A water diuretic should be efficacious for the treatment of hyponatremia, i.e., low plasma sodium concentration, and the syndrome of inappropriate antidiuretic hormone secretion (SIADH). In many diseases and conditions, when water is retained to a greater extent as related to sodium ions, hyponatremia results. This is seen in many edema cases arising from congestive heart failure (CHF), hepatic cirrhosis, renal failure, and nephrotic syndrome. In the treatment of these conditions, the conventional diuretics will lose their effectiveness once hyponatremia occurs. Diseases of the brain and the lung, certain surgeries, and some tumors also will cause hyponatremia; in these conditions, with any given plasma osmolality, the plasma antidiuretic hormone (ADH) concentrations are inappropriately high. When this occurs, the patient is inferred to have SIADH.

There is no specific water diuretic marketed as of this writing. Demeclocycline has been used clinically with only limited success.

Economic Aspects

The sales of oral diuretics are declining, and are forecast to continue their decline in constant dollars during the 1990s. Several possible explanations can be offered for these trends. The patents of market leaders are expiring, leading to the introduction of generic brands at ca 40% below the cost of the branded market leaders; physicians are switching to newer treatments for hypertension, e.g., calcium channel blockers and angiotensin-converting enzyme inhibitors; and concerns are growing about the possible adverse effects of diuretics, e.g., hypokalemia, the progression of atherosclerosis, and the increase in mortality, serum cholesterol, glucose tolerance, and diabetes.

DNA (Recombinant). See **RECOMBINANT DNA**.

DOLERITE. The term dolerite, derived from the Greek meaning deceitful, was originally applied to all dark, heavy, fine-grained igneous rocks of doubtful character. It is now used to indicate gabbroid or basaltic types occurring as dikes or sills whose mineralogical composition is plagioclase, feldspar, hornblende or pyroxene or both, olivine and perhaps biotite, magnetite or ilmenite and pyrite. Included in the dolerites are the diabases, which display plagioclase laths in a somewhat radial arrangement, and from this circumstance we have the textural term diabasic which is synonymous with ophitic.

DOLOMITE. The mineral dolomite, the carbonate of calcium and magnesium, corresponds to the formula $CaMg(CO_3)_2$ and closely resembles calcite. Its crystals, rhombohedral in habit, fall in the hexagonal system. Like calcite, it may be massive or granular, some marbles being dolomite rather than calcite. It displays a perfect cleavage parallel to the rhombohedron; subconchoidal fracture, brittle; hardness, 3.5–4; specific gravity, 2.85; luster vitreous to pearly; color varies widely, white, reds, greens, black, browns, yellows or colorless; transparent to translucent. Unlike calcite, dolomite dissolves very slowly if at all in dilute cold hydrochloric acid; powdered dolomite will dissolve in warm acid. This is the common test for the two minerals.

Much dolomite occurs as stratified rocks where it is believed to have been formed by a secondary process, probably by the action of waters charged with magnesium compounds. Dolomite also is found as a vein mineral, as is calcite. Iron or manganese, rarely zinc or cobalt, may replace some of the magnesium. Ankerite is the name given to a mineral whose composition is essentially a calcium-magnesium-iron carbonate. Among the many noted localities for dolomite are Saxony, Switzerland, Italy, France, Spain, Brazil, Mexico; in the United States, Roxbury, Vermont; Lockport, New York, Phoenixville, Pennsylvania; Alexander County, North Carolina; Hancock County, Illinois, and the Joplin District, Missouri. Dolomite was named for Deodat deDolomieu, who first described its characteristics. See also **Lime and Limestone**.

DOMAIN STRUCTURE. The theory of the macroscopic behavior of ferromagnetic and ferroelectric crystals depends on their consisting of large numbers of domains, each polarized to saturation but pointing in different directions so as to minimize the energy. An applied field tends to make those domains grow which are already favorably oriented, at the expense of those opposed to the field. Due to anisotropy energy, domains tend to be oriented along certain directions of easy magnetization, but the detailed

arrangement of domains in a crystal is a complicated compromise between the tendency of each domain to be as large as possible and the necessity of creating closed loops of magnetic flux.

DOUBLE SALT. A hydrated compound resulting from crystallization of a mixture of ions in aqueous solution. Common examples are the alums, made by crystallizing from solution either potassium or ammonium sulfate and aluminum sulfate; Rochelle salt (potassium sodium tartrate), made from a water solution of potassium acid tartrate treated with sodium carbonate; and Mohr's salt (ferrous ammonium sulfate), crystallized from mixed solutions of ferrous sulfate and ammonium sulfate.

DOUBLET. 1. Two elements that are shared by two atoms so as to form a nonpolar valence bond.

2. A pair of spectral lines resulting from transitions between a common state and two states which differ only in total angular momentum (J), i.e., have identical values of orbital (L) and spin (S) angular momenta.

3. Two stationary states having common values of (L) and (S), but different values of (J).

DRYING OILS. Drying oils oxidize upon exposure to air from a liquid film to a solid, dry film. Consumption of drying oils in the United States peaked in the late 1940s or early 1950s; in the early 1990s much smaller, but still significant, amounts are used. The use of synthetic drying oil-based resins has exceeded the use of natural drying oils; however, their consumption is declining owing to discoloration and embrittlement caused by continued oxidation after film formation.

Natural Oils

Occurrence and Isolation. Most drying oils are derived from plant seeds. The largest volume drying oil, linseed oil, is obtained from flaxseed, *Linum usitatissimum*. In the United States flax is grown in North Dakota, Minnesota, and South Dakota. Flax for oil is also raised in Canada, Argentina, India, and parts of the former USSR. Soybean oil, the second most important oil, is obtained from soybeans, the seed of *Glycine max* (L) Merrill. It is produced in the United States, Brazil, Argentina, and China. Without modification, it is semidrying oil, not a drying oil. Perilla, safflower, sunflower, and walnut oils have limited uses as drying oils. Tung oil, also called wood oil or chinawood oil, is obtained from the seed kernels of the tung tree, *Aleurites fordii*. The principal source of the oil is China. Limited quantities of another conjugated oil, oiticica oil from the oiticica tree, *Licania rigida*, also are used. The only animal oils used as drying oils on a significant scale are marine fish oils, primarily from anchovy, menhaden, pilchard, and sardines. Fish oil is isolated by steam treatment of the fish.

Castor oil, derived from the beans of *Ricinus communis*, is converted to a drying oil by heating with catalysts to yield dehydrated castor oil.

Trees, especially conifers, contain tall oils. Tall oil is not isolated directly; tall oil fatty acids are isolated from the soaps generated as by-products of the sulfate pulping process for making paper.

A wide variety of other oils have been investigated and, in many cases, used commercially over the years. More complete listings are available.

Composition and Analysis. Naturally occurring drying oils are triglycerides. The reactivity of the oils results from the presence of esters of fatty acids with two or more nonconjugated double bonds separated by single methylene groups, $-CH=CHCH_2CH=CH$ hose with two or more conjugated double bonds. Typical compositions of some of the more important oils are listed in Table 1.

Autoxidation. Oils are classified as drying oils, which form solid films on exposure to air; semidrying oils, which form tacky, sticky films; and nondrying oils, which do not undergo marked increase in viscosity on exposure to air. Drying oils are further classified as nonconjugated and conjugated oils, depending on whether the double bonds in the predominant fatty acids are separated by one methylene group or are conjugated.

A general statement, useful in considering synthetic drying oils as well as natural oils, is that if the average number of methylene groups between two double bonds per molecule is greater than 2.2, the oil is a drying oil; if less than 2.2, the oil is a drying oil. There is no sharp dividing line between semidrying and nondrying oils.

The reactivity of nonconjugated drying oils is related to the average number of methylene groups between double bonds per molecule. Such

TABLE 1. TYPICAL FATTY ACID COMPOSITION OF DRYING OILS FROM SEEDS.[a] %

Oil	Saturated[b]	Oleic	Linoleic	Linolenic
linseed	10	22	16	52
perilla	7	14	16	63
safflower	10	13	77	
soybean	16	24	51	9
sunflower[c]	14	14	72	
sunflower[c]	9	72	19	
tung[d]	6	4	8	
walnut	8	16	72	

[a] Proportions shown are approximate; actual compositions can vary greatly.
[b] Palmitic and stearic acids.
[c] Examples of the especially large variations in composition of available sunflower oils.
[d] Also 82% α-eleostearic acid.

methylene groups are allylic to two double bonds, and show much greater reactivity than methylene groups allylic to only one double bond.

The reactions taking place during drying are complex, with many side reactions. Films form from a drying oil, such as linseed oil, in the following steps: an induction period during which naturally present antioxidants, mainly tocopherols, are consumed; a period of rapid oxygen uptake with a weight gain of about 10% (ftir shows an increase in hydroperoxides and appearance of conjugated dienes during this stage); a complex sequence of autocatalytic reactions in which hydroperoxides are consumed and the cross-linked film is formed; and cleavage reactions to form low mol wt by-products.

The rates at which nonconjugated drying oils dry are slow. Metal salts (driers) are known to catalyze the drying rate. The most widely used are the oil-soluble cobalt, manganese, lead, zirconium, and calcium salts of 2-ethylhexanoic acid or naphthenic acids. See also **Paints and Coatings**.

Combinations of metal salts are almost always used. Although mixtures of lead with cobalt and/or manganese are particularly effective, toxicity regulations ban the use of lead driers in consumer paints sold in interstate commerce in the United States. Combinations of cobalt and/or manganese with zirconium, and frequently also with calcium, are commonly used. The amounts of driers needed are very system specific. Their use should be kept to the minimum possible level since they not only catalyze drying but also catalyze the post-drying embrittlement and discoloration reactions.

Oils containing conjugated double bonds, such as tung oil, dry more rapidly than nonconjugated drying oils. Free-radical polymerization of the conjugated diene systems can lead to chain-growth polymerization rather than just combination of free radicals to form cross-links. In general, the water and alkali resistance of films formed using conjugated oils are superior, presumably because more of the cross-links are stable carbon-to-carbon bonds. However, because α-eleostearic acid in tung oil has three double bonds, discoloration on baking or aging is severe.

Both nonconjugated and conjugated drying oils can be polymerized by heating under an inert atmosphere to form so-called bodied oils. Bodied oils have higher viscosities and are often used in oil paints to improve application and performance characteristics.

Synthetic and Modified Drying Oils

Varnishes. The drying rate of drying oils can be increased by dissolving a solid resin in the oil and diluting with a hydrocarbon solvent. Such a solution is called a varnish. The solid resin serves to increase the glass-transition temperature, T_g, of the solvent-free film so that film hardness is achieved more rapidly.

In varnish manufacture, the drying oil, i.e., linseed oil, tung oil, or mixtures of the two, and the resin are cooked together to high temperatures to yield a homogeneous solution for the proper viscosity. The varnish is then thinned with hydrocarbon solvents to application viscosity. Varnishes were widely used in the nineteenth and early twentieth centuries. They have been replace almost completely by a wide variety of other products, especially alkyds, epoxy esters, and urethane oils.

Synthetic Conjugated Oils. Tung oil dries rapidly, but is expensive, and its films discolor rapidly owing to the presence of three double bonds. These defects led to efforts to synthesize conjugated oils, especially those containing esters of fatty acids with two conjugated double bonds.

Esters of Higher Functionality Polyols. When oil-derived fatty acids react with polyols having more than three hydroxyl groups per molecule,

the average number of cross-linking sites per molecule increases proportionally to the functionality of the polyol. Because the number of reactive sites in soybean oil with the composition listed in Table 1 is 2.07. soybean oil is a semidrying oil. However. the pentaerythritol (2,2-bis(hydroxymethyl)-1,3-propanediol) ester of soybean fatty acids with 2.76 reactive sites per molecule is a drying oil.

Oxidizing alkyds can be considered as still-higher functionality drying oils. Their drying speed is faster owing to both the higher functionality and the higher T_g of the rigid aromatic rings in the phthalate esters.

Oils Modified with Maleic Anhydride (Maleated Oils). Oils, with either conjugated or nonconjugated double bonds, react with maleic anhydride (2,5-furandione) to form adducts. The products of these reactions with maleic anhydride, termed maleated oils, react with polyols to give moderate mol wt derivatives that dry faster than the unmodified oils. Such products have not found significant commercial use, but similar reactions with alkyds and epoxy esters are used on a large scale to make water-dilutable derivatives.

Vinyl-Modified Oils. Both conjugated and nonconjugated drying oils react in the presence of free-radical initiators with such vinyl monomers as styrene, vinyltoluene, acrylic esters, and cyclopentadiene. High degrees of chain transfer cause the formation of wide varieties of products, including low mol wt homopolymers of the vinyl monomer, short-chain graft copolymers, and dimerized drying oil molecules. The reaction products with drying oils, except cyclopentadiene, are not commercially important, but the same principle is widely used in making modified alkyds.

Uses

Although some drying oils continue to be used as drying oils, the largest use of drying and semidrying oils in the early 1990s is as raw materials, either directly or as the fatty acids obtained by saponification, in the manufacture of oxidizing alkyds, epoxy esters, urethane oils, and synthetic drying oils. Tall oil fatty acids also are used to manufacture dimer acids.

Since drying oils are considered a renewable resource, they may again become important in paints and printing inks, depending on the cost of drying oils compared with petroleum-derived raw materials. However, in many cases, the properties that can be obtained with synthetic binders, especially retention of flexibility, gloss, and color, are superior to those that can be obtained with a drying oil or drying oil-derived binder.

Paints. Although most drying oils have been replaced as paint vehicles by latexes and other synthetic resins, oils are still being used to a degree in paint and allied products. In exterior house paints, linseed oil or oxidizing alkyds are used when paint must be applied at temperatures as low as 4 to 5°C, i.e., temperatures at which latexes do not coalesce satisfactorily. They also are used in primers over chalky surfaces where latex paints do not provide adequate adhesion.

Most stains used for finishing shingles and other natural wood exterior products are made with pigmented linseed oil, diluted with hydrocarbon solvents for penetration.

Red lead-in-oil primers have been used for many years for corrosion protection of steel where it is not practical to remove oily rust particles from the surface of the steel; concern about lead content has resulted in use reduction.

Printing Inks. The use of drying oils in printing inks has decreased. Some inks based on drying oils are still used for sheet-fed letterpress printing. The principal remaining use is in lithographic printing, particularly sheet-fed lithographic printing.

DRYING (Process). Frequently in the process industries, materials must be dried, i.e., liquid must be removed from a solid or gaseous phase. In most instances, the liquid to be removed is water, although in solvent recovery systems, for example, the liquid may be an organic solvent. See **Dehumidification** for a discussion of the drying of gases. Some materials which must be dried include: (1) solutions, colloidal suspensions, and emulsions, such as extracts, milk, blood, waste liquors, rubber latex, and inorganic salt solutions; (2) slurries, which are pumpable suspensions, as found in calcium carbonate, bentonite, clay slip, and lead concentrates; (3) sludges and pastes, such as centrifuged solids, starch, filter-press cakes, and sedimentation sludges; (4) powders that may be relatively free-flowing when wet, but very dusty when dry, including pigments, cement, clay, and centrifuged precipitates; (5) fibrous solids and granular and crystalline solids, such as sand, ores, rayons staple, salt crystals, and synthetic rubber; (6) formed and shapes solids, such as pottery, rayon cakes, shotgun shells, brick, rayon skeins, lumber, and objects that have been painted or otherwise coated; (7) sheeted materials, such as impregnated fabrics, paper, plastic, and fiber-board—in the continuous form; or veneers, wallboards, foam-rubber sheets, and photographic prints—in the individual-piece configuration. Because of this very wide variety of drying requirements, it is obvious that there does not exist what might be termed a universal dryer. Further, universal dryer design criteria are difficult to develop and summarize. See Table 1.

Basic Concepts of Drying

Two criteria hold for a large number of drying situations, and they break the drying process down into two main periods: (1) the constant-rate period, the rate of removal of liquid per unit of drying surface is essentially steady, but to qualify the surface of the material must remain fully wet (saturated) during this period; and (2) the falling-off period, during which time the rate of drying decreases as it becomes increasingly difficult to move moisture from the capillaries and interstices of the material to the surface where the moisture can be taken up and moved away. With temperature and air flow (if air is the absorbing and moisture conveying medium to be used) well established, the constant-rate period is relatively easy to forecast and to design because this situation is somewhat analogous to that of drying a shallow container of water. Knowing the foregoing conditions as well as the wetted area involved, drying time periods can be predicted. But, in the case of the falling-off period, the dryer designer must be intimately familiar with the mechanism whereby moisture is held to the material and the mechanics involved in moving the moisture to the surface where it can be picked up.

Thus, the falling-off period has been broken down into two phases: (1) the unsaturated-surface drying period; and (2) the internal-moisture movement period. This first period does not impose unusually difficult analysis because essentially the condition is analogous to a partially-filled shallow vessel whose surface is decreasing as drying proceeds. Essentially, this is an extension of the analysis of the constant-rate period, still leaving the internal-movement situation to be predicted. Formulas are available to assist the designer, based upon past experience with specific drying situations and materials. This is a process that is difficult to assess theoretically, and almost always requires experimental runs or comparisons with other at least somewhat similar materials that have been dried successfully. One can generally state that where materials are to be dried to a low-moisture content, the internal-moisture movement period will require the largest portion of the total drying time.

Classification of Dryers

In reviewing the wide variety of drying equipment available, there are a few major classifications that are helpful. There is the distinction between continuous and batch operations. If a continuous drying operation is desired because it will fit into the overall manufacturing operations best, then this decision will rule out those drying concepts that can be applied only in a batch manner. In some instances, it may turn out that in an otherwise fully continuous manufacturing process, the drying portion will have to be handled by batches simply because, for the particular product, batch drying offers the greatest efficiency. There is also the distinction between direct heating and indirect heating methods used in dryers. In direct heating, the heat needed is applied by way of immediate contact between the wet material and hot gases. In indirect heating, the heat needed is transferred to the wet material through an intervening medium, commonly pipes or a retaining wall. There are numerous instances, for example, where a product may be too sensitive to withstand exposure to a moving hot gas.

Since a large majority of drying equipment involves the use of hot gases (usually air), other means of heating can be overlooked. Dielectric heating and freeze-drying, for example, are other means where practical.

TABLE 1. MAJOR TYPES OF PROCESS DRYERS

Direct heating	Indirect heating
CONTINUOUS DRYERS	
Tunnel Dryers. Material to be dried is placed on trucks or carts which are moved through a tunnel in which there is a flow of hot gases. Temperature of the tunnel may be zone controlled.	*Drum Dryers.* For materials in liquid and slurry form. One or several drums dip into the liquid or slurry and thus coat the heated drums. The drum temperature is controlled to effect drying during a part of the rotation of the drum from which the dried material is removed by knife prior to dipping one again into the liquid material.
Through-circulation Dryers. Material is supported on a conveying screen that moves continuously. Hot gases from below or above conveyor pass through the material and pick up moisture.	*Cylinder Dryers.* Material in the form of a continuous sheet passes over and around cylinders which rotate and which are heated, usually by steam or hot water.
Rotary Dryers. Material (liquid) is pumped to and showered within a rotating cylinder through which hot gases flow.	*Screw-conveyor Dryers.* A conveyor is housed within a closed, heated housing. This operation may proceed at atmospheric pressure or under vacuum.
Tray Dryers. Material is placed on vibrating trays over or under which hot gases flow.	*Vibrating-tray Dryers.* Similar to the directly heated tray dryer except that the heat is conducted to the trays indirectly (as by electrical heating) rather than by hot gases.
Sheeting Dryers. Material in sheet form passes continuously through a hot chamber. Depending upon product, sheet may be taut (as pinned to a frame), or it may pass through dryer in festoon manner.	*Steam-tube Rotary Dryers.* Material is passed through a long rotating cylinder. A shell around the cylinder contains steam, hot water, or other heating medium.
Pneumatic Conveyor Dryers. Material is moved in a stream of gas at high-velocity and high temperature and finally collected by a cyclone separator.	
BATCH DRYERS	
Through-circulation Dryers. Material is placed on trays with screen bottoms. Hot gases are blown from below through material.	*Agitated-pan Dryers.* Material is placed in covered shallow pans. Pans are jacketed for heating. An agitator stirs the material constantly. This design may be operated at atmospheric pressure or under vacuum.
Vacuum Rotary Dryers. Material is subjected to agitation within a stationary, horizontal shell under vacuum. The agitation may be heated to increase drying effectiveness.	*Vacuum Tray Dryers.* Trays in which material is placed are heated by conduction from supporting shelves. The whole compartment may be under a relatively high vacuum. The material is not agitated.
Tray and Compartment Dryers. Material is placed on trays which then may be placed on trucks or on permanent shelves within are blown dryer. Hot gases across the trays.	

Drying equipment also can be made available with means to accelerate the drying process if these means are acceptable to product quality. For example, agitation, stirring, and otherwise keeping the material to be dried in constant motion naturally assists the amount of exposure of surfaces to the drying medium. Numbers of materials, however, cannot be handled in this fashion and require relatively conservative, still conditions.

Principal design configurations of drum-type dryers are illustrated and described in Figs. 1, 2, 3, and 4; conveyor-type dryers in Figs. 5, 6, and 7.

Dehydration

This operation is sometimes described as the removal of 95% or more of the water from a substance, by exposure to thermal energy by various means. Frequently used in food processing, the aims of dehydration are reduction in volume of the product, increase in shelf life, and lower transportation costs, among other factors. There is no clearly defined line of demarcation between drying and dehydrating, the latter sometimes being considered as a subelement of drying. Usually, the direct use of solar energy, as in the drying of raisins, hay, etc., is not lumped in with dehydrating. The term dehydration also is not generally applied to situations where there is loss of water as the result of evaporation. Rehydration or reconstitution of a dehydrated product is the act of restoring a product to essentially its original condition by the simple addition of water, usually just prior to use (as consumption of a food product). The distinction between the terms drying and dehydrating may be somewhat clarified by the fact that most substances can be dried beyond their capability of restoration.

In the case of drying foodstuffs, this is a complex combination of coupled heat and mass transfer through natural tissues. The need to take

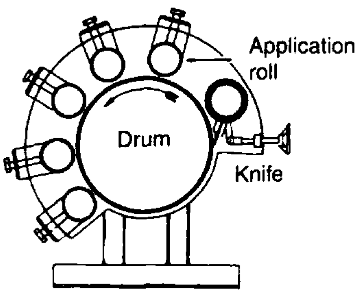

Fig. 1. Single-drum dryer (atmospheric). Dryers of this type may be dip or splash fed (not shown), or, as shown, equipped with applicator rolls. The latter is particularly effective for drying high-viscosity liquids or pasty materials, such as mashed potatoes, applesauce, fruit-starch mixtures, gelatin, dextrine-type adhesives, and various star ches. The applicator rolls eliminate void areas, permit drying between successive layers of fresh material and form the product sheet gradually. While single applications may dry to a lacy sheet or flakes, the multiple layers generally result in a product of uniform thickness and density with minimum dusting tendencies. (*Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc*)

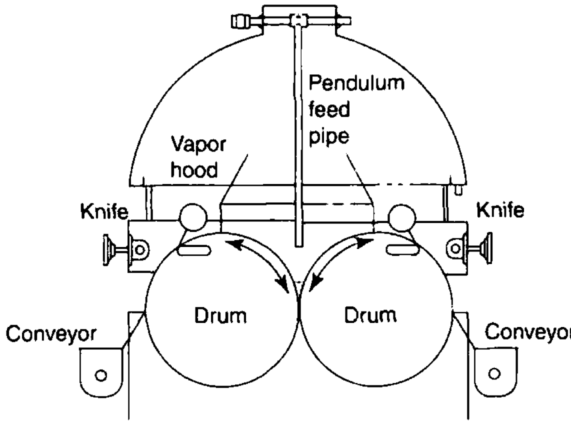

Fig. 2. Double-drum dryer (atmospheric). Dryers of this type handle a variety of food products of widely varying densities and viscosities—dilute solutions, heavy liquids, or pasty materials. A number of products can be dried successfully with this kind of configuration, inasmuch as exposure to temperature above the boiling point is restricted to just a few seconds. The movable drum permits effective control over product film thickness. Feed may be by perforated tube trough, pendulum, or various special configurations. (*Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc*)

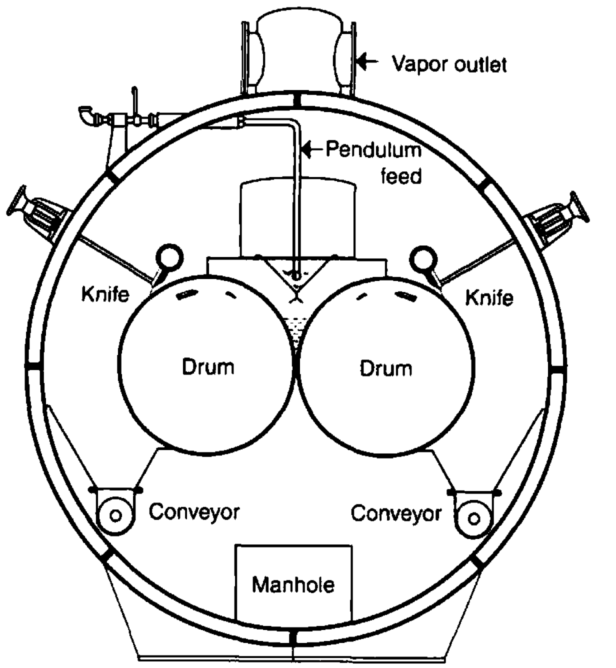

Fig. 3. Single- and double-drum dryer (vacuum). Design configurations like this are applicable whenever products must be dried without exposure to high temperatures or reactive atmospheres. Vacuum operation is particularly suited for vitamin extracts, protein hydrolyzates, soluble coffee, and malt products. Continuous drying without breaking vacuum is achieved by a special conveyance system that utilizes two receivers and air locks. Single-drum feed is usually the pan type with pump and spreading device, or a spray film for materials that are repelled by contact with heated surfaces. Double-drum utilize pendulum or perforated tube feed. Specially designed dispersion devices for feed also can be used. (*Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc*)

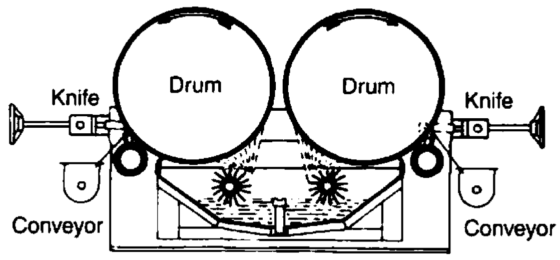

Fig. 4. Twin-drum dryers are designed for handling slurries, corrosive solutions, crystal-bearing or crystal-forming liquids and delicate, heat-sensitive products which may be exposed to high temperatures only for a very limited time. These drums may utilize pendulum or perforated tube for top feed, or splash or spray for bottom feed. Heat-sensitive materials are not in direct contact with the drums. The temperature remains fairly constant and preconcentration is minimized. Cooling and agitation of the material in the pan may also be provided when necessary. (*Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc*)

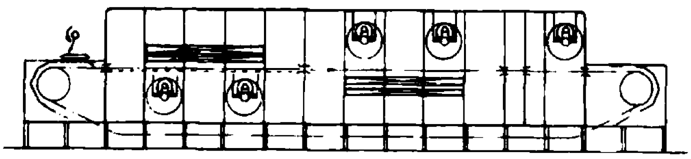

Fig. 5. Single-stage, single-pass conveyor dryer of convection type commonly used to dry, cool, toast, roast, bake, and heat materials. Such units can be zoned for various product drying temperatures, cooling, humidifying, and conditioning requirements. The air flow through the product can be upward or downward and the heat source can be steam, gas, oil, electric, or waste heat. Dryers with this design configuration are applicable to the processing of breakfast cereals, pet foods, fresh vegetables, fruits, and nuts, among numerous other food substances. (*The National Drying Machinery Company*)

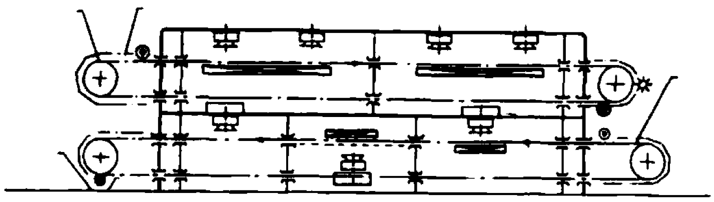

Fig. 6. A multi-tier, multi-pass conveyor dryer. Due to space limitations it is sometimes necessary to tier dryers and use gravity or transfer conveyors to carry the product from one tier to the other. The location of the discharge end will vary with the number of tiers. (*The National Drying Machinery Company*)

into account the structure of the food, as opposed to considering it as an homogenous solid, is important. In general, the main source of water in a tissue is the cell. Thus, the transport of water to the outside involves migration through the cell and its enveloping structure, through the porous structure of the tissue, and then through the outside boundary layer. To be able to predict drying behavior, it is necessary to establish the extent to which the foregoing transport steps are controlling. There is no general answer because both the cellular structure and the characteristics of the porous-like tissue structure are involved and the roles they play in the transport process may differ widely—simply because tissue properties change from one foodstuff to the next.

The energy requirements for drying have been studied rather intensively in recent years because the cost of a product can be markedly affected by this energy intense operation. Some researchers have observed that drying costs are much lower for air drying and drum drying than for freeze-drying.

A simplified flow diagram for the preparation of dehydrated fruits and vegetables is given in Fig. 8.

Combination Drying Operations

For some products, it is sometimes advantageous to combine drying with other associated operations. For example, in a fluidized-bed spray granulation process (FBSG), drying, cooling, granulating, and coating of final products, such as various organic and inorganic salts, minerals, dyestuffs, herbicides, pharmaceuticals, and pulping waste liquors, among others, can be accomplished with a reduction of materials-handling and energy costs. FBSG may be defined as a particle-forming process by which a solid containing liquid and possibly a particulate solid is converted into a granular solid state through interaction between the sprayed liquid and a fluidized layer of granules already formed by the process. The liquid feed can be a solution, suspension, or melt. As observed by Mortensen and Hovmand, the most characteristic and essential part of the FBSG process is the formation of new particles and their growth in the fluidized bed, determining the size distribution and bulk density of the product. New particles are produced in two ways within the fluidized bed: (1) from attrition between the fluidized granules; (2) by spray drying the droplets sufficiently prior to contact with particles in the fluidized layer. The process involves a number of variables, most of which are subject

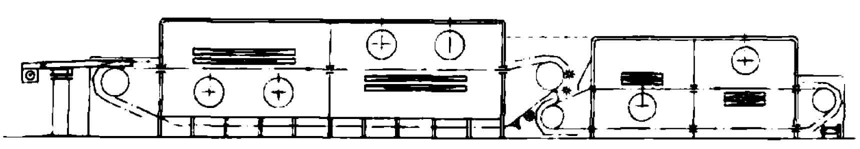

Fig. 7. A multi-stage, 4-zone drying range consisting of a series of single-stage conveyor dryers designed so that the individual stages present a new set of conditions to the product being processed. These stages, in turn, can be zoned to give maximum processing flexibility. Transfer devices between stages reorient the product to provide effective processing uniformity. (*The National Drying Machinery Company*)

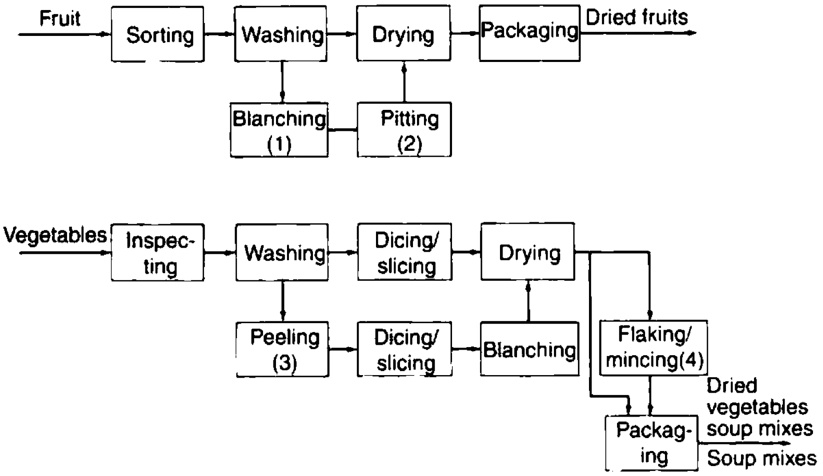

Fig. 8. Simplified flowsheets of operations required in preparation of **(a)** dried fruit and **(b)** dried vegetable products. Operations (1) and (2) are required only for certain fruits, such as prunes. Operation (3) is required only for certain vegetables, such as potatoes. Operation (4) is required only for certain end products

to control: (1) feed concentration, (2) ambient air temperature, (3) dryer inlet gas temperature, (4) dryer outlet gas temperature, (5) heating surface temperature, and (6) fluidizing gas velocity.

Spiral Drying Technique

Also sometimes referred to as the DRT (*Drallrohr Trocknung*) technique, this is a relatively recent, innovative process targeted at reducing energy costs. As pointed out by Hess and Rossi, the dryer is designed for continuous moisture removal from wetwater products via fresh ambient air or of solvents via recirculated inert gas. The product's residence time is a matter of seconds, thus precluding thermal degradation of the product. A jacketed outer cylinder is designed for pressurized heat transfer media. The cylinder rests on a base which also incorporates the product inlet. Dry powder is discharged at the top of the cylinder after the product film has moved spirally up the inner wall. Placed within the cylinder is a steam-heated concentric displacement body, which rotates slowly via an external geared motor. The body's outer surface has numerous segmented air-guide plates that are arranged at an appropriate angle. The distance between these plates and the inner wall is greater than the product film thickness. A blower moves the conveying gas tangentially into the tube base, entering opposite a wet-feed metering screw. Thus, the gas disperses the wet feed via intense mixing. This mixture is prevented from bypassing up the column by the displacer's segmented guide plates and is forced into a corkscrew-shaped path along the jacketed surface inner face. Inertial force creates a product film that threads its way upward at constant speed, but in a spiral path until it reaches the top of the dryer. Claims for energy conservation, protection of product, and corrosion resistance, among other factors, are well detailed in the Hess/Rossi reference.

Molecular Sieve Dehydration

This is also a relatively new technology that extends the use of molecular sieve adsorptive dehydration to the removal of over 20% water from organic admixtures.

Numerous other improvements in drying technology are described in the references given. See also **Spray Drying**.

See also **Dielectric Heating**; and **Freeze-Drying**.

DUBNIUM. See **Chemical Elements**.

DULONG AND PETIT LAW OF SPECIFIC HEATS. It has long been known that the atomic heats of the great majority of elements have nearly the same value at room temperature; in fact, the thermal capacity of a gram-atom of most elements is not far from 6 calories per degree. Dulong and Petit expressed this by stating that the specific heats of elements are in inverse proportion to their atomic weights.

That this should be the case for gases, easily follows from the kinetic theory and the principle of equipartition of energy. For example, if the same mean energy per molecule is necessary to raise the temperature of oxygen and of hydrogen 1°, the same is true per atom, and weights of these gases having the same number of atoms will have equal thermal capacities.

For solids the matter is not quite so simple, and the more exacting theories of Einstein, Debye, and others show that the atomic heat should be expected to vary with the temperature. According to Debye, there is a certain characteristic temperature for each crystalline solid at which its atomic heat should equal 5.67 calories per degree. Einstein's theory expresses this temperature as $h\nu_m/k$, in which h is Planck's constant, k is Boltzmann's constant, and ν_m is a frequency characteristic of the atom in question vibrating in the crystal lattice.

DUMORTIERITE. This mineral found within schists and gneisses is valuable for use in the manufacture of high-grade porcelain. It is a borosilicate of aluminum $Al_7(BO)_3(SiO_4)O_3$, crystallizing in the orthorhombic system. Crystals are rare; commonly occurs as fibrous aggregates of blue to pink color, with vitreous luster. Transparent to translucent with hardness of 8.5, and specific gravity of 3.41.

World occurrences include France, Madagascar, Brazil, and Mexico, with California and Nevada the principal United States localities.

DU VIGNEAUD, VINCENT (1901–1978). An American biochemist who won the Nobel prize for chemistry in 1955. His work involved the study of the metabolism of biologically significant sulfur compounds, which led to the finding of transmethylation in mammalian metabolism. He isolated and proved the structure of the vitamin biotin, and synthesized penicillin, oxytocin, and the vasopressin hormone of the posterior pituitary. His education was at Rochester, Yale, St. Louis, and George Washington Universities.

DYE CARRIERS. Dye carriers are needed for complete dye penetration of polyester fibers. Carriers cause the glass-transition temperature, T_g, of the polyester polymer to become lower and allow the penetration of water-insoluble dyes into the fiber.

Dye carriers, occasionally called dyeing accelerants, are used on cellulose triacetate fibers, but have found their greatest use in the dyeing of polyester.

Carrier Properties

Most carriers are aromatic compounds, and have similar solubility parameters to the poly(ethylene terephthalate) fibers and to some disperse dyes.

Table 1 lists the four main groups of compounds most commonly used as dye carriers. In order for these compounds to act effectively as carriers, they must be homogeneously dispersed in the dyebath. Because the carrier-active compounds have little or no solubility in water, emulsifiers are needed to disperse these compounds in the dyebath.

Carrier Formulation

The formulation of a carrier depends on four considerations: *(1)* the carrier-active chemical compound; *(2)* the emulsifier; *(3)* special additives; and *(4)* environmental concerns. Additional parameters to be considered in the formulation of a carrier product with satisfactory and repeatable performance arise from the equipment in which the dyeing operation is to be carried out. The choice of equipment is usually dictated by the form in which the fiber substrate is to be processed, e.g., loose fiber, staple, continuous or texturized filament, woven or knot fabric, yarn on packages or in skeins.

Carrier Selection

A carrier is selected by the dyer according to various criteria. The type of equipment and conditions under which it is to be used have already been mentioned. Other considerations include color yield, dye migration, and product and emulsion stability.

Health and Safety Factors

Most carrier-active compounds are based on aromatic chemicals with characteristic odor. An exception is the phthalate esters, which are often preferred when ambient odor is objectionable or residual odor on the fabric cannot be tolerated. The toxicity of carrier-active compounds and of their ultimate compositions varies with the chemical or chemicals involved. The environment surrounding the dyeing equipment where carriers are used should always be well-ventilated, and operators should wear protective clothing (e.g., rubber gloves, aprons, and safety glasses or face shields, and possibly an appropriate respirator). Specific handling information can be obtained from the supplier or manufacturer.

OSHA and EPA have established exposure limits that must be carefully considered in relation to the waste disposal method available and the environment in which dye carriers are to be used.

The increasingly stringent government regulations and the introduction of carrierless-dyeable polyester have not substantially affected the use of carriers. The factor with the greatest impact on their use has been provided by the spectacular technological advances in dyeing equipment that have taken place since the early 1980s. High temperature dyeing has greatly reduced the time element (dyeing cycle) and the need for carriers.

TABLE 1. COMPOUNDS MOST COMMONLY USED AS DYE CARRIERS

Compounds	Mol wt	Bp, °C
phenolics		
o-phenylphenol	170.2	280–284
p-phenylphenol	170.2	305–308
methyl cresotinate	166.0	240
chlorinated aromatics		
o-dichlorobenzene	147.0	172–178
1,3,5-trichlorobenzene	181.45	214–219
aromatic hydrocarbons and ethers		
biphenyl	154.2	255.9
methylbiphenyl	168.24	255.3
diphenyl oxide	170.0	259.0
1-methylnaphthalene	142.2	244.6
2-methylnaphthalene	142.2	241
aromatic esters		
methyl benzoate	136.14	198–200
butyl benzoate	178.22	250
benzyl benzoate	212.24	323–324
phthalates		
dimethyl phthalate	194.18	298
diethyl phthalate	212.18	298
diallyl phthalate	246.25	290
dimethyl terephthalate	194.18	284

DYE AND DYE INTERMEDIATES

Classification Systems for Dyes

Dyes may be classified according to chemical structure or by their usage or application method. The former approach is adopted by practicing dye chemists who use terms such as azo dyes, anthraquinone dyes, and phthalocyanine dyes. The latter approach is used predominantly by the dye user, the dye technologist, who speaks of reactive dyes for cotton and disperse dyes for polyester. Very often, both terminologies are used, for example, an azo disperse dye for polyester and a phthalocyanine reactive dye for cotton.

Classification of Dyes by Use or Application Method

The classification of dyes according to their usage is summarized in Table 1, which is arranged according to the *Colour Index* (CI) application classification. It shows the principal substrates, the methods of application, and the representative chemical types for each application class.

Although not shown in Table 1, dyes are also being used in high technology applications, such as in the medical, electronics, and especially the reprographics industries.

Nomenclature of Dyes

Dyes are named either by their commercial trade name or by their *Colour Index* (CI) name. In the *Colour Index* these are cross-referenced.

The commercial names of dyes are usually made up of three parts. The first is a trademark used by the particular manufacturer to designate both the manufacturer and the class of dye, the second is the color, and the third is a series of letters and numbers used as a code by the manufacturer to

TABLE 1. USAGE CLASSIFICATION OF DYES

Class	Principal substrates
acid	nylon, wool, silk, paper, inks, and leather
azoic components and compositions	cotton, rayon, cellulose acetate, and polyester
basic	paper, polyacrylonitrile-modified nylon, polyester, and inks
direct	cotton, rayon, paper, leather, and nylon
disperse	polyester, polyamide, acetate, acrylic, and plastics
fluorescent brighteners	soaps and detergents, all fibers, oils, paints, and plastics[c]
food, drug, and cosmetic	foods, drugs, and cosmetics
mordant	wool, leather, and anodized aluminum
natural	food
oxidation bases	hair, fur, and cotton
pigments	paints, inks, plastics, and textiles
reactive	cotton, wool, silk, and nylon
solvent	plastics, gasoline, varnish, lacquer, stains, inks, fats, oils, and waxes
sulfur	cotton and rayon
vat	cotton, rayon, and wool

define more precisely the hue, and also to indicate important properties the dye possesses.

Classification of Dyes by Chemical Structure

The two overriding trends in dyestuffs research for many years have been improved cost-effectiveness and increased technical excellence. Improved cost-effectiveness usually means replacing tinctorially weak dyes such as anthraquinone, the second largest class after the azo dyes, with tinctorially stronger dyes such as heterocyclic azos, triphendioxazines, and benzodifuranones. This theme will be pursued throughout this section discussing dyes by chemical structure.

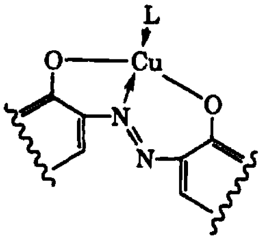
Azo Dyes. These dyes are by far the most important class, accounting for over 50% of all commercial dyes, and having been studied more than any other class. Azo dyes contain at least one azo group (–N=N–) but can contain two (disazo), three (trisazo), or, more rarely, four or more (polyazo) azo groups. The azo group is attached to two radicals of which at least one, but, more usually, both are aromatic.

In monoazo dyes, the most important type, the A radical often contains electron-accepting groups, and the E radical contains electron-donating groups, particularly hydroxy and amino groups.

Almost without exception, azo dyes are made by diazotization of a primary aromatic amine followed by coupling of the resultant diazonium salt with an electron-rich nucleophile.

In theory, azo dyes can undergo tautomerism: azo/hydrazone for hydroxyazo dyes; azo/imino for aminoazo dyes, and azonium/ammonium for protonated azo dyes. A more detailed account of azo dye tautomerism can be found elsewhere.

The three metals of importance in azo dyes are copper, chromium, and cobalt. The most important copper dyes are the 1:1 copper(II): azo dye complexes of formula; they have a planar structure.



In contrast, chromium(III) and cobalt(III) form 2:1 dye:metal complexes that have nonplanar structures. Geometrical isomerism exists.

Premetallized dyes are now used widely in various outlets to improve the properties of the dye, particularly lightfastness. However, this is at the expense of brightness, because metallized azo dyes are duller than nonmetallized dyes.

Carbocyclic azo dyes are the backbone of most commercial dye ranges. Based totally on benzene and naphthalene derivatives, they provide yellow, red, blue, and green colors for all the major substrates such as polyester, cellulose, nylon, polyacrylonitrile, and leather.

The carbocyclic azo dye class provides dyes having high cost-effectiveness combined with good all-around fastness properties. However, they lack brightness, and consequently, they cannot compete with anthraquinone dyes for brightness. This shortcoming of carbocyclic azo dyes is overcome by heterocyclic azo dyes.

One long-term aim of dyestuffs research has been to combine the brightness and high fastness properties of anthraquinone dyes with the strength and economy of azo dyes. This aim is now being realized with heterocyclic azo dyes, which fall into two main groups: those derived from heterocyclic coupling components, and those derived from heterocyclic diazo components.

All the heterocyclic coupling components that provide commercially important azo dyes contain only nitrogen as the hetero atom. They are indoles, pyrazolones, and especially pyridones; they provide yellow to orange dyes for various substrates.

In contrast to the heterocyclic coupling components, virtually all the heterocyclic diazo components that provide commercially important azo dyes contain sulfur, either alone or in combination with nitrogen (the one notable exception is the triazole system). These S or S/N heterocyclic azo dyes provide bright, strong shades that range from red through blue to green, and therefore complement the yellow-orange colors of the nitrogen heterocyclic azo dyes in providing a complete coverage of the entire shade gamut.

Anthraquinone Dyes. Anthraquinone dyes are based on 9,10-anthraquinone, which is essentially colorless. To produce commercially useful dyes, powerful electron-donor groups such as amino or hydroxy are introduced into one or more of the four alpha positions (1,4,5, and 8). The most common substitution patterns are 1,4-, 1,2,4-, and 1,4,5,8-. To maximize the properties, primary and secondary amino groups (not tertiary) and hydroxy groups are employed.

Anthraquinone dyes are prepared by the stepwise introduction of substituents on to the performed anthraquinone skeleton or ring closure of appropriately substituted precursors.

The principal advantages of anthraquinone dyes are brightness and good fastness properties, but they are both expensive and tinctorially weak. However, they are still used extensively, particularly in the red and blue shade areas, because other dyes cannot provide the combination of properties offered by anthraquinone dyes, albeit at a price.

Benzodifuranone Dyes. BDFs are unusual in that they span the whole color spectrum from yellow through red to blue, depending on the electron-donating power of the R group on the phenyl ring of the aryl acetic acid, i.e., Ar = =C_6H_4R (R = H, yellow–orange; R = alkoxy, red; R = amino, blue). The first commercial BDF, Dispersol Red C-BN, a red disperse dye for polyester, is already making a tremendous impact. Its brightness even surpasses that of the anthraquinone reds, while its high tinctorial strength (ca 3–4 times that of anthraquinones) makes it cost-effective.

Polycyclic Aromatic Carbonyl Dyes. Structurally, these dyes contain one or more carbonyl groups linked by a quinonoid system. They tend to be relatively large molecules built up from smaller units, typically anthraquinones. Since they are applied to the substrate (usually cellulose) by a vatting process, the polycyclic aromatic carbonyl dyes are often called the anthraquinonoid vat dyes.

Although the colors of the polycyclic aromatic carbonyl dyes cover the entire shade gamut, only the blue dyes and the tertiary shade dyes, namely, browns, greens, and blacks, are important commercially. As a class, the polycyclic aromatic carbonyl dyes exhibit the highest order of lightfastness and wetfastness.

Indigoid Dyes. Like the anthraquinone, benzodifuranone, and polycyclic aromatic carbonyl dyes, the indigoid dyes also contain carbonyl groups. They are also vat dyes.

Indigoid dyes represent one of the oldest known classes of dyes. Although many indigoid dyes have been synthesized, only indigo itself is of any importance today. Indigo is the blue used almost exclusively for dyeing denim jeans and jackets and is held in high esteem because it fades in tone to give progressively paler blue shades.

Polymethine and Related Dyes. Cyanine dyes are the best known polymethine dyes. Nowadays, their commercial use is limited to sensitizing dyes for silver halide photography. However, derivatives of cyanine dyes provide important dyes for polyacrylonitrile. They include azacarbocyanines, hemicyanines, and diazahemicyanines.

Styryl Dyes. The styryl dyes are uncharged molecules containing a styryl group C_6H_5–CH=C usually in conjugation with an *N,N*-dialkylaminoaryl group. Styryl dyes were once a fairly important group of yellow dyes for a variety of substrates. They are synthesized by condensation of an active methylene compound, especially malononitrile with a carbonyl group, especially an aldehyde. As such, styryl dyes have small molecular structures and are ideal for dyeing densely packed hydrophobic substrates such as polyester.

Yellow styryl dyes have now been largely superseded by superior dyes such as azopyridones, but there has been a resurgence of interest in red and blue styryl dyes. The addition of a third cyano group to produce a tricyanovinyl group causes a large bathochromic shift: the resulting dyes are bright red rather than the greenish yellow color of the dicyanovinyl dyes. These tricyanovinyl dyes have been patented by Mitsubishi for the transfer printing of polyester substrates. Two synthetic routes to the dyes are shown: one is by the replacement of a cyano group in tetracyanoethylene, and the second is by oxidative cyanation of a dicyanovinyl dye with cyanide. The use of such toxic reagents could hinder the commercialization of the tricyanovinyl dyes.

Di- and Triaryl Carbonium and Related Dyes. As a class, these dyes are bright and strong, but are generally deficient in lightfastness. Consequently, they are used in outlets where brightness and cost-effectiveness, rather than permanence, are paramount, for example, the coloration of paper. Many dyes of this class, especially derivatives of pyronines (xanthenes), are among the most fluorescent dyes known.

Resurgence of interest in triphendioxazine dyes arose through successful modification of the intrinsically strong and bright triphendioxazine chromogen to produce blue reactive dyes for cotton. These blue reactive dyes combine the advantages of azo dyes and anthraquinone dyes. Thus they are bright, strong dyes with good fastness properties.

Phthalocyanines. Apart from the recent discoveries of benzodifuranone dyes and diketopyrrolopyrrole pigments, phthalocyanine is the only novel chromogen of commercial importance discovered since the nineteenth century.

Phthalocyanines are analogues of the natural pigments chlorophyll and heme. However, unlike these natural pigments, which have extremely poor stability, phthalocyanines are probably the most stable of all the colorants in use today. Substituents can extend the absorption to longer wavelengths, into the near infrared, but not to shorter wavelengths, and so their hues are restricted to blue and green.

Of all the metal complexes evaluated, copper phthalocyanines give the best combination of color and properties and consequently the majority of phthalocyanine dyes are based on copper phthalocyanine.

Besides being extremely stable, phthalocyanines are bright and tinctorially strong ($\epsilon_{max} \sim 100,000$); this renders them cost-effective. Consequently, phthalocyanines are used extensively in printing inks and paints.

Quinophthalones. Like the hydroxy azo dyes, quinophthalone dyes can, in theory, exhibit tautomerism. The dyes are synthesized by the condensation of quinaldine derivatives with phthalic anhydride. Quinophthalones provide important yellow dyes for the coloration of plastics and for the coloration of polyester.

Sulfur Dyes. These dyes are synthesized by heating aromatic amines, phenols, or nitro compounds with sulfur or, more usually, alkali polysulfides. Sulfur dyes are used for dyeing cellulosic fibers. They are insoluble in water and are reduced to the water-soluble leuco form for application to the substrate by using sodium sulfide solution. The sulfur dye proper is then formed within the fiber pores by atmospheric oxidation. Sulfur dyes constitute an important class of dye for producing cost-effective tertiary shades, especially black, on cellulosic fibers.

Nitro and Nitroso Dyes. These dyes are now of only minor commercial importance, but are of interest for their small molecular structures. The most important nitro dyes are the nitrodiphenylamines. Their small molecules are ideal for penetrating dense fibers such as polyester, and are therefore used as disperse dyes for polyester. All the important dyes are yellow. Although the dyes are not terribly strong ($\epsilon_{max} \sim 20,000$), they are cost-effective because of their easy synthesis from inexpensive intermediates.

Nitroso dyes are metal-complex derivatives of *o*-nitrosophenols or naphthols. Tautomerism is possible in the metal-free precursor between the nitrosohydroxy tautomer and the quinoneoxime tautomer. The only nitroso dyes important commercially are the iron complexes of sulfonated 1-nitroso-2-naphthol. These inexpensive colorants are used mainly for coloring paper.

Miscellaneous Dyes. Other classes of dyes that still have some importance are the stilbene dyes and the formazan dyes. Stilbene dyes are in most cases mixtures of dyes of indeterminate constitution that are formed from the condensation of sulfonated nitroaromatic compounds in aqueous caustic alkali either alone or with other aromatic compounds, typically arylamines. The sulfonated nitrostilbene is the most important nitroaromatic, and the aminoazobenzenes are the most important arylamines.

Formazan dyes bear a formal resemblance to azo dyes, since they contain an azo group. The most important formazan dyes are the metal complexes, particularly copper complexes, of tetradentate formazans. They are used as reactive dyes for cotton.

Dye Intermediates

The precursors of dyes are called dye intermediates. They are obtained from simple raw materials, such as benzene and naphthalene, by a variety of chemical reactions. Usually, the raw materials are cyclic aromatic compounds, but acyclic precursors are used to synthesize heterocyclic intermediates. The intermediates are derived from two principal sources, coal tar and petroleum.

Intermediates Classification. Intermediates may be conveniently divided into primary intermediates (primaries) and dye intermediates. Large amounts of inorganic materials are consumed in both intermediates and dyes manufacture.

Inorganic materials include acids (sulfuric, nitric, hydrochloric, and phosphoric), bases (caustic soda, caustic potash, soda ash, sodium carbonate, ammonia, and lime), salts (sodium chloride, sodium nitrite, and sodium sulfide) and other substances such as chloride, bromine, phosphorus chlorides, and sulfur chlorides. The important point is that there is a significant usage of at least one inorganic material in all processes, and the overall tonnage used by, and therefore the cost to, the dye industry is high.

Dye intermediates are defined as those precursors to colorants that are manufactured within the dyes industry, and they are nearly always colorless. Colored precursors are conveniently termed color bases. As distinct from primaries they are only rarely manufactured in single-product units because of the comparatively low tonnages required. Fluorescent brightening agents (FBAs) are neither intermediates nor true colorants.

There are at least 3000 different intermediates in current manufacture (over half that number are specifically mentioned in the *Colour Index*), and in addition there is a comparatively small number of products manufactured by individual companies for their own specialties.

The Chemistry of Dye Intermediates

The chemistry of dye intermediates may be conveniently divided into the chemistry of carbocycles, such as benzene and naphthalene, and the chemistry of heterocycles, such as pyridenes and thiophenes.

Chemistry of Aromatic Carbocycles. Benzene and naphthalene are by far the most important aromatic carbocycles used in the dyes industry. The hundreds of benzene and naphthalene intermediates used can be prepared from these parent compounds by the sequential introduction of a variety of substituents e.g., NO_2, NR^1R^2, Cl, SO_3H, etc. Introduction of these groups are known as unit processes. The substituents are introduced into the aromatic ring by either electrophilic or nucleophilic substitution. In general, aromatic rings, because of their inherently high electron density, are much more susceptible to electrophilic attack than to nucleophilic attack. Nucleophilic attack only occurs under forcing conditions unless the aromatic ring already contains a powerful electron-withdrawing group, e.g., NO_2. In this case, nucleophilic attack is greatly facilitated because of the reduced electron density at the ring carbon atoms.

Unit Processes. The unit processes encountered in intermediate and dye chemistry are summarized in Table 2.

Chemistry of Aromatic Heterocycles. In contrast to the benzenoid intermediates, it is unusual to find a heterocyclic intermediate that

is synthesized via the parent heterocycle. They are synthesized from acyclic precursors.

The most important heterocycles are those with five- or six-membered rings; these rings may be fused to other rings, especially a benzene ring. Nitrogen, sulfur, and to a lesser extent oxygen, are the most frequently encountered heteroatoms. They are often considered in two groups: those containing only nitrogen, such as pyrazolones, indoles, pyridones, and triazoles which, except for triazoles, are used as coupling components in azo dyes, and those containing sulfur (and also optionally nitrogen), such as thiazoles, thiophenes, and isothiazoles, that are used as diazo components in azo dyes. Triazines are treated separately since they are used as the reactive system in many reactive dyes.

Equipment and Manufacture

The basic types of dye (and intermediate) manufacture are shown in Figure 1. There are usually several reaction steps or unit processes.

The reactions for the production of intermediates and dyes are carried out in bomb-shaped reaction vessels made from cast iron, stainless steel, or steel lined with rubber, glass (enamel), brick, or carbon blocks. Wooden vats are also still used in some countries, e.g., India. These vessels have capacities of 2–40 m^3 (ca 500–10,000 gal) and are equipped with mechanical agitators, thermometers or temperature recorders, condensers, pH-probes, etc, depending on the nature of the operation. Jackets or coils are used for heating and cooling by circulating through them high boiling fluids (e.g., hot oil, or Dowtherm), steam, or hot water to raise the temperature, and air, cold water, or chilled brine to lower it. Unjacketed vessels are often used for aqueous reactions, where heating is affected by direct introduction of steam, and cooling by addition of ice or by heat exchangers. The reaction vessels normally span two or more floors in a plant to facilitate ease of operation.

Products are transferred from one piece of equipment to another by gravity flow, pumping, or by blowing with air or inert gas. Solid products are separated from liquids in centrifuges, on filter boxes, on continuous belt filters, and perhaps most frequently, in various designs of plate-and-frame or recessed plate filter presses. The presses are dressed with cloths of cotton, Dynel, polypropylene, etc. Some provide separate channels for efficient washing, others have membranes for increasing the solids content of the presscake by pneumatic or hydraulic squeezing.

The plates and frames are made of wood, cast iron, or now usually hard rubber, polyethylene, and polyester.

When possible, the intermediates are taken for the subsequent manufacture of other intermediates or dyes without drying because of savings in energy costs and handling losses. There are, however, many cases where products, usually in the form of pastes discharged from a filter, must be dried. Where drying is required, air or vacuum ovens (in which the product is spread on trays), rotary dryers, spray dryers, or less frequently, drum dryers (flakers) are used. Spray dryers have become increasingly important.

The final stage in dye manufacture is grinding or milling. Dry grinding is usually carried out in impact mills (Atritor, KEK, or ST); considerable amounts of dust are generated, and well-established methods are available to control this problem. Dry grinding is an inevitable consequence of oven drying, but more modern methods of drying, especially continuous drying, allow the production of materials that do not require a final comminution stage. Wet milling has become increasingly important for pigments and disperse dyes.

In the past the successful operation of batch processes depended mainly on the skill and accumulated experience of the operator. This operating experience was difficult to codify in a form that enabled full use to be made of it in developing new designs. The gradual evolution of better instrumentation, followed by the installation of sequence control systems, has enabled much more process data to be recorded, permitting maintenance of process variations within the minimum possible limits.

Full computerization of multiproduct batch plants is much more difficult than with single-product continuous units because the control parameters vary fundamentally with respect to time. The first computerized azo and intermediates plants were brought on stream by ICI Organics Division (now Zeneca Specialties) in the early 1970s, and have now been followed by many others. The additional cost (ca 10%) of computerization has been estimated to give a saving of 30 to 45% in labor costs. However, highly trained process operators and instrument engineers are required.

Economic Aspects

With the state of the world economy as it stands in 1993, the growth rate for the industry is likely to be as low as 2–3%, but even this low figure represents something like an additional 20,000 t/yr.

Health and Safety Aspects

Toxicology and Registration. The toxic nature of some dyes and intermediates has long been recognized. Acute, or short-term, effects are generally well known. They are controlled by keeping the concentration of the chemicals in the workplace atmosphere below prescribed limits and avoiding physical contact with the material. Chronic effects, on the other hand, frequently do not become apparent until after many years of exposure.

The positive links between benzidine derivatives and 2-naphthylamine with bladder cancer prompted the introduction of stringent government regulations to minimize such occurrences in the future. Currently, the three principal regulatory agencies worldwide are European Core Inventory (ECOIN) and European Inventory of Existing Commercial Substances (EINECS) in Europe, Toxic Substances Control Act (TOSCA) in the United States, and Ministry of Technology and Industry (MITI) in Japan. Each of these has its own set of data and testing protocols for registration of a new chemical substance.

Environmental Concerns. Dyes, because they are intensely colored, present special problems in effluent discharge; even a very small amount is noticeable. However, the effect is more aesthetically displeasing rather than hazardous. Of greater concern is the discharge of toxic heavy metals such as mercury and chromium.

Effluents from both dye works and dyehouses are treated both before leaving the plant, e.g., neutralization of acidic and alkaline liquors and heavy metal removal, and in municipal sewage works. Various treatments are used.

Biological treatment is the most common and most widespread technique used in effluent treatment, having been employed for over 140 years. There are two types of treatment, aerobic and anaerobic.

Removal of color by adsorption using activated carbon is also employed. Activated carbon is very good at removing low levels of soluble chemicals, including dyes. Its main drawback is its limited capacity. Consequently, activated carbon is best for removing color from dilute effluent.

Chemical treatment of the effluent with a flocculating agent is the most robust and generally most efficient way to remove color.

Chemical oxidation is a more recent method of effluent treatment, especially chemical effluent. This procedure uses strong oxidizing agents like ozone, hydrogen peroxide, chlorine, and potassium permanganate in order to force degradation of even some of the more resilient organic molecules. As of this writing (ca 1993), these treatments remain very expensive and are of limited size, thought they may have some promise in the future.

Additional strategies being implemented to minimize dye and related chemical effluent include designing more environmentally friendly chemicals, more efficient (higher yielding) manufacturing processes, and more effective dyes, e.g., reactive dyes having higher fixation.

DYES: ANTHRAQUINONE. The synthesis of an anthraquinone dye generally involves a large number of steps. Highly toxic metals such as mercury or chromium(VI) are sometimes required. Some processes need to employ a large amount of organic solvent, and others involve a great quantity of waste acids. With the increasing demand for environmental protection, the regulation of pollutant effluents has become more stringent year after year, which has caused a sharp increase in the costs for wastewater treatment. This situation has led to intensive improvement of conventional methods and the development of new synthetic routes as well.

Efforts have also been made to overcome complicated processes. Methods to reduce the number of steps or to use new starting materials have been studied extensively.

Because of their small extinction coefficients anthraquinone dyes have less tinctorial strength than azo dyes; that is the intrinsic disadvantage of anthraquinones. This fact and the complexity of preparation have made their production costs higher than those of azo dyes. However, the anthraquinone dyes have excellent properties that are not attainable by azo dyes, such as brilliancy of color, fastness, and excellent dyeing properties (leveling and dye bath stability). Thus the anthraquinone dyes have been widely used in the areas where these properties are required. Cotton or polyester–cotton blend fibers for military wear and working wear that require extreme fastness are dyed mainly with anthraquinone vat dyes. Most polyester fabrics for automobile seats are dyed with anthraquinone disperse dyes, since the requirement for lightfastness is extremely high and, simultaneously, bright shades are needed.

World dye manufacturers have already begun to develop new types of dyes that can replace the anthraquinones technically and economically. Some successful examples can be found in azo disperse red and blue dyes. In the reactive dye area intensive studies have continued to develop triphenodioxazine compounds to replace anthraquinone blues.

Color and Structure

The uv–vis spectrum of anthraquinone shows an absorption maximum at 323 nm ($\varepsilon = 4500$) due to a $\pi - \pi^*$ transition and very weak absorption in the visible range, 405 nm ($\varepsilon = 60$) due to a $n–\pi^*$ transition. Thus anthraquinone is almost colorless. Introduction of electron-donating substituents causes a bathochromic shift. This is due to the charge-transfer band from the lone pair of amino or hydroxyl groups to the oxygen atom of the carbonyl group. By increasing the electron-donating ability of substituents, the bathochromic shifts are enhanced (Table 1). In the case of the same substituent, the bathochromic shift is larger when the substituent is in the 1-position rather than in the 2-position. The introduction of an electron-withdrawing group has little effect on the absorption maximum of the spectrum.

TABLE 1. SPECTRAL DATA FOR SOME MONOSUBSTITUTED ANTHRAQUINONES[a] IN METHANOL

	1-position		2-position

Cl	333	5000	325	3900

[a] Unsubstituted anthraquinone $\lambda_{max} = 323$ nm; $\varepsilon = 4500$.

The absorption maximum of a disubstituted anthraquinone greatly depends on the substituents and their positions. The 1,4-disubstituted compound shows a remarkable bathochromic shift. Larger bathochromic shifts are observed with increasing electron-withdrawing ability of β-substituents.

1,4,5,8-Tetrasubstituted anthraquinones give a slightly reddish blue tint to greenish blue color, depending on the substituents and their positions.

In addition to the color and the tinctorial strength, which are very important factors for the molecular design of anthraquinone dyes, affinity for fibers, various kinds of fastness (light, wet, sublimation, nitrogen oxides (NO_x) gas, washing, etc), and application properties (sensitivity for dyeing temperature, pH, etc) must be considered thoroughly as well.

Method of Synthesis

Anthraquinone dyes are derived from several key compounds called dye intermediates, and the methods for preparing these key intermediates can be divided into two types: *(1)* introduction of substituent(s) onto the anthraquinone nucleus, and *(2)* synthesis of an anthraquinone nucleus having the desired substituents, starting from benzene or naphthalene derivatives (nucleus synthesis). The principal reactions are nitration and sulfonation, which are very important in preparing α-substituted anthraquinones by electrophilic substitution. Nucleus synthesis is important for the production of β-substituted anthraquinones such as 2-methylanthraquinone and 2-chloroanthraquinone. Friedel-Crafts acylation using aluminum chloride is applied for this purpose. Synthesis of quinizarin (1,4-dihydroxyanthraquinone) is also important.

Key Intermediates

1-Aminoanthraquinone and Related Compounds. 1-Aminoanthraquinone is the most important intermediate for manufacturing acid, reactive, disperse, and vat dyes. It has been manufactured from anthraquinone-1-sulfonic acid by ammonolysis of the sulfo group with aqueous ammonia in the presence of an oxidizing agent such as nitrobenzene-3-sulfonic acid. In this process the starting material can only be obtained by mercury-catalyzed sulfonation of anthraquinone with oleum. For improved ecology, the alternative route based on 1-nitroanthraquinone was established. 1-Nitroanthraquinone is prepared from anthraquinone by nitration in sulfuric acid or organic solvent. 1-Aminoanthraquinone is prepared from 1-nitroanthraquinone by reduction with sodium hydrogen sulfide or by catalytic hydrogenation. Highly purified product is manufactured by continuous vacuum distillation.

1-Amino-4-bromoanthraquinone-2-sulfonic acid (bromamine acid) is the most important intermediate for manufacturing reactive and acid dyes. Bromamine acid is manufactured from 1-aminoanthraquinone-2-sulfonic acid by bromination in aqueous medium, or in concentrated sulfuric acid.

1-Amino-2-bromo-4-hydroxyanthraquinone is one of the most important intermediates for manufacturing red disperse dyes. It is prepared by dibrominating 1-aminoanthraquinone in concentrated sulfuric acid and subsequent hydrolysis in the presence of boric acid.

1-Amino-2-chloro-4-hydroxyanthraquinone is another important intermediate in red disperse dye manufacture. 1-Amino-2-chloro-4-hydroxyanthraquinone is prepared via a route from chlorobenzene and phthalic anhydride as the raw materials.

1,4-Dihydroxyanthraquinone. This anthraquinone, also known as quinizarin, is of great importance in manufacturing disperse, acid, and vat dyes. It is manufactured by condensation of phthalic anhydride with 4-chlorophenol in oleum in the presence of boric acid.

1,4-Diaminoanthraquinone and Related Compounds. Leuco-1,4-diaminoanthraquinone (leucamine) is an important precursor for 1,4-diaminoanthraquinone and is prepared by heating 1,4-dihydroxyantraquinone with sodium dithionite in aqueous ammonia under pressure. 1,4-Diaminoanthraquinone is an important intermediate for vat dyes and disperse dyes, and is prepared by oxidizing leuco-1,4-diaminoanthraquinone with nitrobenzene in the presence of piperidine.

1,4-Diamino-2,3-dichloroanthraquinone (CI Disperse Violet 28) is an important compound as an intermediate for CI Disperse Blue 60 and CI Disperse Violet 26, and is prepared by chlorination of leuco-1,4-diaminoanthraquinone with chlorine gas or sulfuryl chloride in an inert organic solvent such as nitrobenzene.

1,4-Diamino-2,3-dicyanoanthraquinone is the key intermediate for manufacturing CI Disperse Blue 60. 1,4-Diamino-2,3-dicyanoanthraquinone is

manufactured by reaction of 1,4-diaminoanthraquinone-2,3-disulfonic acid with alkali metal cyanide.

1,4,-Diaminoanthraquinone-2,3-dicarboxyimide is the intermediate for CI Disperse Blue 60 and is prepared by hydrolysis of 1,4-diamino-2,3-dicyanoanthraquinone in concentrated sulfuric acid.

Anthraquinone-1-Sulfonic Acid and Its Derivatives. Anthraquinone-1-sulfonic acid has become less competitive than 1-nitroanthraquinone as the intermediate for 1-aminoanthraquinone. However, it still has a great importance as an intermediate for manufacturing vat dyes via 1-chloroanthraquinone.

Anthraquinone-1-sulfonic acid is prepared from anthraquinone by sulfonation with 20% oleum in the presence of mercury catalyst, a Hg(II) salt such as $HgSO_4$ or HgO, at 120°C.

1-Chloroanthraquinone is an intermediate for manufacturing vat dyes such as CI Vat Brown 1. 1-Chloroanthraquinone is prepared by chlorination of anthraquinone-1-sulfonic acid with sodium chlorate in hydrochloric acid at elevated temperature.

1-Methylaminoanthraquinone is an important intermediate for manufacturing solvent dyes and acid dyes, and is prepared from anthraquinone-1-sulfonic acid by replacing the SO_3H group with methylamine.

Anthraquinone-α,α'-Disulfonic Acids and Related Compounds. Anthraquinone-α,α'-disulfonic acids and their derivatives are important intermediates for manufacturing disperse blue dyes (via 1,5- or 1,8-dihydroxyanthraquinone, or 1,5-dichloroanthraquinone) and vat dyes (via 1,5-dichloroanthraquinone).

Anthraquinone-1,5-disulfonic acid and anthraquinone-1,8-disulfonic acid are produced from anthraquinone by disulfonation in oleum.

1,5-Dichloroanthraquinone is an important intermediate for vat dyes and disperse blue dyes. 1,5-Dichloroanthraquinone is prepared by the reaction of anthraquinone-1,5-disulfonic acid with $NaClO_3$ in hot hydrochloric acid solution.

1,5-Dihydroxyanthraquinone (anthrarufin) is an important intermediate for manufacturing disperse blue dyes and is prepared from anthraquinone-1,5-disulfonic acid by heating with an aqueous suspension of calcium oxide and magnesium chloride under pressure at 200–250°C.

α,α'-Dinitroanthraquinones and Related Compounds. 1,5- and 1,8-Dinitroanthraquinone are the key intermediates for manufacturing disperse blue dyes via dinitrodihydroxyanthraquinone and vat dyes via diaminoanthraquinones. 1,5-Dinitroanthraquinone and 1,8-dinitroanthraquinone are prepared by nitration of anthraquinone with nitric acid in sulfuric acid. α, β'-Dinitroanthraquinones are also formed in the reaction.

1,5-Diaminoanthraquinone is prepared from 1,5-dinitroanthraquinone by ammonolysis, by catalytic hydrogenation, or by reduction with sodium sulfide. It is also prepared from anthraquinone-1,5-disulfonic acid by ammonolysis. 1,5-Diaminoanthraquinone is an important intermediate for manufacturing vat dyes.

1,5-Dihydroxy-4, 8-dinitroanthraquinone is an important dye precursor for CI Disperse Blue 56, and is prepared from 1,5-diphenoxyanthraquinone by hexanitration in sulfuric acid and subsequent hydrolysis with aqueous alkali. 1,5-Dinitro-4,8-dihydroxyanthraquinone is also prepared from dimethoxyanthraquinone. High purity of 1,5-dimethoxyanthraquinone is required for manufacturing disperse blue dyes.

2-Methylanthraquinone and Related Compounds. 2-Methylanthraquinone and its derivatives are important as intermediates for manufacturing various kinds of vat dyes and brilliant blue (turquoise blue) disperse dyes. 2-Methylanthraquinone is prepared from phthalic anhydride and toluene via a benzoylbenzoic acid. 1-Nitroanthraquinone-2-carboxylic acid is of great importance as an intermediate for manufacture of vat dyes as well as disperse dyes. It is conventionally prepared from 2-methyl-1-nitroanthraquinone, by oxidation in sulfuric acid with sodium dichromate. 1-Aminoanthraquinone-2-carboxylic acid is also an important intermediate for vat dyes and disperse dyes and is prepared from 1-nitroanthraquinone-2-carboxylic acid by reaction with ammonia.

2-Chloroanthraquinone and Its Derivatives. 2-Chloroanthraquinone and its derivatives are the most important intermediates for vat dyes and high performance organic pigments. 2-Chloroanthraquinone is prepared by Friedel-Crafts reaction of chlorobenzene and phthalic anhydride in the presence of aluminum chloride, followed by ring closure in concentrated sulfuric acid. 2-Amino-3-hydroxyanthraquinone is prepared by heating 5-benzoylbenzoxazolone-2'-carboxylic acid in sulfuric acid. This compound is an intermediate for CI Vat Red 10.

Benzanthrone and Related Compounds. Benzanthrone is prepared by the reaction of anthraquinone with glycerol, sulfuric acid, and a reducing agent such as iron. Benzanthrone is an important intermediate for manufacturing vat dyes.

N-Methylanthrapyridone and Its Derivatives. 6-Bromo-3-methylanthrapyridone is an important intermediate for manufacturing dyes soluble in organic solvents. These solvent dyes are prepared by replacing the bromine atom with various kinds of aromatic amines. 6-Bromo-3-methylanthrapyridone is prepared from 1-methylamino-4-bromoanthraquinone by acetylation with acetic anhydride followed by ring closure in alkali. The starting material of this route is anthraquinone-1-sulfonic acid.

Reactive Dyes

Most of the anthraquinone reactive dyes are derived from bromamine acid. These dyes give a bright blue shade and excellent lightfastness. A great number of reactive groups have been proposed; typical examples include sulfatoethylsulfone, dichlorotriazine, monochlorotriazine, monofluorotriazine, and other heterocyclic groups (see **Dyes: Reactive**).

Disperse Dyes

Disperse dyes are water-insoluble, aqueous dispersed materials that are used for dyeing hydrophobic synthetic fibers, including polyester, acetate, and polyamide.

By introducing amino, hydroxy, or methyl groups onto the anthraquinone moiety as the principal auxochromes, dyes that have yellow through greenish blue shades are obtained. Among these dyes many that have brilliant red, violet, blue, and greenish blue shades have great industrial importance in view of their affinity for polyester or cellulose acetate fibers and lightfastness and sublimation resistance. On the contrary, yellow or orange dyes are not satisfactory because of the rather simple molecular structure. Therefore these shades are obtained from other chromophores.

On the basis of the kind and the position of their substituents and their color range, the anthraquinoid disperse dyes may be classified as follows:

Color range	Chemical description
red	1-amino-4-hydroxyanthraquinones
blue, greenish blue	1,1,4,5,8-substituted anthraquinones
greenish blue	1,4-diaminoanthraquinone-2,3-dicarboxyimides
violet, blue	1,4-diaminoanthraquinone derivatives
violet, blue	*N*-substituted 1-amino-4-hydroxyanthraquinones

Acid Dyes

Acid dyes are used for dyeing wool, synthetic polyamides, and silk in aqueous media. Anthraquinone acid dyes give brilliant reds, violets, blues, and greens and exhibit excellent lightfastness. Because of their relatively high cost, they are used to dye high grade textiles in pale and moderate shades. Various kinds of anthraquinone acid dyes have been developed so far mainly by IG-Farbenindustrie in Germany applying chemical reactions that were studied in developing vat dyes. However, the number of commercial products has declined because of poor properties or unavailable raw materials. Anthraquinone acid dyes may be classified into two groups: bromamine acid derivatives and quinizarin derivatives.

Vat Dyes

Anthraquinone vat dyes have been used to dye cotton and other cellulose fibers for many decades. Despite their high cost, relatively muted colors, and difficulty in application, anthraquinone vat dyes still form one of the most important dye classes of synthetic dyes because of their all-around superior fastness.

Anthraquinone vat dyes are water-insoluble dyes. They are converted to leuco compounds (anthrahydroquinones) by reducing agents such as sodium hydrosulfite in alkaline conditions. These water-soluble leuco compounds have an affinity to cellulose fibers and penetrate them. After reoxidation by means of air or other oxidizing agents, the dye becomes water-insoluble again and fixes firmly on the fiber.

The anthraquinone vat dyes can be classified into several groups on the basis of their chemical structures: *(1)* benzanthrone dyes, *(2)* indanthrones, *(3)* anthrimides, *(4)* anthrimidocarbazoles, *(5)* acylaminoanthraquinones, *(6)* anthraquinoneazoles, *(7)* anthraquinone acridones, *(8)* anthrapyrimidines, and *(9)* highly condensed ring systems. Recently, research and

development efforts have focused on improved manufacturing of traditional vat dyes.

Mordant Dyes

Mordant dyes have hydroxy groups in their molecular structure that are capable of forming complexes with metals. Although a variety of metals such as iron, copper, aluminum, and cobalt have been used, chromium is most preferable as a mordant. Alizarin or CI Mordant Red 11 (CI 58000), the principal component of the natural dye obtained from madder root, is the most typical mordant dye. Many mordant dyes have given way to the vat or the azoic dyes, which are applied by much simpler dyeing procedures.

Acid–mordant dyes have characteristics similar to those of acid dyes which have a relatively low molecular weight, anionic substituents, and an affinity to polyamide fibers and mordant dyes. In general, brilliant shades cannot be obtained by acid–mordant dyes because they are used as their chromium mordant by treatment with dichromate in the course of the dyeing procedure. However, because of their excellent fastness for light and wet treatment, they are predominantly used to dye wool in heavy shades (navy blue, brown, and black). In terms of chemical constitution, most of the acid–mordant dyes are azo dyes; some are triphenylmethane dyes; and very few anthraquinone dyes are used in this area. CI Mordant Black 13 is one of the few examples of currently produced anthraquinone acid–mordant dyes.

Functional Dyes

The investigation of new dyes has always been focused on the development of fast, brilliant, inexpensive, and easy applicable dyes. Because a great emphasis has been placed especially on fastness, the dyes with poorer fastness have been ignored in the past. However, in recent years new needs for dyes that change color in response to low energy stimuli including light, electricity, or heat have arisen in the electronics industry. This new application includes information recording, information display, and energy conversion. The term *functional dye* has been applied to dyes that are used in advanced technologies based on optoelectronics since 1981 when the book entitled *The Chemistry of Functional Dyes* was published in Japan.

In order to develop the dyes for these fields, characteristics of known dyes have been re-examined, and some anthraquinone dyes have been found usable. One example of use is in thermal-transfer recording where the sublimation properties of disperse dyes are applied. Anthraquinone compounds have also been found to be useful dichroic dyes for guest-host liquid crystal displays when the substituents are properly selected to have high order parameters. These dichroic dyes can be used for polarizer films of LCD systems as well. Anthraquinone derivatives that absorb in the near-infrared region have also been discovered, which may be applicable in semiconductor laser recording.

Economic Aspects

Production Capacity and Demand. The production capacity for each dye or dye intermediate has rarely been announced officially by the individual manufacturers. Principal manufacturers of anthraquinone dyes and their intermediates are as follows: Bayer, BASF, and Hoechst (Germany); Hoechst Mitsubishi Kasei, Sumitomo Chemical, Mitsui Badische Dyes, and Nippon Kayaku (Japan); Ciba-Geigy and Sandoz (Switzerland); Zeneca and Holliday (U.K.); Crompton & Knowles (U.S.); and IDI (India).

Recent increases in environmental costs have become a serious problem, and future prospects for the anthraquinone dye industry are not optimistic. Some traditional manufacturers have stopped the production of a certain dye class or dye intermediates that were especially burdened by environmental costs, e.g., vat dyes and their intermediates derived from anthraquinone-1-sulfonic acid and 1,5-disulfonic acid. However, several manufacturers have succeeded in process improvement and continue production, even expanding their capacity. In the forthcoming century the worldwide framework of production will change drastically.

Consumption

Anthraquinone dyes are the most important dye class after azo dyes. The consumption of each dye class or set of classes is approximately parallel to the consumption of fibers to which they are applied.

Among these dye classes, anthraquinone dyes are in an important position in reactive dyes and vat dyes for cellulose fibers, disperse dyes for polyester, and acid dyes for polyamide. Applications for high performance organic pigments for plastics and paints are also important areas.

Health and Safety Information

In general, anthraquinone dyes and their intermediates have not been reported as strongly toxic substances, but for many compounds safety data have not been evaluated. 1-Nitroanthraquinone, 1-chloroanthraquinone, and benzanthrone are reported to cause mild skin irritation in a test with rabbits, 500 mg/24 h. Some eye irritation data have been reported.

There are some tumorigenic data for anthraquinone dyes and intermediates which have been evaluated thoroughly. Data for 2-aminoanthraquinone and 2-methyl-1-nitroanthraquinone are available. 2-Aminoanthraquinone has been assessed by the United Nations International Agency for Research on Cancer (IARC) from studies in animals, and is judged to fall into the *Animal: Limited Evidence* group. 2-Aminoanthraquinone has been evaluated by EPA (Genetic Toxicology program) and a positive carcinogenic effect for rat and mouse is designated. 2-Methyl-1-nitroanthraquinone has been assessed by IARC and judged as belonging in the *Animal: Sufficient Evidence* group. 2-Methyl-1-nitroanthraquinone has been evaluated by the National Cancer Institute (NCI) and clear evidence of carcinogenicity for rat and mouse is demonstrated.

Most anthraquinone dyes and their intermediates are handled in a powder form. Their dust poses the threat of contact to eyes and skin or contamination of surroundings. Attention must be paid to avoid these hazards. Special attention should be paid to avoid contact with compounds that are recognized to have probable carcinogenicity.

In the case of handling in relatively small quantities, i.e., for laboratory use, normal personal equipment, i.e., dust masks, safety glasses, and gloves, and hoods with local exhaust ventilation should be used. In plant operations, special technical handling measures should be taken because the possibility of contact is extremely high, especially when charging the raw materials or isolating or packaging the intermediates or final products.

DYES: APPLICATION AND EVALUATION. The global consumption of textiles is estimated at around 30 million t, and this is expected to grow at 3% per year. The coloration of this amount needs ca 700,000 t of dye, with a value of $4400 million. The principal reasons for coloring textiles are for aesthetic appearance and decoration or for utilitarian purposes, and unless there is an unpredicted change in human behavior the majority of textiles will continue to be dyed to produce colored apparel, home furnishings, carpets, etc. Among the aesthetic uses are fashion garments and household articles such as drapes, towels, and carpets. In the utilitarian group are uniforms (military and civil), and work wear.

In order for a colored substance to be regarded as a dyestuff, a number of requirements must be satisfied. A dyestuff must be substantive for a textile and exhaust from an aqueous solution into the fiber; have a high exhaustion; exhaust at a rate allowing economic processing; give a uniform level dyeing; and have satisfactory fastness for the particular end use the textile is intended for. The process of dyeing is therefore a combination of chemistry, application technology, economics, and customer needs.

Classification of Dyestuffs According to Application

The *Colour Index* categorizes all coloring matters according to application characteristics. The following are the main types currently of interest as dyes.

Acid Dyes. These are anionic dyes, usually containing sulfonic acid groups, that are substantive to wool, other protein fibers, and polyamides when dyed from an acidic dyebath. The lower the pH the more rapid the dyeing, and exhaustion efficiency is enhanced by increased acidity.

Mordant Dyes. This group includes many natural as well as synthetic dyes. They have no or low substantivity for textile fibers and are therefore applied to cellulosic or protein fibers that have been treated (mordanted) with metallic oxides to give points of attraction for the dye. The dye forms a complex with the metal and depending on the metal and fiber can simply form a large macromolecule incapable of desorbing, or a dye molecule bound to the fiber resulting from chelation with the metal. An important subgroup is chrome dyes where wool is treated with Cr^{3+} with which it reacts; dye is then applied which in turn complexes with the chromium.

Metals such as chromium and cobalt can be introduced into dye molecules to give larger molecules. They can be regarded as being a special form of mordant dye. The complexes can be formed by chelating one or two molecules of dye with metal. They are applied in a similar manner to acid dyes.

Direct Dyes. These are defined as anionic dyes, again containing sulfonic acid groups, with substantivity for cellulosic fibers. They are usually azo dyes and can be mono-, dis-, or polyazo, and are in general planar structures. They are applied to cellulosic fibers from neutral dyebaths, i.e., they have direct substantivity without the need of other agents. Salt is used to enhance dyebath exhaustion. Some direct dyes can be applied to wool and polyamides under acidic conditions, but these are the exception.

Fiber-Reactive Dyes. These dyes can enter into chemical reaction with the fiber and form a covalent bond to become an integral part of the fiber polymer. They therefore have exceptional wetfastness. Their main use is on cellulosic fibers where they are applied neutral and then chemical reaction is initiated by the addition of alkali. Reaction with the cellulose can be by either nucleophilic substitution, using, for example, dyes containing activated halogen substituents, or by addition to the double bond in, for example, vinyl sulfone, $-SO_2CH{=}CH_2$, groups.

Basic Dyes. These are usually the salts of organic bases where the colored portion of the molecule is the cation. They are therefore sometimes referred to as cationic dyes. They are applied from mild acid, to induce solubility, and applied to fibers containing anionic groups. Their main outlet is for dyeing fibers based on polyacrylonitrile.

Vat Dyes. The basic mechanism of vat dye application is the conversion of an insoluble complex polycyclic molecule based on the quinone structure into a soluble leuco form by treatment with alkaline-reducing agents. This leuco form is then absorbed onto cellulose. Once the dye has been exhausted into the cellulose it is reconverted *in situ* to the insoluble pigment form which is trapped within the fiber. These dyes have high wet- and lightfastness. A subgroup of vat dyes is the solubilized vat dyes which are temporarily solubilized to allow easy application without reducing agents followed by regeneration of the insoluble dye after dyeing. These dyes are no longer of commercial importance.

Sulfur Dyes. These are complex molecules containing sulfur obtained from the reaction between selected organic intermediates such as 4-aminophenol, or *p*-phenylenediamine and molten sulfur or polysulfide. The actual structures of sulfur dyes are largely unknown although it is considered that they possess sulfur-containing heterocyclic rings. They are applied like vat dyes with the leuco form being generated by using a reducing agent such as sodium sulfide.

Disperse Dyes. These are substantially water-insoluble dyes applied from aqueous dyebath in a finely dispersed form. They are the most important class of dye for dyeing hydrophobic synthetic fibers such as polyester and acetates.

Ingrain Dyes/Azoic Dyes. These are dyes that are formed in the fiber by applying precursors. An example of this class are the azoic dyes. With these dyes a coupling component is applied to the fabric followed by a diazonium compound to form the insoluble dyes. Alternatively, a stabilized mix of the two can be applied and the insoluble azoic dye created on the fiber in a separate treatment, e.g., acid steaming. This is a traditional method for obtaining bright heavy shades cheaply but has lost some popularity as a result of poor rubbing fastness and the decreasing availability of the amines and diazonium salts. Other dyes in this group are phthalocyanine compounds which still have commercial importance, particularly in textile printing.

Other Dyes. Other dye classes listed in the *Colour Index* include dyes for leather, solvents, paper, and food. Leather dyes are those acid, direct, mordant, and basic dyes that show substantivity for leather, good diffusion into it, and acceptable fastness. They are essentially applied in an analogous manner to acid or basic dyes. Paper is colored by both inorganic pigments and natural and synthetic organic colorants. The main dyes used are basic, acid, and direct dyes. Solvent dyes can be regarded as similar to disperse dyes. They are small, unsulfonated molecules, plus a few basic dyes that show high solubility in solvents. Finally food dyes, nontoxic colored substances that can be added to food, are included. See also **Colorants (Food)**.

Fluorescent Whitening Agents. These are fluorescent substances that transform invisible ultraviolet light into visible blue light. Fluorescent whitening agents change the appearance of substrates in two ways: by emitting light and therefore increasing the luminosity (brightness); and by changing the shade from yellowish white to bluish white. They are unfavorably influenced by factors such as low uv content light and high uv light absorption of the substrate or other chemicals present on the substrate. Like dyes, fluorescent whitening agents are available in classes analogous to acid, basic, direct, and disperse dyes for application to all substrates, including paper.

Physical and Organic Chemistry of Dyes and the Dyeing Process

The practical characteristic of a dyestuff is that when a textile is immersed in a solution containing a dye, the dye preferentially adsorbs onto and diffuses into the textile. The thermodynamic equations defining this process have been reviewed in detail. The driving force for this adsorption process is the difference in chemical potential between the dye in the solution phase and the dye in the fiber phase. In practice it is only necessary to consider changes in chemical potential and to understand that the driving force is the reduction in free energy associated with the dye molecule moving from one phase to the other, as the molecule always moves to the state of lowest chemical potential.

Influence of the Fiber. In order for a dye to move from the aqueous dyebath to the fiber phase the combination of dye and fiber must be at a lower energy level than dye and water. This in turn implies that there is a more efficient, lower energy sharing of electrons or intramolecular energy forces, and there are a number of mechanisms that allow this to happen.

Fibers exist as natural, or synthetic, hydrophilic, hydrophobic, nonionic, and ionic. Natural fibers have complex chemical structures with a multitude of possible points of attraction for a dyestuff and are difficult to characterize because of the structure being strongly influenced by regional, climatic variations and the species of plant or animal. Dyeing of natural fibers is therefore much more complex than dyeing synthetic fibers where structures can be characterized and the availability of points of attraction can be deliberately engineered into the fiber's molecular chain. The various types of fiber are summarized in Table 1. The fiber type dictates the type of dye needed.

Modes of Attraction

The force of attraction between a dye and fiber results from the usual electronic interactions. They include ionic forces (coulombic attraction), ion-dipole forces, hydrogen bonds, charge-transfer forces, van der Waals forces, hydrophobic interaction, and covalent bonds.

Dyestuff Organic Chemistry

Dyestuffs impart color to textiles because of their ability to absorb electromagnetic radiation in the wavelengths visible to the human eye (400–650 nm). When white light strikes a dyestuff molecule certain wavelengths are absorbed, depending on the molecular construction, and others are reflected. The wavelengths of the reflected light give the specific color of the dyestuff.

Dyestuff organic chemistry is concerned with designing molecules that can selectively absorb visible electromagnetic radiation and have affinity for the specified fiber, and balancing these requirements to achieve optimum performance. To be colored the dyestuff molecule must contain unsaturated chromophore groups, such as azo, nitro, nitroso, carbonyl, etc. In addition, the molecule can contain auxochromes, groups that supplement the chromophore. Typical auxochromes are amino, substituted amino, hydroxyl, sulfonic, and carboxyl groups.

There is little correlation between classifications according to chemical type and application properties. Application classifications are of most practical usefulness to the dyer.

The Dyeing Process

The physical chemistry associated with dyeing has been described elsewhere both in detail and in summary. The purpose of this treatment is

to outline those basic concepts that have a direct impact on dyeing in order to appreciate the fundamental processes taking place.

Zeta Potential. When a textile is immersed in water a negative charge is developed on its surface. This is called the zeta potential. This happens even with ionic fibers in neutral dyebaths. Negatively charged dyes therefore are coulombically repelled.

Internal and External Phases. When dyeing hydrated fibers, for example, hydrophilic fibers in aqueous dyebaths, two distinct solvent phases exist, the external and the internal. The external solvent phase consists of the mobile molecules that are in the external dyebath so far away from the fiber that they are not influenced by it. The internal phase comprises the water that is within the fiber infrastructure in a bound or static state and is an integral part of the internal structure in terms of defining the physical chemistry and thermodynamics of the system. Thus dye molecules have different chemical potentials when in the internal solvent phase than when in the external phase. Further, the effects of hydrogen ions (H^+) or hydroxyl ions (OH^-) have a different impact. In the external phase acids or bases are completely dissociated and give an external or dyebath pH. In the internal phase these ions can interact with the fiber polymer chain and cause ionization of functional groups. This results in the pH of the internal phase being different from the external phase and the theoretical concept of internal pH.

Isotherms. When a fiber is immersed in a dyebath, dye moves from the external phase into the fiber. Initially the rate is quick but with time this slows and eventually an equilibrium is reached between the concentration of dye in the fiber and the concentration of dye in the dyebath. For a given initial dyebath concentration of a dye under given dyebath conditions, e.g., temperature, pH, and conductivity, there is an equilibrium concentration of dye in fiber, D_f, and dye in the dyebath external solution, D_s. Three models describe this relationship: simple partition isotherm, Freundlich isotherm, and Langmuir isotherm.

With simple partition the situation is comparable to the partition of a solute between two solvents. The bonding forces involved between uncharged dye and uncharged fiber, and uncharged dye and uncharged solvent are considered to be the same. The dye is sometimes referred to as in solid solution in the fiber. The simple partition isotherm is found in practice with disperse dyes on cellulose acetate and polyester. It represents the dyeing situation with the minimum restrictions for the dye to enter the fiber; the only restriction is when the fiber solution becomes saturated.

The Freundlich isotherm, where the dye in fiber D_f is directly proportional to $(D_s)^x$ and a plot of log D_f against log D_s gives a straight line, is generally found with cellulosic and other ionic hydrophobic fibers.

In a Langmuir isotherm, the reciprocal of dye in fiber $1/DF_f$ is directly proportional to the reciprocal of dye in the dyebath $1/DF_s$. A plot of $1/D_f$ against $1/D_s$ therefore gives a straight line. Langmuir isotherms are typically found with ionic synthetic fibers and ionic dyes, e.g., dyeing polyacrylonitrile with modified basic dyes, and on hydrophilic fibers in situations when the number of sites becomes very low. This may arise when the internal pH is such that only a small number of sites ionize.

Aggregation, Activity, and Solution. Theoretical treatments use the term activity which assumes that the dyestuff is present in a monomolecular dissociated state in solution. Dyes are not generally in this state except at very dilute concentrations; some molecular interaction is more likely. Thus practical situations are not fully described or characterized by theoretical treatments assuming monomolecularity, but the errors involved are usually of no practical consequence. However, when gross aggregation takes place there is significant interference as the dyestuff available for absorption is removed and previous theoretical considerations become invalid. Where aggregation takes place less dye is absorbed than predicted by theory. In general, aggregation is therefore to be avoided, except in exceptional situations where it is introduced to deliberately slow down the rate of dyeing. Dyebath conditions are usually adopted to minimize the potential for aggregation.

Rate of Diffusion. Diffusion is the process by which molecules are transported from one part of a system to another as a result of random molecular motion. This eventually leads to an equalization of chemical potential and concentration throughout the system, and in the case of dyeing an equilibrium between dye in the fiber and dye in the dyebath. In dyeing there are three stages to diffusion: diffusion of dye through the bulk solution of the dyebath to the fiber surface, diffusion through this surface, and diffusion of dye from the surface into the body of the fiber to allow for more dye to diffuse through the surface layer. These processes have been summarized elsewhere.

Level Dyeing. The concept of obtaining a level dyeing in reasonable time is fundamental in practical processes. Dyes that have a low affinity are likely to diffuse to the fiber surface slowly (a low rate of strike), and once in the fiber quickly diffuse through the fiber to give a uniform distribution of dye molecules. Because of the low affinity of these dyes there are no strong forces of attraction restricting movement. These dyes exhibit good migration and are likely to give level dyeings.

Level dyeings can be obtained by applying dyes of low affinity that dye quickly if unevenly, and allow them to migrate to give uniform level dyeings by extending the time of dyeing. This simple approach has the disadvantage that such low affinity dyes produce dyeings of relatively low wetfastness. Good wetfastness requires high affinity dyes. Because these exhibit low migration it is necessary to ensure that a level dyeing is obtained from the start and maintained throughout the dyeing process.

In order to ensure level dyeings from high affinity dyes it is necessary to make them behave as if they were of low affinity. This is done by reducing the difference between their chemical potential in solution and fiber. The techniques used include: higher temperature for more diffusion; change in pH to control the number of sites available; addition of an electrolyte to either compete with the dye for sites, or neutralize the sites preventing ionic attraction; and addition of auxiliary agents that either compete with the dye for the fiber by lowering the chemical potential in the dyebath phase thus making it a more attractive environment for the dye, or by removing dye from the equilibrium by forming a temporary complex or aggregate in the dyebath. In essence, in order to obtain level dyeings with higher affinity dyes the objective is to slow down the rate of dyeing.

Compatibility. To produce a desired shade more than one dye is usually needed. Often combinations of three dyes are used, e.g., yellow, red, and blue, in order to obtain the maximum number of shades available from the minimum number of dyestuffs. In order to give uniform coloration it is necessary to apply such mixtures of dyes from the same dyebath. As the dyeing proceeds the textile takes up more of the dyes. If the hue of the fabric is the same throughout all stages of dyeings, simply becoming stronger with time, and the hue of the final textile is reproducibly uniform both on its surface and within its interior, e.g., for a wound package of yarn, then the dyes are said to be compatible under the dyeing conditions used. Compatibility is mainly a function of exhaustion rate, but can also be influenced by migration.

Dyeing of Cellulosic Fibers

Preparation for Dyeing. Cotton fibers are coated with natural waxes and pectins. These can be removed by aqueous alkalies at 80°C or above or by solvent treatment to improve the absorbancy and dyeability of the fibers. Cotton may be made suitable for dyeing in a variety of forms, such as raw stock, yarn, or piece goods. Raw stock is normally dyed without thorough dewaxing, since the natural waxes aid in subsequent spinning operations. Careful preparation of cotton piece goods is essential to achieve suitable dye penetration, fastness, and general appearance. Fabric construction dictates whether the fabrics will be processed in rope or open-width forms. Heavy piece goods, and those which are subject to rubs and crease marks, are handled in open width.

Before dyeing in light or bright shades, the goods should be bleached with hydrogen peroxide and caustic soda to bleach the motes. This operation also helps in the removal of trace impurities that remain after boil-off.

Mercerizing is accomplished by passing the cotton fabric through 15–30% caustic soda under tension. Improved luster and increased dye affinity result. With knitted fabrics it is necessary to remove the knitting oils by either alkali treatment or solvents. Viscose rayon, because of its low wet strength, must be processed under minimum tension at all stages of preparation. Skeins contain few impurities and require only light scouring.

The Dyeing Process. When cotton fiber is immersed in water it develops a negative charge. In order for dyes to show good buildup on cotton the dyes must be soluble, planar, aromatic structures. Solubility is obtained by incorporating negatively charged sulfonic acid groups, i.e., the anions. Therefore the dyes show long-range, coulombic (ionic) repulsion, but very strong short-range van der Waals forces of attraction. Thus there is a potential barrier that the dyestuff molecule has to overcome. Natural and introduced thermal agitation tend to equalize the distribution of ions.

TABLE 1. FIBER-DYE PROPERTY REQUIREMENTS

Fiber name	Type/general classification	Chemical constitution	Ionic nature in dyebath
cotton, linen, and other vegetable fibers	natural, hydrophilic	cellulose	anionic
viscose rayon	synthetic,[a] hydrophilic	regenerated cellulose	anionic
wool, silk, hair	natural, hydrophilic	complex proteins	cationic
nylon	synthetic, somewhat hydrophobic	polyamide	usually cationic
acrylics	synthetic, hydrophobic	modified polyacrylonitriles	anionic
acetate	synthetic,[a] hydrophobic	acetylated cellulose	nonionic
triacetate	synthetic,[a] hydrophobic	acetylated cellulose	nonionic
polyester	synthetic, hydrophobic	polyester	usually nonionic
polypropylene	synthetic, hydrophobic	polyolefin	nonionic

[a] Some references distinguish between synthetic fibers made from synthetic polymers and those made by modification of cellulose (man-made fibers).

The use of salt or similar electrolyte is critical in the dyeing of cellulose. When sodium chloride is added to the dyebath, sodium ions (Na^+) diffuse to the negative charges on the cellulose and neutralize them. With the introduction of the sodium ions (Na^+) the coulombic repulsion force between fiber and negatively charged dye is removed and only the strong attraction forces exist. It is then possible for negatively charged dye to diffuse unhindered to the fiber surface.

Direct Dyes

The simplest way of coloring cellulosic fibers is with direct dyes. The dyeing mechanism follows exactly the outline just described where the addition of salt is used to allow dyestuff to be absorbed on the fiber. This is done carefully to ensure that level dyeing is achieved, especially during the early stages of dyeing.

Leveling Power. Direct dyes are classified according to their leveling characteristics. Class A direct dyes migrate well and have high leveling power, i.e., they have low affinity and high diffusion. Class B direct dyes have poor leveling power and exhaustion must be brought about by controlled salt addition. Class C direct dyes are dyes of poor leveling power which exhaust well in the absence of salt and the only way of controlling the rate of exhaustion is by temperature control.

In all these application methods the same procedure is adopted. At the beginning the rate of dyeing must be as slow as needed to give levelness; once this has been achieved the rate of dyeing is systematically increased to give complete exhaustion.

Wetfastness. Class A direct dyes offer the most trouble-free process for dyeing cellulose. However, they do not always provide sufficient wetfastness.

The Class B and C dyes show better resistance to desorption, i.e., they show higher wetfastness, but they do not overcome it fully, and even the Class C direct dyes show inadequate wetfastness and poor staining of adjacents in fastness tests as a result of the reversible nature of the dyeing process. Attempts to overcome this problem have concentrated on chemical treatment of the direct dyes after they were applied. These treatments essentially make the direct dye molecules already on the fiber much bigger and thereby increase the nonionic forces of attraction or reduce solubility in order to reduce desorption and give good wetfastness. Methods used include applying dyes containing free amino groups, diazotizing them and coupling with a base; aftertreatment with formaldehyde; applying dyes containing hydroxyl groups ortho to the azo group and then aftertreating with metallic salts, e.g., Cu; and applying 1–4% of a cationic surface-active agent (over 15–30 min at 25–60°C) to form a sparingly soluble complex with the dye. Today only the latter two processes are used.

Fiber-Reactive Dyes

Because of the limitations of direct dyes and the ability to use simple acid dye chromophores to give bright washfast dyeings, fiber-reactive dyes have become a well-established, popular way of dyeing cellulose. The growth rate of reactive dye consumption of 3.9% per annum is four times the growth rate of other dyes for cellulosic fibers.

A reactive dye for cellulose contains a chemical group that reacts with ionized hydroxyl ions in the cellulose to form a covalent bond. When alkali is added to a dyebath containing cellulose and a reactive dye, ionization of cellulose and the reaction between dye and fiber is initiated. As this destroys the equilibrium more dye is then absorbed by the fiber in order to re-establish the equilibrium between active dye in the dyebath and fiber phases. At the same time the addition of extra cations, e.g., Na^+ from using Na_2CO_3 as alkali, has the same effect as adding extra salt to a direct dye. Thus the addition of alkali produces a secondary exhaustion.

At the end of the dyeing process there is fixed dye on the fiber, and hydrolyzed dye in both the dyebath and fiber. All active dye disappears. In order to take advantage of the fastness offered by covalently bonding the dye to the cellulose it is necessary to remove all the hydrolyzed dye from the fiber. Unfortunately, the hydrolyzed dye does exhibit some affinity for the cellulose and removing it is a desorption process rather than a rapid physical removal. Thus the removal is a relatively difficult procedure that is a critical part of the total dyeing process. Once a dye is fixed it cannot migrate and therefore dyeings achieved using fiber-reactive dyes must be level before they are fixed.

The Ideal Fiber-Reactive Dye Profile. Figure 1 shows the general profile for the application of a reactive dye. In addition to showing the rate profile of fixation between dye and fiber, three other practical parameters (A–C) are noted.

The overall objective is to make the fixation (C) as high as possible for economic reasons. The closer the fixation (C) is to the total dye on the fiber (B) then the smaller the concentration of [dye–OH] and the less that needs to be removed in the washing-off process after dyeing.

Application Methods. There are many detailed application methods used for applying reactive dyes, and all have been described in detail. Examples of the main methods include cold exhaust dyeing fiber-reactive dyes, warm, hot exhaust dyeing dyes, migration exhaust technique for less than 0.5% depth of shade, all-in method, continuous dyeing, and cold pad-batch dyeing.

Chemical Types. A wide range of reactive groups have been investigated, with 20–30 used commercially and over 200 patented. These have been described in detail elsewhere. Because these reactive groups differ chemically the activation of the reactive systems is different as are the rates of reaction with cellulose, from one reactive system to another. This rate of reaction with cellulose, or reactivity, dictates the temperature and pH needed for dyeing.

The most important reactive groups are those based on halotriazine or halopyrimidine systems, where an activated halogen substituent undergoes a nucleophilic substitution reaction with ionized cellulose, or dyes based on sulfatoethylsulfonyl groups.

Bifunctional fiber-reactive dyes have been developed. The concept behind bifunctional dyes is that if two distinct reactive groups are used, the probability of obtaining dye covalently bonded to the cellulose at the end of dyeing instead of being hydrolyzed is increased because each molecule must react twice with OH to be fully hydrolyzed. The claimed benefits of bifunctional reactive dyes are a generally higher level of fixation, and in the case of mixed reactive groups, suitability for application over a range of temperatures and methods.

Correlation of Application, Affinity, and Reactivity. Figure 2 correlates fiber-reactive dye application suitability to reactivity and affinity.

Vat Dyes on Cellulose

Most are based on the quinone structure and are solubilized by reduction with alkaline reducing agents such as sodium dithionite. Conversion back to the insoluble pigment is achieved by oxidation. The dyes are applied by either exhaust or continuous dyeing techniques. In both cases the process is comprised of five stages: preparation of the dispersion, reduction, dye exhaustion, oxidation, and soaping.

Uses of Vat Dyes. The main characteristic of vat dyes is their excellent fastness to light, water, and other agents, e.g., chlorine. Vat dyes are

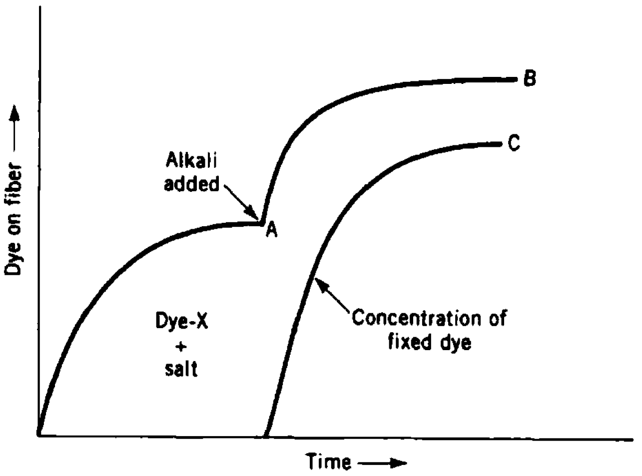

Fig. 1. Amounts and forms of fiber-reactive dye on the fiber as a function of time for a low affinity dye, where X represents the reactive group. Point A represents the amount of dye exhausted in neutral conditions; B is the total amount of dye exhausted at the end of the dyeing process, i.e., [dye-OH] + [dye-X] + [dye-O-cell]; and C is the amount of dye fixed [dye-O-cell].
